State of
North Dakota
Office of the Governor

John Hoeven
Governor

March 3, 2010

Lisa P. Jackson, Administrator
United States Environmental Protection Agency
c/o Ms. Carol Rushin
Acting Regional Administrator
United States Environmental Protection Agency, Region 8
1595 Wynkoop Street
Denver, CO 80202-1129

Re: North Dakota State Implementation Plan for Regional Haze

Dear Administrator Jackson:

The State of North Dakota is hereby submitting an amendment to the State Implementation Plan (SIP) to address the requirements for Regional Haze of Section 308 of 40 CFR Part 51, Requirements for Preparation, Adoption, and Submittal of Implementation Plans, Subpart P - Protection of Visibility. This SIP amendment was prepared by the North Dakota Department of Health, Air Quality Division.

Seven steam electric generating units in North Dakota have been identified as being subject to the BART requirements of 40 CFR 51.308(e). The installation of BART on these sources will result in a reduction of 98,618 tons per year of sulfur dioxide emissions and a reduction of 21,137 tons per year of nitrogen oxides emissions from the 2000-2004 average emissions. These reductions will significantly improve visibility in North Dakota's Class I areas as well as those in surrounding states.

With this submission, I am requesting the United States Environmental Protection Agency's approval of this SIP amendment.

If you have any questions regarding this submittal, please contact Terry O'Clair, P.E., Director, Division of Air Quality, North Dakota Department of Health, at 701-328-5178.

Sincerely,

John Hoeven
Governor

i Governor's Submittal Letter 1

ii Executive Summary 2

1. Purpose/Legal Authority 3

2. Overview 4
   - 2.1 Introduction 4
   - 2.2 Visibility Impairment 8
   - 2.3 Description of North Dakota's Class I Areas 8
   - 2.4 Class I Areas in Other States Impacted by North Dakota Sources 9
   - 2.5 Programs to Address Visibility Impairment 11
   - 2.6 Reasonable Progress Toward the 2064 Visibility Goals 14

3. Plan Development and Consultation 16
   - 3.1 Consultation with Federal Land Managers (FLM) 16
     - 3.1.1 FLM Comments Provided During 60 Day Comment Period 16
     - 3.1.2 Response to FLM Comments 16
     - 3.1.3 FLM Comments Provided on BART Portion of SIP in 2008 16
   - 3.2 Consultation with EPA 17
   - 3.3 Consultation with Other States 17
   - 3.4 Regional Planning Consultation 18
   - 3.5 Consultation with Tribes 18
   - 3.6 Other Consultation 18

4. Monitoring Strategy and Other Implementation Plan Requirements 19
   - 4.1 RAVI Monitoring Strategy in Current North Dakota Long Term Strategy 19
   - 4.2 Regional Haze Visibility Impairment Monitoring Strategy and Other Implementation Plan Requirements 20
   - 4.3 Overview of the IMPROVE Monitoring Network 25

5. Baseline and Natural Visibility Conditions and Uniform Rate of Progress for North Dakota Class I Areas 30
   - 5.1 The Deciview 30
   - 5.2 Baseline Visibility Conditions 30
   - 5.3 Natural Visibility Conditions 33
   - 5.4 Uniform Rate of Progress 35

6. Sources of Visibility Impairment in North Dakota Class I Areas 38
   - 6.1 Introduction 38
   - 6.2 Emissions in North Dakota 38
   - 6.3 Emissions from Other States and Canadian Provinces 42

8.6 Modeling Process and Results 128
    8.6.1 Hybrid CMAQ-CALPUFF Performance Evaluation 128
    8.6.2 Results for Default EPA Methodology 135
        8.6.2.1 Cumulative Results 135
        8.6.2.2 Apportionment by Species 139
        8.6.2.3 Apportionment by Source Group 147
        8.6.2.4 Apportionment by Source Region 153
        8.6.2.5 Conclusions 156
    8.6.3 Weight of Evidence Options 157
        8.6.3.1 Discounting the Impact of Canadian Source Emissions 158
        8.6.3.2 Discounting the Impact of All Sources Located Outside of North Dakota 162
        8.6.3.3 Use Default EPA Methodology with Zero North Dakota Future Emissions 164
        8.6.3.4 Base 20% Worst Days on Modeling Results Rather Than IMPROVE Monitoring Data 167
        8.6.3.5 Weight of Evidence Summary and Conclusions 168

9. Reasonable Progress Goals 172
    9.1 Introduction 173
    9.2 Establish Baseline and Natural Conditions 173
    9.3 Determine the Glide Path or Uniform Rate of Progress 173
    9.4 Identify and Analyze the Measures Aimed at Achieving the Uniform Rate of Progress 173
    9.5 Additional Controls 177
        9.5.1 Point Sources Contributing to Visibility Impairment in the North Dakota Class I Areas 177
        9.5.2 Agricultural Tillage Operations 188
        9.5.3 Smoke Management for Agricultural, Forest Management and Prescribed Burning 190
        9.5.4 Reserved 190
        9.5.5 Oil and Gas Exploration and Production 190
    9.6 Visibility Modeling and Weight of Evidence 192
    9.7 Establish Reasonable Progress Goals 195

10. Long-Term Strategy 198
    10.1 Long-Term Strategy Requirements 198
    10.2 Consultation With Other States 198
    10.3 Demonstration of Inclusion of Measures to Obtain RPGs Established for Class I Areas 199
    10.4 Documentation of the Technical Basis for Modeling, Monitoring and Emissions Information 199
    10.5 Identification of Anthropogenic Sources of Visibility Impairment 200

Page

10.6 Seven Factors That Must be Considered in Developing the LTS 200
  10.6.1 Emission Reductions Due to Ongoing Air Pollution Control Programs 201
  10.6.2 Measures to Mitigate the Impacts of Construction Activities 202
  10.6.3 Emission Limitations and Schedules for Compliance 205
  10.6.4 Source Retirement and Replacement Schedules 205
  10.6.5 Smoke Management Techniques for Agriculture and Forest Management 205
  10.6.6 Enforceability of Emission Limitations and Control Measures 207
  10.6.7 The Anticipated Net Effect on Visibility Due to Projected Changes in Point, Area and Mobile Source Emissions 207
10.7 Prevention of Significant Deterioration 208

11. Commitment to Consultation, Progress Reports, Periodic Evaluations of Plan Adequacy, and Future SIP Revisions 209
11.1 Future Consultation Commitments 209
  11.1.1 FLM Consultation and Coordination 209
  11.1.2 Tribal Consultation 210
  11.1.3 Interstate Consultation and Coordination 210
11.2 Commitment to Progress Reports 211
11.3 Determination of Current Plan Adequacy 212
11.4 Commitment to Future SIP Revisions 213
11.5 Monitoring Strategy 214
11.6 Rules for Non-BART Point and Area Sources 215

12. Public Participation and Review Process 216
12.1 Summary of Comments Received during Public Comment Period/Hearing 216
12.2 Response to Public Comments 216
12.3 Revisions to the State Implementation Plan 216
12.4 Revisions to the BART Air Pollution Control Permits to Construct 217

List of Appendices

YELL	Yellowstone National Park, MT & WY
ZION	Zion National Park, UT

i Submittal Letter

Lisa P. Jackson, Administrator
United States Environmental Protection Agency
c/o Ms. Carol Rushin
Acting Regional Administrator
United States Environmental Protection Agency Region 8
1595 Wynkoop Street
Denver Colorado 80202-1129

Re: North Dakota State Implementation Plan for Regional Haze

Dear Ms. Jackson:

The State of North Dakota is hereby submitting an amendment to the State Implementation Plan (SIP) to address the requirements for Regional Haze of Section 308 of 40 CFR Part 51, Requirements for Preparation, Adoption, and Submittal of Implementation Plans, Subpart P - Protection of Visibility. This SIP amendment was prepared by the North Dakota Department of Health, Air Quality Division.

We are enclosing two hard copies and three electronic copies of the SIP for your review.

Seven steam electric generating units in North Dakota have been identified as being subject to the BART requirements of 40 CFR 51.308(e). The installation of BART on these sources will result in a reduction of 98,618 tons per year of sulfur dioxide emissions and a reduction of 21,137 tons per year of nitrogen oxides emissions from the 2000-2004 average emissions. These reductions will significantly improve visibility in North Dakota's Class I areas as well as those in surrounding states.

With this submission, I am requesting the U. S. Environmental Protection Agency's approval of this SIP amendment and the BART for the seven Subject-to-BART Electrical Generating Units in North Dakota.

We would also call to your attention that visibility in the North Dakota Class I areas is adversely impacted by emissions from coal-fired electrical generating plants located north of the international border in southeastern Saskatchewan, Canada. These impacts and their sources are identified and discussed in Sections 6 and 8 of the SIP revision.

If you have any questions regarding this submittal, please feel free to contact Terry O'Clair, P.E., Director, Division of Air Quality, North Dakota Department of Health, at 701-328-5178.

Sincerely,

John Hoeven
Governor

Enclosures

Terry O'Clair, Director, Division of Air Quality, Department of Health

ii Executive Summary

This document comprises the State of North Dakota’s State Implementation Plan (SIP) submittal to EPA to meet the requirements of Section 308 of the Regional Haze Regulation (40 CFR Part 51, Subpart P, Section 51.308). Adoption of the North Dakota State Implementation Plan For Regional Haze amends the Implementation Plan for the Control of Air Pollution for the State of North Dakota.

Section 1 describes the purpose of and legal authority of the SIP. Section 2 provides introductory and background information on the federal regional haze law and regulation, visibility impairment, a description of North Dakota’s Class I areas and reasonable progress towards the 2064 visibility goals. Section 3 describes plan development and consultation with federal land managers, other states, the EPA, and stakeholders. Section 4 describes the North Dakota monitoring strategy and commitments for future monitoring. Section 5 describes baseline and natural visibility conditions for the North Dakota Class I areas and the uniform rate of progress for each Class I area. Section 6 describes the sources of visibility impairment at North Dakota=s Class I areas. Section 7 describes and provides the results of the Best Available Retrofit Technology (BART) process including the Air Pollution Control Permits to Construct issued to the seven power plant boilers subject to BART. Section 8 describes the CMAQ and CALPUFF modeling used in developing the SIP. Section 9 describes the process for determining the reasonable progress goals for North Dakota’s Class I areas and what they are. Section 10 describes the long term strategy. Section 11 describes the commitments to future consultation, progress reports, periodic evaluations of SIP adequacy, and future SIP revisions. Section 12 summarizes the public participation and review process and the revisions made subsequent to the public hearing for the SIP. Appendices at the end of this document provide additional information on BART and reasonable progress modeling protocols, company BART analyses, Department BART determinations, the BART Air Pollution Control Permits to Construct, FLM and EPA comments during the 60-day FLM comment period, the public hearing record, Department responses to FLM, EPA, and public comments, consultation with the FLMs, EPA and other states, the legal opinions of the Attorney General, and the State BART rule.

The North Dakota BART determination process identified seven electrical generating units that are subject to the BART requirements. The installation of new control devices or modifications to existing control devices will reduce sulfur dioxide emission from point sources in the state by 98,618 tons per year and nitrogen oxides emissions by 21,139 tons per year. The BART reductions must be implemented no later than five years after EPA approves this SIP. The anticipated date of implementation is 2013. These reductions are expected to make a significant improvement in visibility in the affected Class I areas. Total sulfur dioxide emissions in North Dakota are expected to decline by 105,729 tons per year (60%) and nitrogen oxides emissions by 57,970 tons per year (25%) during this planning period.

The 2018 reasonable progress goals for the twenty percent worst days in the North Dakota Class I areas have been established at 16.9 deciviews for each unit of Theodore Roosevelt National Park (TRNP) and 18.9 deciviews at Lostwood Wilderness Area (LWA). The analyses conducted by the North Dakota Department of Health (NDDoH) and the Western Regional Air Partnership (WRAP) indicates there will be no degradation during the 20% best days.

1. **Purpose / Legal Authority**

The purpose of this submittal is to address the State Implementation Plan requirements for the State of North Dakota found in Paragraph 40 CFR 51.308, Regional Haze Program Requirements, of 40 CFR Part 51 Subpart P - Protection of Visibility.

The North Dakota Department of Health (the Department), the agency designated to administer and coordinate a statewide program of air pollution control, has general legal authority under North Dakota Century Code Sections 23-25-03 and 28-32-02 to adopt and enforce rules for visibility protection including regional haze visibility impairment.

The Department adopted rules in 1987 to implement Sections 40 CFR 51. 300 - 307 (NDAC Chapter 33-15-19 Visibility Protection, Effective date October 1, 1987) and in 2006 to implement Paragraph 40 CFR 51.308(e) (NDAC Chapter 33-15-25 Regional Haze Requirements, Effective Date January 1, 2007).

It is the legal opinion of the North Dakota Attorney General that the State Implementation Plan (SIP) is legal, valid and the Air Pollution Control Permits to Construct for the BART sources, and the Coyote Station, included within the SIP in Appendix D and Appendix A.4 have the force and effect of law. A copy of the Attorney General opinion is contained in Appendix G.

2. Overview

2.1 Introduction

The Clean Air Act (CAA) defines the general concept of protecting visibility in each of the 156 Mandatory Class I Federal Areas across the nation as shown in Figure 2.1. Section 169A from the 1977 CAA set forth the following national visibility goal:

> "Congress hereby declares as a national goal the prevention of any future, and the remedying of any existing, impairment of visibility in mandatory Class I Federal areas which impairment results from man-made air pollution."

The federal visibility regulations (40 CFR Part 51, Subpart P - Visibility Protection Section 51.300 - 309) detail a two-phased process to determine existing impairment in each of the Class I areas, how to remedy such impairment, and how to establish goals to restore visibility to "natural conditions" by the year 2064 in each of these areas. The federal regulations require states to prepare a SIP to: include a monitoring strategy, address existing impairment from major stationary facilities (Reasonably Attributable Visibility Impairment), prevent future impairment from proposed facilities, address Best Available Retrofit Technology (BART) for certain stationary sources, consider other major sources of visibility impairment, calculate baseline, current and natural visibility conditions, consult with the Federal Land Managers (FLMs) in the development or change to the SIP, develop a long-term strategy to address issues facing the state, set and achieve reasonable progress goals for each Class I area, and review the SIP every five years.

EPA promulgated regulations to implement the statute in December, 1980. Following litigation, a court settlement divided visibility protection into two phases.

Phase 1 of the visibility program, also known as Reasonably Attributable Visibility Impairment (RAVI), addresses impacts in Class I areas by establishing a process to evaluate source specific visibility impacts, or plume blight, from individual sources or small groups of sources. Part of that process relates to the evaluation of sources prior to construction through the Prevention of Significant Deterioration (PSD) permit program for major stationary sources. The plume blight part of the Phase 1 program also allows for the evaluation, and possible control, of reasonably attributable impairment from existing sources. North Dakota has developed, and EPA approved, a SIP for Phase 1 of the visibility program. The Phase 1 rule is NDAC 33-15-19, Visibility Protection.

Section 169B was added to the Clean Air Act Amendments of 1990 to address regional haze. Since regional haze does not respect state and tribal boundaries, the amendments authorized EPA to establish visibility transport regions as a way to combat regional haze.

Phase 2 of the visibility program addresses regional haze. This form of visibility impairment focuses on overall decreases in visual range, clarity, color, and ability to discern texture and details in Class I areas. The responsible air pollutants can be generated in the local vicinity or transported by the wind often many hundreds or even thousands of miles from where they originated. For technical and legal reasons the second part of the visibility program was not implemented in regulation until 1999.

In July 1999, the EPA finalized the Regional Haze Rule (RHR) requiring States to adopt State Implementation Plans to address this aspect of visibility impairment in the Class I areas. The rule was amended in July, 2005. Under the current rules the Regional Haze SIP was to be submitted to the EPA by December 17, 2007.

The two key requirements of the regional haze program are:

1. Improve visibility for the most impaired days, and
2. Ensure no degradation in visibility for the least impaired days.

Though the national visibility goals are to be ultimately achieved by the year 2064, the SIP seeks to meet the two requirements stated above by 2018, the first planning period established by the federal rule.

Pursuant to the requirements of 51.308(a) and (b), the SIP is intended to meet the requirements of EPA=s Regional Haze rules that were adopted to comply with requirements set forth in Section 169B of the Clean Air Act. Elements of this SIP are to address:

- The core regional haze program requirements pursuant to 40 CFR 51.308(d),
- The Best Available Retrofit Technology (BART) requirements of 40 CFR 51.308(e),
- The requirements for comprehensive periodic revisions of regional haze SIPs of 40 CFR 51.308(f),
- The requirements for periodic reports describing progress towards the reasonable progress goals of 40 CFR 51.308(g),
- The requirement for determination of the adequacy of the existing implementation plan of 40 CFR 51.308(h), and
- The requirements for State and Federal Land Manager coordination of 40 CFR 51.308(i).

In addition, 40 CFR 51.308(c) of the original July 1999 regulation provided options for a regional planning process to allow states to develop a coordinated approach to regional haze. In March 1999, North Dakota became a member of the Western Regional Air Partnership (WRAP), the regional planning organization serving 13 western states, tribes and federal agencies. Section 51.308(c) was deleted on July 6, 2005 when the BART Guidelines were added to the regional haze rule.

Figure 2.1 - Map of United States Class I Areas

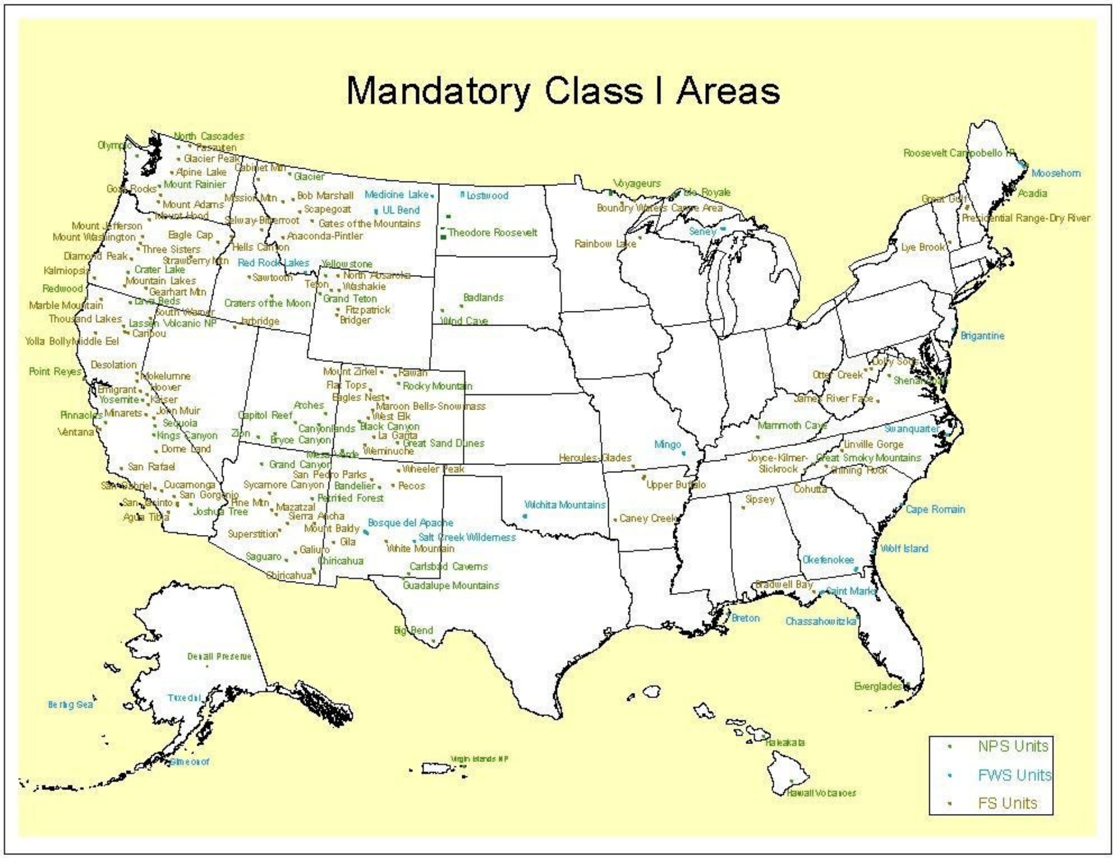

Figure 2.2 – Map of North Dakota Class I Areas

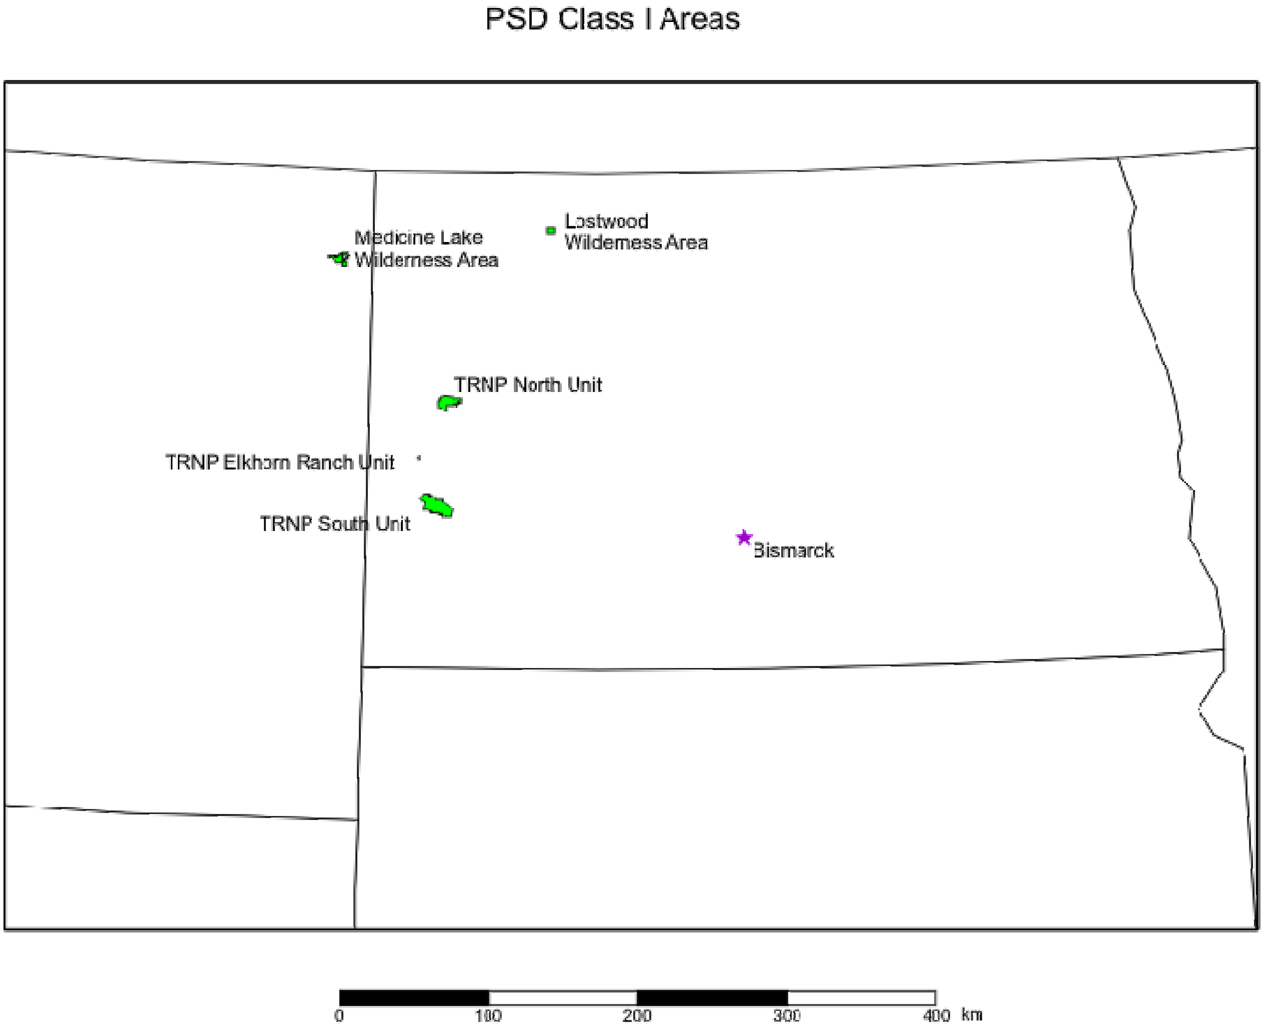


2.2 Visibility Impairment

Most visibility impairment occurs when pollution in the form of small particles scatters or absorbs light. Air pollutants come from a variety of natural and anthropogenic sources. Natural sources can include windblown dust and smoke from wildfires. Anthropogenic sources can include motor vehicles, electric utility and industrial fuel burning and manufacturing operations. More pollutants mean more absorption and scattering of light, which reduce the clarity and color of a scene. Some types of particles such as sulfates and nitrates, scatter more light, particularly during humid conditions. Other particles like elemental carbon from combustion processes are highly efficient at absorbing light. Commonly, the receptor is the human eye and the object may be a single viewing target or a scene.

In the 156 Class I areas across the country, visual range has been substantially reduced by air pollution. In eastern parks, average visual range has decreased from 90 miles to 15-25 miles. In the West, visual range has decreased from an average of 140 miles to 35-90 miles.

Some haze causing particles are directly emitted to the air. Others are formed when gases emitted to the air form particles as they are carried many miles from the source of the pollutants. Some haze-forming pollutants are also linked to human health problems and other environmental damage. Exposure to very small particles in the air has been linked with increased respiratory illness, decreased lung function and premature death. In addition, particles such as nitrates and sulfates contribute to acid deposition potentially making lakes, rivers and streams unsuitable for some forms of aquatic life and impacting flora in the ecosystem. These same acid particles can also erode materials such as paint, buildings or other natural and man-made structures.

2.3 Description of North Dakota’s Class I Areas

The Class I areas in North Dakota include: the Theodore Roosevelt National Park (TRNP) which consists of three separate, distinct units and the Lostwood National Wildlife Refuge Wilderness Area (LWA). The North Dakota Class I Areas are shown on Figure 2.1 and Figure 2.2.

Theodore Roosevelt National Park is located within Billings and McKenzie Counties in North Dakota. The colorful badlands and Little Missouri River of western North Dakota provide the scenic backdrop to the park which memorializes the 26th president for his enduring contributions to the conservation of our nation’s resources. The park contains 70,447 acres divided among three separate units: South Unit, Elkhorn Ranch and North Unit and is managed by the National Park Service. The park is comprised of badlands, open prairie and hardwood draws that provide habitat for a wide variety of wildlife species including bison, prairie dogs, elk, deer, big horn sheep and other wildlife. The Little Missouri River passes through the three units of the park.

Lostwood National Wildlife Refuge Wilderness Area is located in Burke County in the northwestern part of the State. Created by an act of Congress in 1975, the wilderness covers an area of 5,577 acres. It is contained within Lostwood National Wildlife Refuge and is managed by the U.S. Fish and Wildlife Service. Lostwood National Wilderness Area is designated to preserve a region well known for numerous lakes and mixed grass prairie. The wilderness ensures that the finest duck and waterfowl breeding region in North America remains wild and unimproved.

2.4 Class I Areas in Other States Impacted by North Dakota Sources

In accordance with 40 CFR 51.308, emissions sources within North Dakota have or may be reasonably expected to have impacts on the following Class I Areas: Boundary Waters Canoe Area Wilderness Area (BOWA) and Voyageurs National Park (VOYA) in Minnesota, Isle Royale National Park (ISLE) and Seney National Wildlife Refuge Wilderness Area (SENE) in Michigan, Medicine Lake National Wildlife Refuge Wilderness Area (MELA) and U. L. Bend National Wildlife Refuge Wilderness Area ((ULBE) in Montana, and Badlands National Park (BADL) and Wind Cave National Park (WICA) in South Dakota. As shown in Table 2.1 and Figure 2.1, sources in North Dakota have only a small impact on out-of-state Class I areas. For Class I areas that are more distant, the impact will be even smaller. Impacts from emission sources in North Dakota contribute 5 percent or more of the total 2002 extinction (Bext) in the above Class I areas except those in Michigan and BOWA. A 5 percent or larger contribution is considered a significant contribution.

Table 2.1
North Dakota
Species Contribution (%)
20% Worst Days
2000-2004

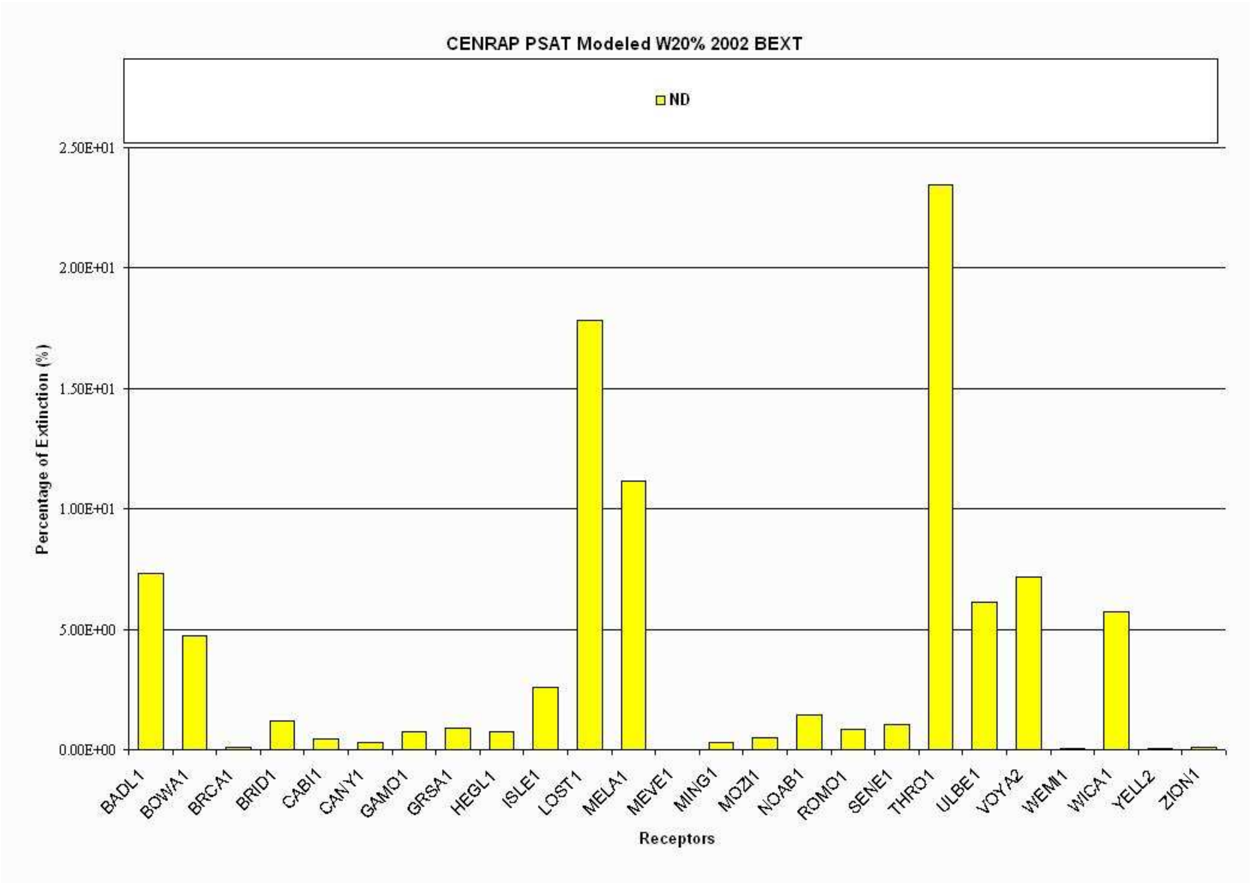
Class I Area	Sulfate	Nitrate	OC	EC	PMF	PMC	Sea Salt
TRNP	21	19	12	29	44	45	0
LWA	18	13	23	35	28	32	0
Badlands	8	10	2	4	3	3	0
Wind Cave	8	8	1	2	4	3	0
U.L. Bend	9	5	1	1	1	1	0
Medicine Lake	11	7	9	15	17	16	0
Gates of the Mountains	< 1	< 1	< 1	< 1	< 1	< 1	0
North Absaroka	1	1	< 1	< 1	< 1	< 1	0
Voyageurs	6	9	3*	6*	15*	22*	0
Boundary Waters*	3	10	2	4	10	7	0
Isle Royale*	2	4	1	2	6	6	0
Seney*	1	3	<1	<1	2	4	0

Based on WRAP's tracer analyses (SO_4 and NO_3) and weighted emissions potential (WEP) analyses unless otherwise noted.

*Based on CENRAP data.

From CENRAP's PSAT analysis, North Dakota's contribution to total extinction (20% worst days in base year 2002) at the nearby Class I areas is shown in Figure 2.3.

Figure 2.3



2.5 Programs to Address Visibility Impairment

North Dakota and EPA have many existing emission control programs/rules to improve and protect visibility in Class I areas.

North Dakota adopted and EPA approved a SIP for Phase 1 of the visibility program. This program addresses major source PSD permitting, source specific haze and plume blight aspects of visibility impairment. The Phase 1 rule is NDAC 33-15-19, Visibility Protection. It has an effective date of October 1, 1987.

North Dakota adopted NDAC 33-15-25, Regional Haze Requirements in 2006 with an effective date of January 1, 2007. This rule implements the BART provisions of the federal RHR.

North Dakota has several other emission control programs/rules that while not specifically written to address visibility impairment, do address visibility and work to improve and protect visibility in Class I areas. These include:

NDAC Chapter 33-15-02, Ambient Air Quality Standards, Section 33-15-02-03. Air quality guidelines. This rule states in part:

> "In keeping with the purpose of these ambient air quality standards, the quality should be such that:
>
> 4. Visibility will be protected.
>
> 7. Natural scenery will not be obscured."

NDAC Chapter 33-15-04, Open Burning Restrictions. Section 33-15-04-02. Permissible open burning. This rule states in part:

> "2. The following conditions apply to all types of permissible burning listed in subsection 1.
>
> h. Except in an emergency, burning may not be conducted is such proximity of any Class I area, as defined in chapter 33-15-15, that the ambient air of such area is adversely impacted.
>
> i. Except in an emergency, the visibility of any Class I area cannot be adversely impacted as defined in chapter 33-15-19."

NDAC Chapter 33-15-15, Prevention of Significant Deterioration of Air Quality, requires that a visibility analysis be prepared in accordance with chapter 33-15-19 as a part of the requirements for a PSD permit to construct.

NDAC Chapter 33-15-17. Restriction of Fugitive Emissions. Section 33-15-17-02 Restriction of fugitive particulate emissions. This rules states in part: "No person shall emit or cause to be emitted into the ambient air from any source of fugitive emissions as specified in section 33-15-17-01 any particulate matter which:

> 5. Would have an adverse impact on visibility, as defined in chapter 33-15-19, on any federal class I area."

In addition to the above programs, the following emission control programs/rules, which do not specifically address visibility impairment, control the emission of pollutants that cause or contribute to visibility impairment:

NDAC Chapter 33-15-03	Restriction of Emission of Visible Air Contaminants
NDAC Chapter 33-15-05	Emissions of Particulate Matter Restricted
NDAC Chapter 33-15-06	Emissions of Sulfur Compounds Restricted
NDAC Chapter 33-15-07	Control of Organic Compounds Emissions
NDAC Chapter 33-15-08	Control of Air Pollution from Vehicles and Other Internal Combustion Engines
NDAC Chapter 33-15-12	Standards of Performance for New Stationary Sources
NDAC Chapter 33-15-14	Designated Air Contaminant Sources, Permit to Construct, Minor Source Permit to Operate, Title V Permit to Operate
NDAC Chapter 33-15-20	Control of Emissions from Oil and Gas Well Production Facilities
NDAC Chapter 33-15-21	Acid Rain Program
NDAC Chapter 33-15-22	Emissions Standards for Hazardous Air Pollutants for Source Categories

It should be noted that unless specifically stated in the text, all references to existing rules or emission control programs are intended only to provide information about various aspects of the program described and are neither being submitted to EPA for approval nor being incorporated into the SIP as Federally enforceable measures if they haven't previous been incorporated.

This SIP is North Dakota's comprehensive visibility plan which now contains both Phase 1 and Phase 2 visibility requirements. It addresses all aspects of North Dakota's visibility improvement program.

North Dakota is also setting emission limits as a part of this SIP for those sources subject to Best Available Retrofit Technology (BART) requirements of Phase 2 of the RHR which are described in detail in chapter 7 of this SIP.

This SIP documents those programs, rules, processes and controls deemed appropriate as measures to reduce regional haze and protect good visibility in North Dakota toward meeting the 2018 and 2064 goals established in the EPA RHR and CAA.

EPA has several existing emission control programs/rules which do not specifically address visibility impairment that will control the emission of pollutants that cause or contribute to visibility impairment which will impact North Dakota Class I areas. They include:

CAIR. CAIR will permanently cap emissions of SO_2 and NO_x from EGUs in the eastern United States by 2015. When fully implemented, CAIR as originally promulgated would have reduced SO_2 emissions from EGUs in these states by more than 70%, and NO_x emissions by more than 60%, from 2003 levels. CAIR has been remanded with a replacement rule likely to take 2 years to finalize. Any emission reductions from a CAIR replacement rule are unknown at this time. When winds are from an easterly direction, North Dakota Class I areas will see some benefit from the CAIR reductions.

NO_x SIP Call. Phase I of the NO_x SIP call applies to certain EGUs and large non-EGUs, including large industrial boilers and turbines, and cement kilns in the eastern United States. It is expected to reduce NO_x emissions by 90% to mitigate ozone transport. When winds are from an easterly direction, North Dakota Class I areas will see some benefit.

Heavy Duty Diesel (2007) Engine Standard (for on-road trucks and buses). The EPA set a PM emissions standard for new heavy-duty engines of 0.01 grams per brake-horsepower-hour(g/bhp-hr), to take full effect for diesel engines in the 2007 model year. This rule also includes standards for NO_x and non-methane hydrocarbons (NMHC) of 0.20 g/bhp-hr and 0.14 g/bhp-hr, respectively. These NO_x and NMHC standards will be phased in together between 2007 and 2010, for diesel engines. Sulfur in diesel fuel must be lowered to enable modern pollution control technology to be effective on these trucks and buses. The EPA will require a 97 percent reduction in the sulfur content of highway diesel fuel from its current level of 500 parts per million (low sulfur diesel, or LSD) to 15 parts per million (ultra-low sulfur diesel, or ULSD).

Tier 2 Tailpipe (On-road vehicles). The EPA mobile source rules include the Tier 2 fleet averaging program, modeled after the California LEV II standards. Manufacturers can produce vehicles with emissions ranging from relatively dirty to zero emissions, but the mix of vehicles a manufacturer sells each year must have average NO_x emissions below a specified value. Tier 2 standards became effective in the 2005 model year.

Large Spark Ignition and Recreational Vehicle Rule. The EPA has adopted new standards for emissions of NO_x, hydrocarbons, and carbon monoxide from several groups of previously unregulated nonroad engines. Included in these are large industrial spark-ignition engines and recreational vehicles. Nonroad spark-ignition engines are those powered by gasoline, liquid propane gas, or compressed natural gas rated over 19 kilowatts (kW) (25 horsepower). These engines are used in commercial and industrial applications, including forklifts, electric generators, airport baggage transport vehicles, and a variety of farm and construction applications. Nonroad recreational vehicles include snowmobiles, off-highway motorcycles, and all-terrain-vehicles. These rules were initially effective in 2004 and will be fully phased-in by 2012.

Nonroad Diesel Rule. This rule sets standards that will reduce emissions by more than 90 percent from nonroad diesel equipment, and reduce sulfur levels by 99 percent from current levels in nonroad diesel fuel starting in 2007. This step will apply to most nonroad diesel fuel in 2010 and to fuel used in locomotives and marine vessels in 2012.

Industrial Boiler/Process Heater MACTs. The EPA issued final rules to substantially reduce emissions of toxic air pollutants from industrial, commercial and institutional boilers and process heaters. These rules reduce emissions of a number of toxic air pollutants, including hydrogen chloride, manganese, lead, arsenic and mercury by 2009. This rule also reduces emissions of SO_2 and PM in conjunction with the toxic air pollutant reductions. The applied Maximum Achievable Control Technology (MACT) control efficiencies were 4 percent for SO_2 and 40 percent for PM_{10} and $PM_{2.5}$. The EPA's industrial boiler MACT rules were vacated on June 8, 2007, however it is believed that by 2018 the USEPA will have re-promulgated a boiler MACT rule; however, the emission reductions may change from those of the vacated rule.

Combustion Turbine and Reciprocating Internal Combustion Engines MACTs. The EPA MACT regulations for Gas Turbines and stationary Reciprocating Internal Combustion will have NO_x co-benefit effects.

VOC 2-, 4-, 7-, and 10-year MACT Standards. Various point source MACTs and associated emission reductions have been implemented by EPA.

2.6 Reasonable Progress Toward the 2064 Visibility Goals

Section 51.308(d) contains the core requirements for the regional haze SIP. The requirements for reasonable progress goals (RPG) are found in 51.308(d)(1) which reads:

> "Reasonable progress goals. For each mandatory Class I Federal area located within the State, the State must establish goals (expressed in deciviews) that provide for reasonable progress towards achieving natural visibility conditions. The reasonable progress goals must provide for an improvement in visibility for the most impaired days over the period of the implementation plan and ensure no degradation in visibility for the least impaired days over the same period."

The reasonable progress goals are interim goals that represent incremental visibility improvement over time for the most-impaired (20% worst) days and no degradation in visibility for the least-impaired (20% best) days. The first regional haze plan that States must submit to EPA needs to include RPGs for the year 2018, also known as the "2018 milestone year". The State has the flexibility in establishing different RPGs for each Class I area. In establishing the RPG, the State must consider four factors:

- the costs of compliance;
- the time necessary for compliance;
- the energy and non-air quality environmental impacts of compliance; and
- the remaining useful life of any potentially affected sources.

States must demonstrate how these factors were taken into consideration in selecting the RPG for each Class I area.

The North Dakota Department of Health has worked with the Western Regional Air Partnership (WRAP) and with the WRAP's ongoing modeling program as well as implemented our own modeling program to establish and refine RPGs for 2018 for the North Dakota Class I areas. This process is described in detail in sections 8 and 9.

The RPGs for each North Dakota Class I area established for 2018 are found in section 9. Required BART controls will be installed and become operational as expeditiously as practicable, but no later than five years after this SIP is approved by EPA. The controls are expected to be operational in 2013 - 2014.

The technical analyses described in this SIP demonstrate that emissions both inside and outside of North Dakota have an appreciable impact on the State's Class I areas. This includes emissions from neighboring states as well as international emissions from Canada, especially from the provinces of Alberta and Saskatchewan. Emission controls from many sources outside of North Dakota will not be fully defined during this round of the Regional Haze SIP process, necessitating consideration of outside controls and further interstate and possibly tribal consultation in the reasonable progress process to establish refined reasonable progress goals. The EPA, through the Department of State, will have to work with Canada and its provinces to reduce visibility impairing pollutants that impact North Dakota and other states' Class I areas. Until SIP controls including BART and other programs outside of North Dakota are defined, modeled and analyzed, North Dakota cannot fully determine progress toward the 2018 goal or the 2064 goal. North Dakota will make its best attempt at demonstrating progress toward the goals based on addressing sources within its control.

3. Plan Development and Consultation

The State is required by Section 51.308(d) (3) (i) of the EPA Regional Haze Rule to consult with other states to develop coordinated emission management strategies for Class I areas in those states North Dakota's emissions impact or those states whose emissions impact North Dakota's Class I areas and by Section 51.308(i) to consult with the federal land managers of the Class I areas in our state and the Class I areas in other states that emissions from North Dakota impact.

3.1 Consultation with Federal Land Managers

The North Dakota Department of Health consults with the FLMs as a part of the WRAP and as needed directly with the National Park Service and U.S. Fish and Wildlife Service in Denver, CO. They have reviewed and commented on North Dakota's BART modeling protocol and draft BART determinations submitted by the BART sources.

The National Park Service, the U.S. Fish and Wildlife Service, and the U.S. Forest Service (federal land manager of Boundary Waters Canoe Area Wilderness in Minnesota) were each furnished copies of the draft SIP for review and comment as part of the required 60 day FLM comment period (Section 51.308(i)(2)). Continuing consultation with the three FLM's in the future as required by 40 CFR 51,308(i)(4) is addressed in Section 11.1.1.

3.1.1 FLM Comments Provided During 60 Day Comment Period

A draft was provided to the FLMs in August 2009 for their 60-day consultation period. The FLM comments are included in Appendix J.

3.1.2 Response to FLM Comments

The Department's responses to the FLM's comments are included in Appendix J.

3.1.3 FLM Comments Provided on BART Portion of SIP in 2008

The Department had originally planned to submit the BART portion of the regional haze SIP separately from the Reasonable Progress portion of the SIP. The BART portion (which is now Section 7) was submitted to the FLMs in June of 2008 as part of the required 60-day FLM comment period.

Comments that were received from the FLMs in August of 2008 are attached in Appendix J.1.1 and discussed further in Section 7. They have been reviewed and considered by the Department and included as appropriate in Section 7 of this current SIP. The Department's responses to the FLM comments are attached in Appendix J.1.2.

3.2 Consultation with EPA Region 8

The North Dakota Department of Health has consulted with EPA as a part of the WRAP and as needed directly with Air Program staff of the EPA Region 8 office in Denver, CO in developing this SIP. EPA has reviewed and commented on the State BART modeling protocol, the BART Air Pollution Control Permit to Construct template and the draft BART determinations submitted by the BART sources.

In June of 2008, the Department submitted the BART portion of the SIP to EPA Region 8 at the same time it was submitted to the FLMs as discussed in Section 3.1.3. Comments were received from EPA and are attached as Appendix J.3.1. The Department's responses to the EPA comments are attached as Appendix J.3.2.

EPA was also provided a copy for comment of the draft SIP at the time it was provided to the FLMs as a part of the FLM 60 day comment period. The Department considered the EPA comments and made appropriate revisions to the SIP.

The Department also consulted with EPA Region 8 concerning Class I areas in Montana as they are preparing a federal implementation plan for Montana.

3.3 Consultation with Other States

The North Dakota Department of Health has consulted with our neighboring states of South Dakota and Montana through the WRAP and as needed individually. We also participated in monthly teleconferences from 2004 through 2008 with Minnesota and Michigan, the states containing the four northern Class I areas (Boundary Waters Canoe Wilderness Area and Voyageurs National Park in Minnesota, Isle Royale National Park and Seney National Wildlife Refuge Wilderness Area in Michigan), and other states in CENRAP and LADCO. We also individually consulted as needed with Minnesota, our neighbor directly to the east.

As a result of the consultations, Minnesota sent a memorandum dated September 19, 2007 to North Dakota and other states impacting Minnesota's Class I areas. Minnesota requested a response documenting these consultations have taken place to the satisfaction of North Dakota or detailing areas where additional consultation should occur. In those states Minnesota has identified as additional contribution states, they asked those states to respond with their agreement or disagreement with Minnesota's determination of contributing states and the additional control strategies that will be evaluated. Minnesota's memorandum and the NDDoH letter of response dated August 22, 2008 are attached in Appendix J.2.

These states were notified of the availability of the draft SIP at the time it was sent to the FLMs.

3.4 Regional Planning Consultation

The North Dakota Department of Health became a member of the Western Regional Air Partnership (WRAP) in March of 1999. WRAP is one of five regional planning organizations representing 13 western states, tribes in those states, federal agencies including EPA and FLMs, environmental organizations, industry, academics, and other stakeholders. Department staff has participated and continues to participate in many WRAP committees and workgroups including the Air Managers Committee, the Initiatives Oversight Committee, the Technical Oversight Committee, the Emissions Forum, the Stationary Sources Joint Forum, the Technical Analysis Forum, the Implementation Workgroup, and the BART Workgroup. Membership in the WRAP and participation in its many committees, forums and workgroups allows consultation with the many organizations WRAP represents.

3.5 Consultation with Tribes

The Department notified the tribes in North Dakota of the public hearing and comment period on the draft RH SIP. The Department also notified the WRAP Tribal Caucus Coordinator of its intent to draft a SIP to address regional haze and provided a list of contacts within the Department (see Appendix J.4).

3.6 Other Consultation

The Department has monthly teleconferences with the Subject-to-BART sources in North Dakota and has quarterly meetings with the Lignite Energy Council, an organization representing lignite coal mines and users within the State.

4. Monitoring Strategy and Other Implementation Plan Requirements

Part 40 CFR 51.305 and 51.308(d)(4) of the Federal Regional Haze Rule requires states to have a monitoring strategy in the SIP for addressing reasonably attributable visibility impairment (RAVI) and regional haze visibility impairment in the federal Class I areas within the State. The monitoring strategy required by 40 CFR 51.305 is discussed in Section 4.1. The monitoring strategy required by 40 CFR 51.308(d)(4) is summarized in Section 4.2 and is made a part of this RH SIP.

4.1 RAVI Monitoring Strategy in Current North Dakota Long Term Strategy

The RAVI monitoring strategy required by 40 CFR 51.305 was first included in the long term strategy section of North Dakota's first visibility protection SIP dated October 1, 1987 as Section 6.10. The visibility monitoring strategy was replaced on March 1, 1994 with Section 6.12. It was again replaced on January 1, 1996 with Section 6.13 of the SIP which is the present RAVI monitoring strategy. Section 6.13 is:

> Air Quality Surveillance
>
> In April 1994, Section 6.12 of the SIP was submitted to EPA indicating visibility monitoring was not necessary due to a lack of visibility impairment and a database indicating stable conditions. In late 1994 and early 1995, there has been a resurgence of activity in the oil fields of Western North Dakota. The purpose of Section 6.13 is to withdraw Section 6.12 and identify current activities regarding visibility monitoring.
>
> An increase in oil drilling activities in 1995 has prompted the Park Service to revisit the idea of establishing visibility monitoring sites at the Class I areas in North Dakota. The Department has met with the Park Service to discuss arrangements for financing visibility monitoring. The Department has offered to use funds from an environmental trust that was established through deposits from penalties collected on several enforcement cases. Theodore Roosevelt National Park (TRNP) Service officials were receptive and have transmitted requests to their offices in Denver. Plans currently call for the Department and the Park Service to enter into a memorandum of understanding to proceed with establishing visibility monitoring at TRNP.

The Federal Land Managers installed IMPROVE monitors in Theodore Roosevelt National Park South Unit and Lostwood National Wildlife Refuge Wilderness Area in December of 1999.

The Department also worked with the National Park Service to install a webcam at the South Unit of TRNP using funds from the environmental trust as included in Section 6.13. The webcam became operational in August of 2002. It can be accessed on the internet at:

http://www.nature.nps.gov/air/WebCams/parks/throcam/throcam.cfm. In addition to the webcam picture, current conditions for ozone, sulfur dioxide, fine particulate matter ($PM_{2.5}$) and weather have been added and can be observed.

4.2 Regional Haze Visibility Impairment Monitoring Strategy and Other Implementation Plan Requirements

Section 51.308(d)(4) requires that the State must submit with the implementation plan a monitoring strategy for measuring, characterizing, and reporting of regional haze visibility impairment that is representative of all mandatory Class I Federal areas within the State. This monitoring strategy must be coordinated with the monitoring strategy required in section 51.305 for reasonably attributable visibility impairment. Compliance with this requirement may be met through participation in the Interagency Monitoring of Protected Visual Environments (IMPROVE) network. The IMPROVE monitoring program is discussed in section 4.3.

The state of North Dakota will depend on the Interagency Monitoring of PROtected Visual Environments (IMPROVE) monitoring program to collect and report aerosol monitoring data for long-term reasonable progress tracking as specified in the Regional Haze Rule (RHR). Because the RHR is a long-term tracking program with an implementation period nominally set for 60 years, the state expects that the IMPROVE program will provide data based on the following goals:

1. Maintain a stable configuration of the individual monitors and sampling sites, and stability in network operations for the purpose of continuity in tracking reasonable progress trends;
2. Assure sufficient data capture at each site of all visibility-impairing species;
3. Comply with EPA quality control and assurance requirements; and
4. Prepare and disseminate periodic reports on IMPROVE program operations.

The state of North Dakota is relying on the IMPROVE program to meet these monitoring operation and data collection goals, with the fundamental assumption that network data collection operations will not change, or if changed, will remain directly comparable to those operated by the IMPROVE program during the 2000-2004 RHR baseline period. Technical analyses and reasonable progress goals in this implementation plan for Regional Haze are based on data from these sites. As such, the State asks that the IMPROVE program identify potential issues affecting RHR implementation trends and/or notify the State before changes in the IMPROVE program affecting a RHR tracking site are made.

Further, the state of North Dakota notes that the human resources to operate these monitors are provided by Federal Land Management agencies. Beyond that in-kind contribution, resources for operation and sample analysis of a complete and representative monitoring network of these long-term reasonable progress tracking sites by the IMPROVE program are a collaborative responsibility of the EPA, states, tribes, and FLMs and the IMPROVE program steering committee. The state of North Dakota will collaborate with the EPA, FLMs, other states, tribes, and the IMPROVE committee to assure adequate and representative data collection and reporting by the IMPROVE program. North Dakota will consult with the FLMs if IMPROVE monitoring budget changes will threaten Class I area monitoring within North Dakota, or in Class I areas affected by emissions from North Dakota.

Section 51.308(d)(4)(i) requires that the implementation plan must also provide for the following:

(i) The establishment of any additional monitoring sites or equipment needed to assess whether reasonable progress goals to address regional haze for all mandatory Class I Federal areas within the State are being achieved.

The state of North Dakota depends on the following IMPROVE program-operated monitors listed in Table 4.1 for tracking RHR reasonable progress.

Table 4.1
IMPROVE Monitoring Sites in North Dakota

IMPROVE Monitoring Site	**Class I Area**	**Sponsor**	**Start Date**	**Elevation MSL**
LOST1	Lostwood National Wilderness Area	US Fish and Wildlife Service	12/1999	696 m 2283 ft
THRO1	Theodore Roosevelt National Park-South Unit, North Unit, Elkhorn Ranch Unit	National Park Service	12/1999	862 m 2828 ft

Note that the THRO1 IMPROVE monitor is located at the Painted Canyon Overlook in the South Unit of Theodore Roosevelt National Park. The THRO1 IMPROVE monitor also serves and is representative of haze conditions in the separate North Unit and the separate Elkhorn Ranch Unit of the Park. The monitor was sited at the existing monitoring site at the Painted Canyon Overlook in December 1999 by the federal agencies running the IMPROVE program. Site selection followed criteria in the Improve Particulate Monitoring Network Procedures for Site Selection, February 24, 1999, to be representative of the Park's three units. The existing site at the Painted Canyon Overlook met all the siting criteria including that all areas represented by the site should be within 100 km of a current or potential site. The northern boundary of the North Unit is approximately 80 km away from the site and the Elkhorn Ranch Unit is approximately 45 km away.

The state of North Dakota will also operate additional non-IMPROVE monitors that may be used in the future evaluations of Class I area visibility. These may include $PM_{2.5}$ speciation or Federal Reference Methods, monitoring systems for SO_2, NO_x, ozone, continuous $PM_{2.5}$, continuous PM_{10}, and meteorological monitors for wind speed, wind direction, ambient temperature, ambient pressure, relative humidity, solar radiation, and precipitation. Monitors presently operating are listed in Table 4.2.

Table 4.2
Additional non-IMPROVE Monitors

Monitoring Site	Parameter	Sampling &Analysis Method	Operating Schedule
Lostwood National Wildlife Refuge AQS#: 38-013-0004 Co-located with the LOST1 IMPROVE site.	Sulfur Dioxide	Instrumental Pulsed Florescent	Continuous
	Nitrogen Dioxide	Instrumental Chemiluminescence	Continuous
	Ozone	Instrumental Ultra Violet	Continuous
	$PM_{2.5}$	$PM_{2.5}$ SCC W/No Correction TEOM Gravimetric 40^0 Celsius	Continuous
	PM_{10}	PM_{10} TEOM Gravimetric 50^0 Celsius	Continuous
	Wind Speed	Elec. or Mach Avg. Level 1	Continuous
	Wind Direction	Elec. or Mach Avg. Level 1	Continuous
	Ambient Temperature	Elec. or Mach Avg.	Continuous
	Delta Temperature	Elec. or Mach Avg.	Continuous
	Ambient Pressure	Barometric Pressure Transducer	Continuous
	Solar Radiation	Pyranometer	Continuous
	Relative Humidity	Hydgroscopic Plastic Film	Continuous
Theodore Roosevelt National Park North Unit AQS# 38-053-0002	Sulfur Dioxide	Instrumental Pulsed Florescent	Continuous
	Nitrogen Dioxide	Instrumental Chemiluminescence	Continuous
	Ozone	Instrumental Ultra Violet	Continuous
	$PM_{2.5}$	$PM_{2.5}$ SCC W/No Correction TEOM Gravimetric 40^0 Celsius	Continuous
	PM_{10}	PM_{10} TEOM Gravimetric 50^0 Celsius	Continuous
	Wind Speed	Elec. or Mach Avg. Level 1	Continuous
	Wind Direction	Elec. or Mach Avg. Level 1	Continuous
	Ambient Temperature	Elec. or Mach Avg.	Continuous
	Ambient Pressure	Barometric Pressure Transducer	Continuous
	Relative Humidity	Hydroscopic Plastic Film	Continuous
Theodore Roosevelt National Park South Unit Co-located with the THRO1 IMPROVE Site.	Sulfur Dioxide	Instrumental Pulsed Florescent	Continuous
	Ozone	Instrumental Ultra Violet	Continuous
	$PM_{2.5}$	$PM_{2.5}$ SCC W/ No Correction TEOM Gravimetric 50^0 Celsius	Continuous
	Wind Speed	Elec. or Mach Avg. Level 1	Continuous

	Ambient Temperature	Elec. or Mach Avg.	Continuous
	Relative Humidity	Hydroscopic Plastic Film	Continuous
	Solar Radiation	Pyranometer	Continuous
	Precipitation	Recording Weighting	Continuous

It should be noted that the two IMPROVE monitors located at the Theodore Roosevelt National Park South Unit and the Lostwood National Wilderness Area have complete data for the period 2000 through 2004 and are relied upon in this Regional Haze SIP to establish the baseline deciview conditions.

In addition, the National Park Service monitors dry deposition at the Theodore Roosevelt National Park South Unit monitoring site. The dry deposition is analyzed for SO_4, NO_3, HNO_3, NH_4, and SO_2 weekly.

Section 51.308(d)(4)(ii) requires that the implementation plan must also provide for the following:

> (ii) Procedures by which monitoring data and other information are used in determining the contribution of emissions from within the State to regional haze visibility impairment at mandatory Class I Federal areas both within and outside the State.

The state of North Dakota will use data reported by the IMPROVE program as part of the regional technical support analysis tools found at the Visibility Information Exchange Web System (VIEWS), as well as other analysis tools that are available from EPA, FLMs and other states and tribes. The state of North Dakota will participate in any ongoing regional analysis activities to collectively assess and verify the progress toward reasonable progress goals, also supporting interstate consultation as the RHR is implemented, and collaborate with EPA, states, tribes, and FLMs to ensure the continued operation of existing technical support analysis tools and systems developed by WRAP. If the WRAP systems disappear, North Dakota will develop or contract for other technical support analysis tools and systems as necessary.

The state of North Dakota may conduct additional analyses as needed.

Section 51.308(d)(4)(iv) requires that the implementation plan must also provide for the following:

> (iv) The implementation plan must provide for the reporting of all visibility monitoring data to the Administrator at least annually for each mandatory Class I Federal area in the State. To the extent possible, the State should report visibility monitoring data electronically.

The state of North Dakota will depend on the routine timely reporting of haze monitoring data by the IMPROVE program for the reasonable progress tracking sites to the EPA air quality data system and VIEWS. The state of North Dakota will collaborate with EPA, states, tribes, and FLMs to ensure the continued operation of existing WRAP technical support analysis tools and systems.

The additional non-IMPROVE monitoring is conducted and the data collected and reported in accordance with EPA guidance. It is reported through electronic data transfer techniques quarterly.

Section 51.308(d)(4)(v) requires that the implementation plan must also provide for the following:

> (v) A statewide inventory of emissions of pollutants that are reasonably anticipated to cause or contribute to visibility impairment in any mandatory Class I Federal area. The inventory must include emissions for a baseline year, emissions for the most recent year for which data are available, and estimates of future projected emissions. The State must also include a commitment to update the inventory periodically.

The state of North Dakota has prepared a statewide inventory of emissions that can reasonably be expected to cause or contribute to visibility impairment in Federal Class I Areas. Section 6 of this plan summarizes the emissions by pollutant and source category.

The state of North Dakota commits to updating statewide emissions inventories periodically and submitting data to the EPA NEI system. The updates will be used for state tracking of emission changes, trends, and evaluation of whether reasonable progress goals are being achieved and other regional analyses. The inventories will be updated every one to three years on the same schedule as the every three-year reporting required by EPA's Consolidated Emissions Reporting Rule and the Air Emissions Reporting Requirements Rule. The Air Emissions Reporting Requirements Rule will completely replace the Consolidated Emissions Reporting Rule after the 2008 emission inventory data submittal which is due to June 1, 2010.

As a member of the WRAP, North Dakota will continue to use the WRAP-sponsored Emissions Data Management System (EDMS) and Fire Emissions Tracking System (FETS) to store and access emission inventory data for the region as long as they are maintained and available. If they are not available, North Dakota stores its data in house. North Dakota will continue to conduct its own modeling to simulate the air quality impacts of emissions for haze and other related air quality planning purposes. The state of North Dakota will collaborate with EPA, states, tribes and FLMs to ensure the continued operation of existing WRAP technical support analysis tools and systems.

Section 51.308(d)(4)(vi) requires that the implementation plan must also provide for the following:

> (vi) Other elements, including reporting, recordkeeping, and other measures, necessary to assess and report on visibility.

The state of North Dakota will track data related to RHR haze plan implementation for sources for which the state has regulatory authority, and will depend on the IMPROVE program for monitoring data. To ensure the availability of data and analyses to report on visibility conditions and progress toward Class I area visibility goals, the state of North Dakota will collaborate with EPA, states, tribes and FLMs to ensure the continued operation of the IMPROVE program and the existing WRAP-sponsored technical support analysis tools and systems for emissions inventory data.

4.3 Overview of the IMPROVE Monitoring Network

In the mid-1980's, the Interagency Monitoring of PROtected Visual Environments (IMPROVE) program was established to measure visibility impairment in mandatory Class I Federal areas throughout the United States. The monitoring sites are operated and maintained through a formal cooperative relationship between the EPA, National Park Service, U.S. Fish and Wildlife Service, Bureau of Land Management, NOAA and U.S. Forest Service. In 1991, several additional organizations joined the effort: National Association of Clean Air Agencies, Western States Air Resources Council (WESTAR), Mid-Atlantic Regional Air Management Association (MARAMA) and Northeast States for Coordinated Air Use Management (NESCAUM).

The objectives of the IMPROVE program include establishing the current visibility and aerosol conditions in mandatory Class I Federal areas; identifying the chemical species and emission sources responsible for existing human-made visibility impairment; documenting long-term trends for assessing progress towards the national visibility goals; and supporting the requirements of the Regional Haze Rule by providing regional haze monitoring representing all visibility-protected Federal Class I areas where practical. Figure 4.1 shows the IMPROVE site at Lostwood National Wilderness Area, and Figure 4.2 shows the four separate modules used for sampling the different pollutant species.

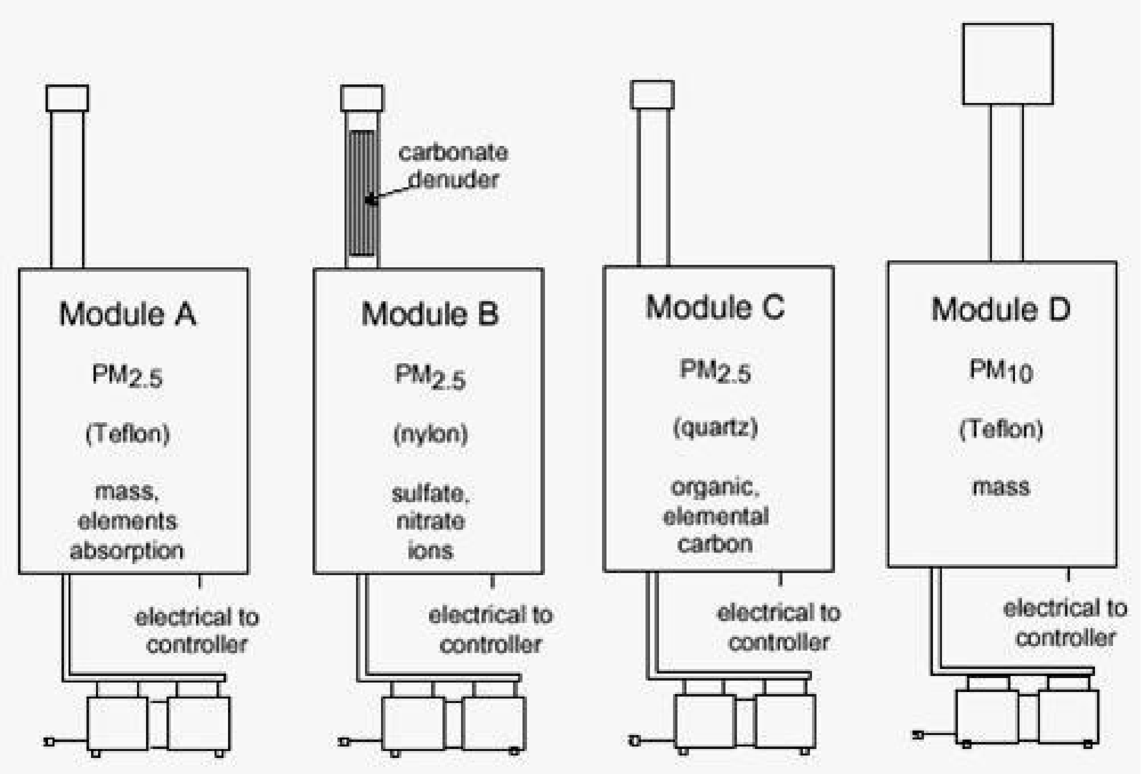
Figure 4.1
Pictures of the IMPROVE Monitoring Site at
Lostwood National Wilderness Area

Exterior

Interior

The IMPROVE sampler consists of four separate modules for measuring regional haze

Figure 4.2
IMPROVE Sampler Module



The data collected at the IMPROVE monitoring sites are used by land managers, industry planners, scientists, public interest groups and air quality regulators to better understand and protect the visual air quality resource in Class I areas. Most importantly, the IMPROVE Program scientifically documents the visual air quality of the wilderness areas and national parks.

The IMPROVE program has developed methods for estimating light extinction from speciated aerosol and relative humidity data. The three most common metrics used to describe visibility impairment are:

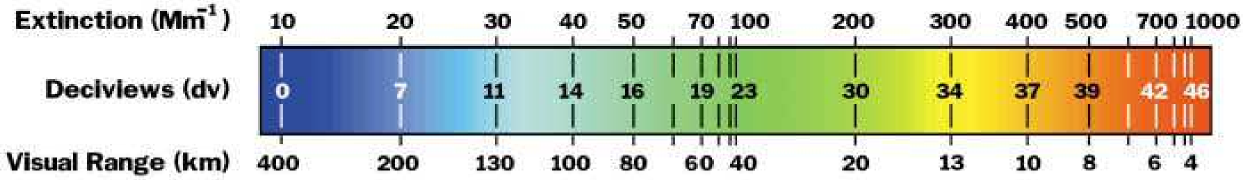
Extinction (b_{ext}) – Extinction is a measure of the fraction of light lost per unit length along a sight path due to scattering and absorption by gases and particles, expressed in inverse Megameters (Mm^{-1}). This metric is useful for representing the contribution of each aerosol species to visibility impairment and can be practically thought of as the units of light lost in a million meter distance.

Visual Range (VR) – Visual range is the greatest distance a large black object can be seen on the horizon, expressed in kilometers (km) or miles (mi).

Deciview (dv) – This is the metric used for tracking regional haze in the RHR. The deciview index was designed to be linear with respect to human perception of visibility. A one deciview change is approximately equivalent to a 10% change in extinction, whether visibility is good or poor. A one deciview change in visibility is generally considered to be the minimum change the average person can detect with the naked eye. See Section 5.1 for additional information.

For reference, Figure 4.3 compares b_{ext} in Mm^{-1}, deciviews (dv) which are unitless, and visual range in kilometers (km).

Figure 4.3
Comparison of Extinction (Mm^{-1}), Deciview (dv), and Visual Range (km)



The IMPROVE network estimates light extinction based upon the measured mass of various contributing aerosol species. EPA's 2003 guidance for calculating light extinction is based on the original protocol defined by the IMPROVE program in 1988. For further information, see: http://vista.cira.colostate.edu/improve/Publications/GuidanceDocs/guidancedocs.htm.

In December 2005, the IMPROVE Steering Committee voted to adopt a revised algorithm for use by IMPROVE as an alternative to the original approach.

The choice between use of the default or the revised equation for calculating the visibility metrics for each Class I area is made by the state in which the Class I area is located. North Dakota has chosen to use the revised equation. The revised algorithm for estimating light extinction is calculated as recommended for use by the IMPROVE steering committee using the following equations:

$$\begin{aligned}
b_{ext} \approx\ & 2.2\times f_S(RH)\times[\text{Small Amm. Sulfate}] + 4.8\times f_L(RH)\times[\text{Large Amm. Sulfate}] \\
& +2.4\times f_S(RH) \times [\text{Small Amm. Nitrate}] + 5.1\times f_L(RH) \times [\text{Large Amm. Nitrate}] \\
& +2.8\times [\text{Small Particulate Organic Matter}] + 6.1\times [\text{Large Particulate Organic Matter}] \\
& +10\times [\text{Elemental Carbon}] \\
& +1\times [\text{Fine Soil}] \\
& +1.7\times f_{SS}(RH) \times [\text{Sea Salt}] \\
& +0.6\times [\text{Coarse Mass}] \\
& +0.33\times [NO_2\ (\text{ppb})] \\
& +\text{Rayleigh Scattering (Site Specific)}
\end{aligned}$$

Where:
b_{ext} = light extinction in units of inverse megameters (Mm^{-1}),
$f_S(RH)$ = function of relative humidity for small size fraction,
$f_L(RH)$ = function of relative humidity for large size fraction,
$f_{SS}(RH)$ = function of relative humidity for sea salt, and
all species concentrations are provided in $\mu g/m^3$.

The revised algorithm splits ammonium sulfate ($(NH_4)_2SO_4$), ammonium nitrate (NH_4NO_3) and total particulate organic matter (POM =1.8 × organic carbon) concentrations into small and large size fractions. The equations for ammonium sulfate are:

$[\text{Large } (NH_4)_2SO_4] = [\text{Total } (NH_4)_2SO_4]^2 \div 20$, for $[\text{Total } (NH_4)_2SO_4] < 20\ \mu g/m^3$
$[\text{Large } (NH_4)_2SO_4] = [\text{Total } (NH_4)_2SO_4]$, for $[\text{Total } (NH_4)_2SO_4] \geq 20 \mu g/m^3$

$[\text{Small } (NH_4)_2SO_4] = [\text{Total } (NH_4)_2SO_4] - [\text{Large } (NH_4)_2SO_4]$

Similar equations are used to apportion total ammonium nitrate and total particulate organic matter concentrations into small and large size fractions.

Light extinction is converted to deciview using the following relationship:

$$dv = 10 \times \ln(b_{ext}/10)$$

Where:
dv = deciview,
b_{ext} = light extinction in units of inverse megameters (Mm^{-1}).

5. Baseline and Natural Visibility Conditions and Uniform Rate of Progress for North Dakota Class I Areas

5.1 The Deciview

The Clean Air Act (Section 169A(a)(1)) states “Congress hereby declares as a national goal the prevention of any future, and remedying of any existing impairment of visibility in mandatory Class I Federal areas which impairment results from man-made air pollution.” In order to achieve this goal, all man-made pollution must be eliminated such that natural conditions (visibility) are restored. Natural conditions include naturally occurring phenomena that reduce visibility as measured in terms of light extinction, visual range, contrast, or coloration (40 CFR 51.301). The State is required to develop a SIP that contains measures that make reasonable progress toward the national goal of no man-made visibility impairment.

The primary metric for assessing baseline conditions, natural conditions and the rate of progress is the deciview. A deciview is a haze index derived from calculated light extinction, such that uniform changes in haziness correspond to uniform incremental changes in perception across the entire range of conditions, from pristine to highly impaired. The deciview index is calculated based on the following equation:

Deciview haze index = 10 ln (b_{ext}/10 Mm^{-1})

Where: b_{ext} = the atmospheric light extinction coefficient expressed in inverse megameters (Mm^{-1})

The deciview scale is zero for pristine conditions and increases as visibility degrades. Each one deciview change represents a perceptible or small just-noticeable change in visual air quality or haziness to the average person under most circumstances when viewing scenes in Class I areas regardless of background visibility conditions. This is approximately a 10% change in the light extinction (Mm^{-1}) reading.

In order to determine the rate of progress of visibility improvement, the baseline conditions and natural conditions must be determined for each Class I area. The baseline visibility conditions are calculated from IMPROVE data for the years 2000-2004. Natural visibility conditions are determined by estimating the natural concentrations of visibility impairing pollutants that existed prior to man’s influence. These concentrations are then used to calculate light extinction and the deciview metric.

5.2 Baseline Visibility Conditions

The Class I Federal Areas in North Dakota are the North Unit, South Unit and Elkhorn Ranch Unit of Theodore Roosevelt National Park and the Lostwood Wilderness Area. Although IMPROVE monitoring data is not available for the North Unit and Elkhorn Ranch Units of

TRNP, the Department considers monitoring data from the South Unit to be representative of conditions at the other two units. See Section 4.2 for a discussion of the representativeness of the monitor in the South Unit for the other two units of TRNP. Since the monitoring is representative, we only refer to the TRNP although there are three distinct separate areas.

Baseline visibility is the average of the IMPROVE monitoring data for 2000 through 2004. Baseline visibility is calculated for both the 20 percent best and 20 percent worst days. The monitoring data from the IMPROVE sites as plotted by WRAP and displayed on their TSS website are shown in Figures 5.1 - 5.4.

Figure 5.1

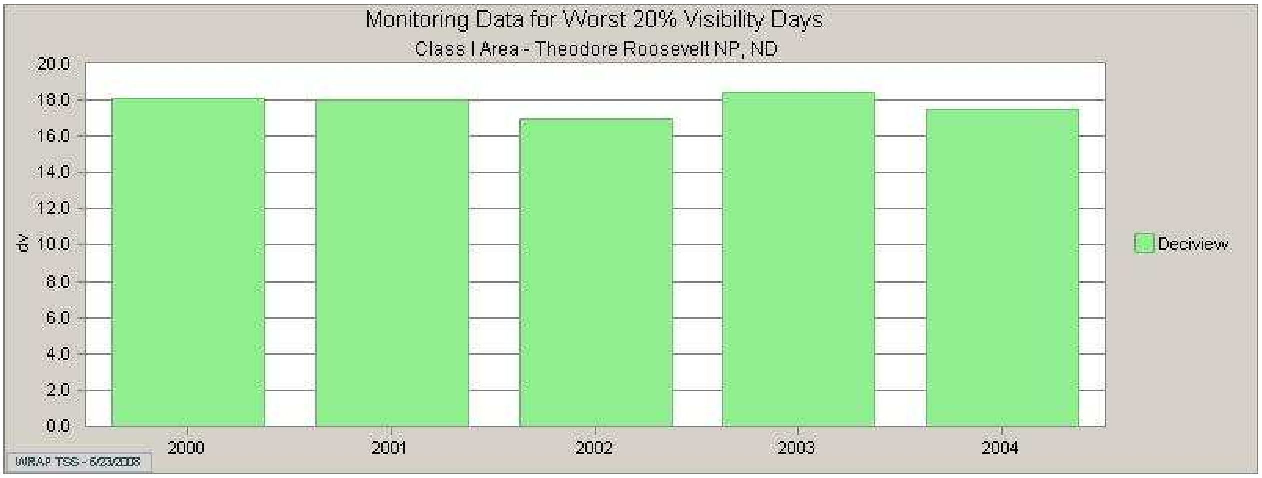


Figure 5.2

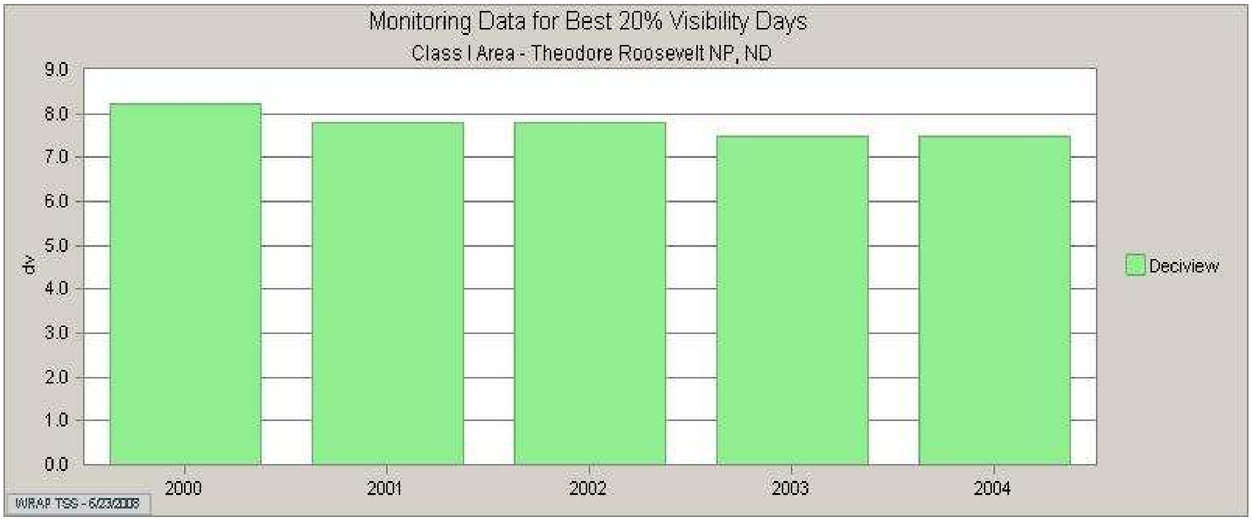

Figure 5.3

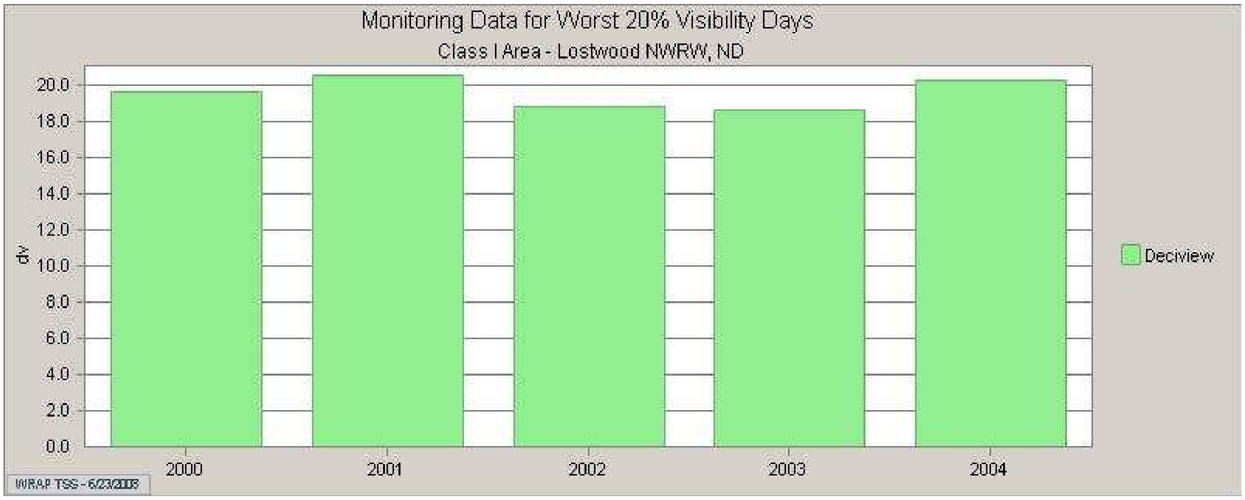

Figure 5.4

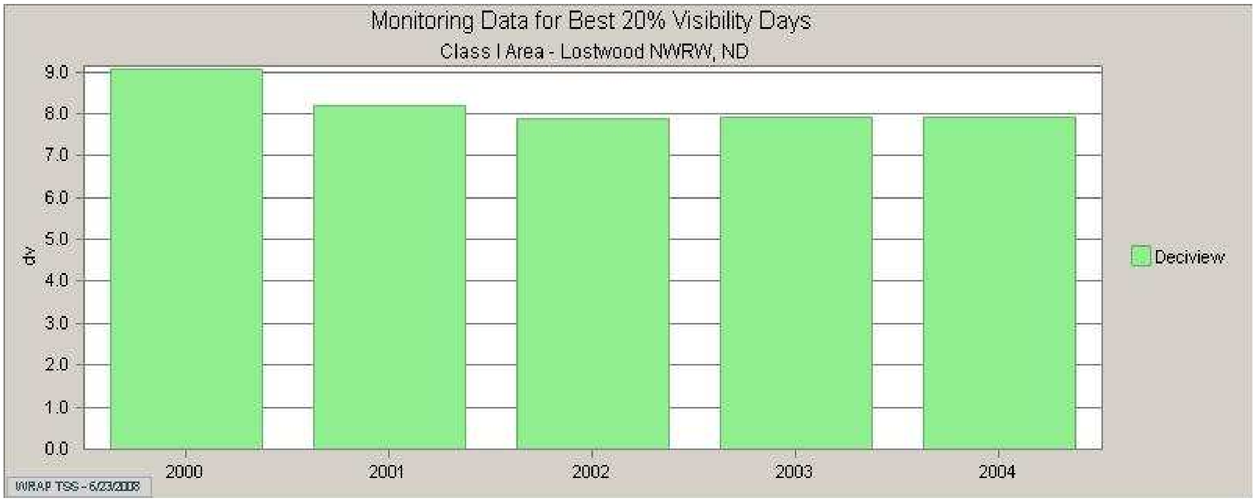


Based on the IMPROVE data, the baseline visibility conditions in the North Dakota Class I areas are shown in Table 5.1.

Table 5.1
Baseline Visibility (Deciviews)

	TRNP		**LWA**	
Year	**20% Best Days**	**20% Worst Days**	**20% Best Days**	**20% Worst Days**
2000	8.2	18.1	9.1	19.7
2001	7.8	18.0	8.2	20.6
2002	7.8	17.0	7.9	18.8
2003	7.5	18.4	7.9	18.6
2004	7.5	17.5	7.9	20.2
Baseline (avg.)	7.8	17.8	8.2	19.6

Note: Figures 5.1-5.4 and Table 5.1 are based on the revised IMPROVE Algorithm. The source of the figures and data is the WRAP TSS website. A description of the WRAP methodology is found in Appendix A.5.

5.3 Natural Visibility Conditions

EPA has prepared "Guidance for Estimating Natural Visibility Conditions Under the Regional Haze Program" (EPA-454/B-03-005, Sept. 2003) to aid states in estimating natural visibility conditions. Natural visibility conditions represent the long-term degree of visibility that is estimated to exist in a given Class I area in the absence of man-made impairment. Natural visibility conditions are not constant, but vary with changing natural processes such as fire, windblown dust, volcanic activity and biogenic emissions. EPA has developed a default approach which will satisfy the requirements for the initial SIP which addresses regional haze. The default approach defines two separate regions of the United States (1) The East, which consists of all states east of the Mississippi River, and up to one tier of states west of the Mississippi; and (2) the West, including the regions of the Mountain and Pacific time zones. States that are near the boundary between East and West are free to choose which set of natural visibility values are more appropriate and adopt those values. North Dakota is considered to be in the West Region; however, it is one of those states that are on the boundary of East and West. Appendix B of EPA guidance document provides the default natural extinction values (deciviews) for both the best and worst days. The values for the North Dakota Class I areas are shown in Table 5.2.

Table 5.2
EPA Default Natural Visibility Conditions (Deciviews)

Area	**Best Days**	**Worst Days**
TRNP	2.19	7.31
LWA	2.21	7.33

These natural visibility condition values were calculated based on an IMPROVE algorithm which has since been modified. The new IMPROVE equation accounts for the effect of particle size distribution on light extinction efficiency of sulfate, nitrate and organic carbon. The mass multiplier for organic carbon is increased from 1.4 to 1.8. New terms were added to the equation to account for light extinction by sea salt and light absorption by gaseous nitrogen dioxide. Site specific values are used for Rayleigh scattering to account for variations in elevation and temperature. Separate relative humidity enhancement factors are used for small and large size distributions of ammonium sulfate, ammonium nitrate and sea salt.

The WRAP calculated the natural background visibility conditions consistent with EPA's guidance using the revised IMPROVE equation. The results of that calculation are shown in Table 5.3.

Table 5.3
WRAP Calculated Natural Visibility Conditions (Deciviews)

Area	**Best Days**	**Worst Days**
TRNP	3.0	7.8
LWA	2.9	8.0

The values in Table 5.3 have been established as the natural background values for North Dakota and are used to establish the uniform rate of progress. The improvement necessary to achieve natural conditions is shown in Table 5.4.

Table 5.4
Improvement Necessary To Achieve Natural Conditions
(Deciviews)

Area	Baseline Best Days	Natural Best Days	Improvement Required	Baseline Worst Days	Natural Worst Days	Improvement Required
TRNP	7.8	3.0	4.8	17.8	7.8	10.0
LWA	8.2	2.9	5.3	19.6	8.0	11.6

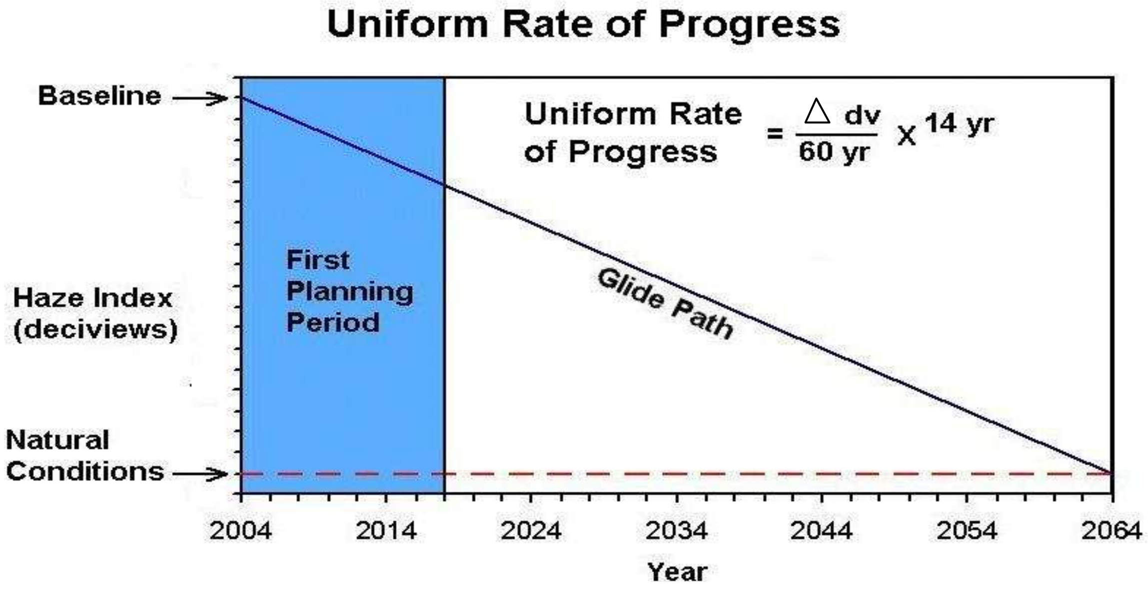
5.4 Uniform Rate of Progress

The uniform rate of progress to achieve natural conditions in any Class I Federal area is calculated as the difference between baseline condition for the 20% worst days and natural condition for the 20% worst days divided by 60 years (2004-2064). Mathematically it is determined by the following equation:

URP = [Baseline Condition - Natural Condition]) 60 yrs dv/yr

By multiplying the uniform rate of progress by 14 years in the first planning period (10 years thereafter), the progress needed by 2018 to be on the path to achieving natural conditions can be calculated as shown in Figure 5.5.

Figure 5.5



Δ dv = Baseline conditions minus natural conditions

Based on the above data, the uniform rate of progress is calculated as follows:

Theodore Roosevelt National Park

URP = (17.8 – 7.8)(14/60) dv
URP = 2.3 dv

Lostwood Wilderness Area

URP = (19.6 – 8.0)(14/60) dv
URP = 2.7 dv

The uniform rate of progress for the Theodore Roosevelt National Park and Lostwood Wilderness Area for the first planning period is shown graphically in Figures 5.5 and 5.6. For the best days, the State must ensure that no degradation occurs over the same planning period.

WRAP TSS - 6/23/2008

6. Sources of Visibility Impairment in North Dakota Class I Areas

6.1 Introduction

40 CFR 51.308(d)(4)(v) requires a statewide inventory of emissions of pollutants that are reasonably anticipated to cause or contribute to visibility impairment in any mandatory Class I Federal Area be included in the SIP. Emissions within North Dakota are both naturally occurring and man-made. Naturally occurring emissions include wildfires, windblown dust and others. In North Dakota, the primary sources of anthropogenic emissions include electric utility steam generating units (EGUs), energy production and processing sources, agricultural production and processing sources, prescribed burning and fugitive dust sources. The North Dakota inventory includes emissions of sulfur dioxide (SO_2), nitrogen oxides (NO_x), fine particulate matter (PMF), coarse particulate matter (PMC), organic carbon (OC), volatile organic compounds (VOC), elemental carbon (EC) and ammonia (NH_3).

6.2 Emissions in North Dakota

The most recent complete inventory of all emission categories is from 2002. The point source data was compiled by the State while the rest of the inventory was prepared by the WRAP and its contractors with input from the state (Case Plan 02d – see Section 9 for a discussion of this case plan). A summary of the inventory is shown in Table 6.1. The WRAP Oil and Gas inventory for sulfur dioxide was adjusted to include sulfur dioxide emissions from flaring and lease use of sour gas at well sites (WRAP did not include flaring and lease use emissions). The adjustment was based on hydrogen sulfide data for the combusted gas, which is compiled by the Health Department, and the amount of gas flared or used onsite which is compiled by the North Dakota Oil and Gas Division.

Table 6.1
North Dakota 2002 Emissions Inventory (tons)

	Point	All Fire	Biogenic	Area	Area O&G	On-Road Mobile	Off-Road Mobile	Road Dust	Fugitive Dust	Wind Blown Dust	Total

NH_3	518	812	0	118,398	0	732	33	0	0	0	120,493
VOC	2,086	3,849	233,561	60,455	7,740	12,814	13,515	0	0	0	334,020
CO	11,944	60,735	67,769	21,933	36	211,842	95,869	0	0	0	470,129
Total	261,912	73,200	345,898	220,719	17,365	251,590	176,825	32,020	210,610	176,391	1,766,529

A complete emissions inventory is not available for a more recent year. However, more recent data for point source emissions are available for 2007. Those data are shown in Table 6.2.

Table 6.2

WRAP has developed a future inventory for North Dakota for the year 2018. The PRP18b emissions inventory for North Dakota is shown in Table 6.3. Again, sulfur dioxide emissions for the Area Oil and Gas inventory were increased by the Department to include emissions from flaring and lease use of sour gas. The PRP18b emissions inventory also included the proposed Gascoyne 500 coal-fired power plant. The Permit to Construct application for this facility has been withdrawn. The sulfur dioxide and nitrogen oxides emissions for this plant were removed from the inventory by the Department. The Department does not expect any additional coal-fired power plants to be constructed in North Dakota before 2018.

The Department does not agree with WRAP's estimate of nitrogen oxides emissions from the Area Oil and Gas industry for 2018. WRAP has predicted that 2018 NO_x emissions would be 4.5 times greater than 2002 emissions. The Department discussed this estimate with the Oil and Gas Division of the North Dakota Industrial Commission. It was the opinion of the Oil and Gas Division that most of the Bakken formation development will be over by 2018 and drilling rig activities are expected to settle back to the same ratio as production (i.e., 2-2.5 times the 2002 levels). Based on discussions with the Oil and Gas Division, it is believed that an increase of 2 – 2.5 times the 2002 emission rate is appropriate for 2018. In subsequent discussions with WRAP, representatives of WRAP admitted that 2018 estimates of NO_x emissions related to oil and gas activity in North Dakota may have been overstated. The inventory in Table 6.3 represents a 2.5 times increase for Area Oil and Gas sources.

The Department also disagrees with WRAP's estimate of PMF and PMC emissions for 2018. As explained in Section 9.5.2, agricultural conservation tillage practices, which reduce emissions, are expected to increase by 2018. Since agricultural activities and farm land are the major sources of fugitive and windblown PMF and PMC emissions, it is expected these emissions will decrease. Even though a decrease is expected, the emissions of PMF and PMC shown in Table 6.3 were not adjusted by the Department.

In future Regional Haze SIP reviews, the Department will use the most current, refined emissions inventories available.

6.3 Emissions from Other States and Canadian Provinces

The visibility in the Class I areas in North Dakota is influenced by emissions from surrounding states, Canada and sources outside WRAP's modeling domain. The three contiguous states to North Dakota are Montana, South Dakota and Minnesota. The 2002 emissions from the respective states are shown in Table 6.5.

Table 6.5
Nearby States 2002 Emissions (tons)

[a] Source - WRAP TSS (Case Plan 02d)
[b] Source - Minnesota Draft Haze SIP

North Dakota's contribution to visibility impairment in TRNP and LWA is generally small (see Table 6.6). Sulfates and nitrates, as discussed further in Section 8, are the primary pollutants of concern in these Class I areas. In-state sources contribute 21 percent or less of sulfate or nitrate during the 20 percent worst baseline days at TRNP or LWA. It should be noted in Table 6.6 the sulfate and nitrate values are based on WRAP regional modeling using the CAM_x – PSAT source apportionment total, while the analyses of weighted emissions potential for organic carbon (OC), elemental carbon (EC), and particulate matter (PM) are based on emissions and residence time, not modeling.

Table 6.6
ND Sources Extinction Contribution
2000-2004
20% Worst Days

Class I Area	Pollutant Species	Extinction (Mm^{-1})	Species Contribution To Total Extinction (%)	ND Sources Contribution To Species Extinction (%) [a]

	OC	11.05	18	23
	EC	2.84	5	35
	PMF	0.62	1	28
	PMC	3.93	6	32
	Sea Salt	0.26	0	0

[a] North Dakota contribution for sulfate and nitrate based on WRAP's tracer analysis and OC, EC, PMF, PMC and Sea Salt contribution based on WRAP's weighted emissions potential analysis.

In general, sources within Canada and sources outside WRAP's modeling domain are bigger contributors to regional haze in TRNP and LWA than North Dakota sources.

The influence of sources outside of North Dakota on TRNP and LWA for the 2000-2004 period can be seen in Figures 6.1-6.16 and Table 6.7. These figures and data were obtained from the WRAP TSS website. Figures 6.3, 6.4, 6.9 and 6.10 are based on WRAP's tracer analysis study which is considered a more rigorous analysis than the weighted emissions potential analysis (Figures 6.5 – 6.8 and 6.11 – 6.16). The Department does not agree with the WRAP's estimate of nitrogen oxides emissions from the oil and gas source category for 2018 (see Section 6.2). The Department believes WRAP has overestimated the 2018 nitrogen oxides emissions. Therefore, Figures 6.4 and 6.12 overestimate the percentage of oil and gas nitrogen oxides contribution for 2018.

Other	10.5%	13.7%	8.3%	14.0%

The primary Canadian provinces which influence visibility in the Class I areas of North Dakota are Saskatchewan, Alberta, Manitoba and British Columbia. Emissions from these provinces in 2002, as reported in WRAP's TSS website, totaled more than one million tons of sulfur dioxide, 1.4 million tons of nitrogen oxides and 2 million tons of particulate matter as shown in Table 6.8.

Table 6.8
2002 Canadian Emissions (tons)

	SO_2	NO_x	PMC	PMF
Saskatchewan	126,528	292,539	364,739	78,108
Manitoba	398,806	142,685	144,928	25,403
Alberta	433,394	752,966	503,835	807,738
British Columbia	101,990	214,914	64,545	39,695

The location of sulfur dioxide and nitrogen oxides emissions, as reported by Environment Canada, are shown in Figures 6.17 and 6.18. As can be seen, the heaviest concentration of emissions of sulfur dioxide and nitrogen oxides are northwest, in the prevailing wind direction of North Dakota's Class I areas, especially the Lostwood Wilderness Area.

Three major coal-fired electric utility steam generating plants within Saskatchewan are located just north of the U.S./Canada border within 250 km of the Lostwood Wilderness Area. During 2002, emissions from these plants totaled nearly 110,000 tons of sulfur dioxide and 38,000 tons of nitrogen oxides as shown in Table 6.9. The Boundary Dam plant, which has the largest amount of emissions, is located within 60 kilometers of LWA.

7. Best Available Retrofit Technology (BART)

7.1 Introduction

7.1.1 Overview of Paragraph 51.308(e) of the Federal Regional Haze Regulation - Best Available Retrofit Technology (BART) Requirements for Regional Haze Visibility Impairment

The requirements for Best Available Retrofit Technology (BART) are found in Section 51.308(e) of the federal regional haze regulation.

Paragraph (e) has six subparagraphs which identify the requirements as follows:

1. 51.308(e)(1) - BART for individual sources;
2. 51.308(e)(2) and (3) - An emissions trading program, or other alternative measure, rather than to require sources subject to BART to install, operate, and maintain BART;
3. 51.308(e)(4) - Participation in the EPA administered Clean Air Interstate Rule (CAIR) trading programs for sulfur dioxide and nitrogen oxides;
4. 51.308(e)(5) - Status of BART-eligible sources after a state has met the requirements for BART; and
5. 51.308(e)(6) - An exemption from BART requirements for BART-eligible sources.

Section 51.308(e) requires the State to submit an implementation plan containing emission limitations representing BART and schedules for compliance with BART for each BART-eligible source that may reasonably be anticipated to cause or contribute to any impairment of visibility in any mandatory Class I Federal area, unless the State demonstrates that an emissions trading program or other alternative measures will achieve greater reasonable progress toward natural visibility conditions, or the State participates in a Clean Air Interstate Rule (CAIR) trading program.

The Department has decided not to develop an emissions trading program or other alternate measures and is not eligible to participate in the CAIR program. Therefore only Sections 308(e)(1), (5), and (6) apply in North Dakota.

Each state implementation plan must contain two elements related to BART.

The first, found in Section 308(e)(1)(i), is the requirement that the State submit a list of the BART-eligible sources in the State.

The second requirement is detailed in Section 308 (e)(1)(ii) and requires the State to determine and include in the plan BART emission reductions for each BART-eligible source in the State which may reasonably be anticipated to cause or contribute to any impairment of visibility in any mandatory Class I area.

BART must be determined for each visibility-impairing pollutant that is emitted by a BART-eligible source which may reasonably be anticipated to cause or contribute to regional haze. The definition for BART 51.301 reads:

> Best Available Retrofit Technology (BART) means an emission limitation based on the degree of reduction achievable through the application of the best system of continuous emission reduction for each pollutant which is emitted by an existing stationary facility. The emission limitation must be established, on a case-by-case basis, taking into consideration the technology available, the costs of compliance, the energy and the non air quality environmental impacts of compliance, any pollution control equipment in use or in existence at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology.

Visibility-impairing pollutants include sulfur dioxide (SO_2), nitrogen oxides (NO_x), particulate matter (PM_{10} and $PM_{2.5}$) volatile organic compounds (VOC), and ammonia (NH_3).

In developing source specific emission limits for BART, the State must take into consideration the control technology available and a number of specific factors:

- The costs of compliance;
- The energy and non-air environmental impacts of compliance;
- Any existing pollution control technology in use at the source;
- The remaining useful life of the source; and
- The degree of improvement in visibility which may reasonably be anticipated from the use of such technology.

The State has the discretion as to how much weight will be given to each of the factors.

EPA issued final guidance for the determination of BART on July 6, 2005 as 40 CFR Part 51 Appendix Y - Guidelines for BART Determinations Under the Regional Haze Rule (BART guideline).

The SIP for source-specific BART (51.308(e)(1)) must contain the requirement that each source subject to BART install and operate BART as expeditiously as practicable, but in no event later than five years after approval of the implementation plan revision by EPA.

The SIP must contain procedures to ensure control equipment is properly maintained and operated in the BART requirements (51.308(e)(1)(v)).

Paragraph 51.308(e)(5) provides that after a State has met the requirements for source-specific BART, BART-eligible sources will be subject to the core requirements of Section 51.308(d) in the same manner as other sources. This would include enforceable emissions limitations, compliance schedules and other measures as necessary to achieve the reasonable progress goals set out in the long-term strategy to attain natural conditions by 2064.

Paragraph 51.308(e)(6) provides that even where a BART-eligible source may reasonably be anticipated to cause or contribute to visibility impairment, section 169A(c) of the Clean Air Act allows for the exemption of any source from the BART requirements if it can be demonstrated that the source, by itself or in combination with other sources, is not reasonably anticipated to cause or contribute to significant visibility impairment. Significant impairment 51.301 is defined as:

> "Significant impairment means, for purposes of Section 51.303, visibility impairment which, in the judgement of the Administrator, interferes with the management, protection, preservation, or enjoyment of the visitor's visual experience of the mandatory Class I Federal area. This determination must be made on a case-by-case basis taking into account the geographic extent, intensity, duration, frequency and time of the visibility impairment, and how these factors correlate with (1) times of visitor use of the mandatory Class I Federal area, and (2) the frequency and timing of natural conditions that reduce visibility."

EPA believes that the question of whether a source can be reasonably anticipated to cause or contribute to significant visibility impairment requires an analysis of the cumulative effects of emission sources on a region. Regional modeling will be one appropriate method to determine whether a source could qualify for a BART exemption. If a significant cumulative impact is demonstrated from the sources across the relevant regional modeling domain, then any BART-eligible source in the region would most likely be found to be reasonably anticipated to cause or contribute to significant visibility impairment.

A source may apply to EPA for an exemption from the BART requirement. The EPA will grant or deny an application after providing notice and opportunity for a public hearing. Any exemption granted by EPA must have the concurrence from all affected Federal Land Managers. The requirements for an exemption are found in Section 51.303. The authority to grant an exemption is reserved to EPA and will not be delegated to a state.

7.1.2 Visibility-Impairing Pollutants of Concern

For both BART applicability and degree of visibility improvement analyses, the BART guideline specifies that only primary emissions need to be considered. These primary emissions include SO_2, NO_x, and direct particulate matter (PM) emissions specified as either coarse (PM_{10} minus $PM_{2.5}$) or fine ($PM_{2.5}$). If this distinction in size of PM emissions cannot be made, it would be appropriate to consider all PM_{10} emissions as $PM_{2.5}$.

The BART guideline also discusses volatile organic compounds (VOC) or ammonia (NH_3) emissions as possibly impacting visibility. For the BART-eligible sources identified in North Dakota, these emissions (and associated visibility impacts) are negligible, and therefore the Department will not require inclusion of VOC or ammonia species in BART-related visibility analyses.

7.1.3 BART Identification Process

The first step in preparing the RH BART SIP is to develop a list of all BART-eligible sources within the State.

The regional haze rule contains the following definitions in Section 51.301:

> BART-eligible source means an existing stationary facility as defined in this section.
>
> Existing stationary facility means any of the following stationary sources of air pollutants, including any reconstructed source, which was not in operation prior to August 7, 1962, and was in existence on August 7, 1977, and has the potential to emit 250 tons per year or more of any air pollutant. In determining potential to emit, fugitive emissions, to the extent quantifiable, must be counted.

(1) Fossil-fuel fired steam electric plants of more than 250 million British thermal units per hour heat input,
(2) Coal cleaning plants (thermal dryers),
(3) Kraft pulp mills,
(4) Portland cement plants,
(5) Primary zinc smelters,
(6) Iron and steel mill plants,
(7) Primary aluminum ore reduction plants,
(8) Primary copper smelters,
(9) Municipal incinerators capable of charging more than 250 tons of refuse per day,
(10) Hydrofluoric, sulfuric, and nitric acid plants,
(11) Petroleum refineries,
(12) Lime plants,
(13) Phosphate rock processing plants,
(14) Coke oven batteries,
(15) Sulfur recovery plants,
(16) Carbon black plants (furnace process),
(17) Primary lead smelters,
(18) Fuel conversion plants,
(19) Sintering plants,
(20) Secondary metal production facilities,
(21) Chemical process plants,
(22) Fossil-fuel boilers of more than 250 million British thermal units per hour heat input,
(23) Petroleum storage and transfer facilities with a capacity exceeding 300,000 barrels,
(24) Taconite ore processing facilities,
(25) Glass fiber processing plants, and
(26) Charcoal production facilities.

The following three steps identify the key elements in the definition of existing stationary facility and other related definitions that should be considered when determining whether a source is a BART-eligible source.

STEP 1. IDENTIFY EMISSION UNITS IN THE 26 BART LISTED SOURCE CATEGORIES.

Listed Source Categories - The facility must fall within one of the 26 listed categories in the definition of existing stationary facility. These are the same categories that are included in the definitions of major source under PSD. PSD guidance documents and case history can be used to answer any questions related to the 26 categories.

Aggregated Unit Applicability - the definition for existing stationary facility includes stationary sources. Stationary source is defined as:

> Stationary source means any building, structure, facility, or installation which emits or may emit any air pollutant.

Building, structure, or facility are defined as:

> Building, structure, or facility means all of the pollutant-emitting activities which belong to the same industrial grouping, are located on one or more contiguous or adjacent properties, and are under the control of the same person (or persons under common control). Pollutant-emitting activities must be considered as part of the same industrial grouping if they belong to the same Major Group (i.e., which have the same two-digit code) as described in the Standard Industrial Classification Manual, 1972 as amended by the 1977 Supplement (U.S. Government Printing Office stock numbers 4101-0066 and 003-005-00176-0 respectively).

Installation is defined as:

> Installation means an identifiable piece of process equipment.

The above definitions have been interpreted by EPA to mean that all of the units within the source that meet the BART criteria should be aggregated together to determine if the source is BART-eligible.

STEP 2. IDENTIFY THE STARTUP DATES OF THE EMISSION UNITS.

Date of Operation/Construction/Reconstruction - BART review is limited to units that were constructed during a 15-year window between 1962 and 1977. There are several nuances in the definition of existing stationary facility that must be considered when determining if a unit falls within this 15-year window. The unit must not have been in operation prior to August 7, 1962. In operation is defined as:

> In operation means engaged in activity related to the primary design function of the source.

The date that the unit is permitted is not important to meet this test because the focus is on actual operation of the unit.

In addition, the unit must have been in existence as of August 7, 1977. In existence is defined as:

> In existence means that the owner or operator has obtained all necessary preconstruction approvals or permits required by Federal, State, or local air pollution emissions and air quality laws or regulations and either has (1) begun, or caused to begin, a continuous program of physical on-site construction of the facility or (2) entered into binding agreements or contractual obligations, which cannot be canceled or modified without substantial loss to the owner or operator, to undertake a program of construction of the facility to be completed in a reasonable time.

The actual date a unit begins operation may not be important to meet this test. For example, a unit that did not begin operation until 1983 may still be considered BART-eligible if the unit had all the necessary preconstruction approvals or permits and had begun, or caused to begin, a continuous program of physical on-site construction of the facility, or entered into binding agreements or contractual obligations, which cannot be canceled or modified without substantial loss prior to August 7, 1977.

STEP 3. COMPARE THE POTENTIAL TOTAL EMISSIONS FOR EACH POLLUTANT FROM THE EMISSION UNITS TO THE 250 TON PER YEAR CUT OFF.

Potential Emissions - The emission units that meet the source category and date of construction or operation requirements must then be aggregated together to determine if the combined emission units have the potential to emit 250 tons per year of any air pollutant.

Potential to emit is defined as:

> Potential to emit means the maximum capacity of a stationary source to emit a pollutant under its physical and operational design. Any physical or operational limitation on the capacity of the source to emit a pollutant including air pollution control equipment and restrictions on hours of operation or on the type or amount of material combusted, stored, or processed, shall be treated as part of its design if the limitation or the effect it would have on emissions is federally enforceable. Secondary emissions do not count in determining the potential to emit of a stationary source.
>
> Applicability for BART is determined on a pollutant-by-pollutant basis. The total emissions for each pollutant from all the units at the source remaining after step 2 above is compared to the 250 ton per year cut off.

> Pollutants to be considered include the visibility-impairing pollutants, SO_2, NO_x, $PM_{2.5}$ and PM_{10}, VOC, and NH_3.

Fugitive emissions, to the extent quantifiable, must be counted. Fugitive emissions are defined as:

> Fugitive Emissions means those emissions which could not reasonably pass through a stack, chimney, vent, or other functionally equivalent opening.

As noted in the definition for Potential to emit, secondary emissions do not count in determining the potential to emit of a stationary source. Secondary emissions are defined as:

> Secondary emissions means emissions which occur as a result of the construction or operation of an existing stationary facility but do not come from the existing stationary facility. Secondary emissions may include, but are not limited to, emissions from ships or trains coming to or from the existing stationary facility.

A SOURCE THAT PASSES ALL THREE STEPS IS A BART-ELIGIBLE SOURCE.

7.1.4 CALPUFF Screening Model Protocol

The Department has established a protocol for BART-related dispersion modeling applicable to BART-eligible sources in North Dakota. The protocol uses the CALPUFF model and conforms to the requirements of Appendix Y to Part 51- Guidelines for BART Determinations Under the Regional Haze Rule. It follows recommendations for long range transport of Appendix W to Part 51 - The Guideline on Air Quality Models and EPA's Interagency Workgroup on Air Quality Modeling (IWAQM) Phase 2 Summary Report and Recommendations for Modeling Long Range Transport Impacts. The protocol was reviewed by EPA and Federal Land Manager meteorologists in Denver, CO prior to finalizing.

The protocol, "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota, November 2005", is included as Appendix A.1. Both BART applicability and degree of visibility improvement analyses were conducted following this protocol.

7.1.5 Screening Impact Threshold

In general, to determine which BART-eligible sources must apply BART, single facility modeling results for PSD Class I areas are compared with a visibility threshold, expressed in deciviews. The Department will follow recommendations in the July 6, 2005 BART guideline which states:

> "A single source that is responsible for a 1.0 deciview change or more should be considered to "cause" visibility impairment; a source that causes less than a 1.0 deciview change may still "contribute" to visibility impairment and thus be subject to BART .... As

> a general matter, any threshold that you use for determining whether a source "contributes" to visibility impairment should not be higher than 0.5 deciviews."

As a practical matter, the NDDH sees no reason to distinguish among BART-eligible sources which "cause" visibility impairment versus those sources which "contribute" to visibility impairment in PSD Class I areas. Therefore, the Department will generally use one threshold to determine which BART-eligible sources must apply BART.

The Department, in accordance with the BART guidelines, used a contribution threshold of 0.5 deciview for determining which sources were subject to BART. The BART guidelines provide States the discretion to set a threshold below 0.5 deciviews if "the location of a large number of BART-eligible sources within the State and proximity to a Class I area justifies this approach." This decision was based on several factors:

- It equates to the 5 percent extinction threshold for new sources under the PSD New Source Review rules,
- It is consistent with the threshold selected by other States in the West (all selected 0.5 dv),
- It represents the limit of perceptible change

There are only a few major point sources in North Dakota affecting the Class I areas and they are mostly 100 or more miles away, downwind in the prevailing wind direction. BART screening modeling indicates the visibility impact to either be much greater than 1.0 deciview or 0.5 deciview or less (See Section 7.3.1.), and there was no clear rationale or justification for selecting a lower level.

The Department therefore has established 0.5 deciview as the threshold to determine which BART-eligible sources must apply BART and included it in the State rules. Definition 2 of NDAC Section 33-15-25-01, Definitions, is:

> "Contributes to visibility impairment" means a change in visibility impairment in a Class I federal area of five-tenths deciviews or more (24-hour average) above the average natural visibility baseline. A source exceeds the threshold when the ninety-eighth percentile of the modeling results based on any one year of the three years of meteorological data modeled exceeds five-tenths deciviews.

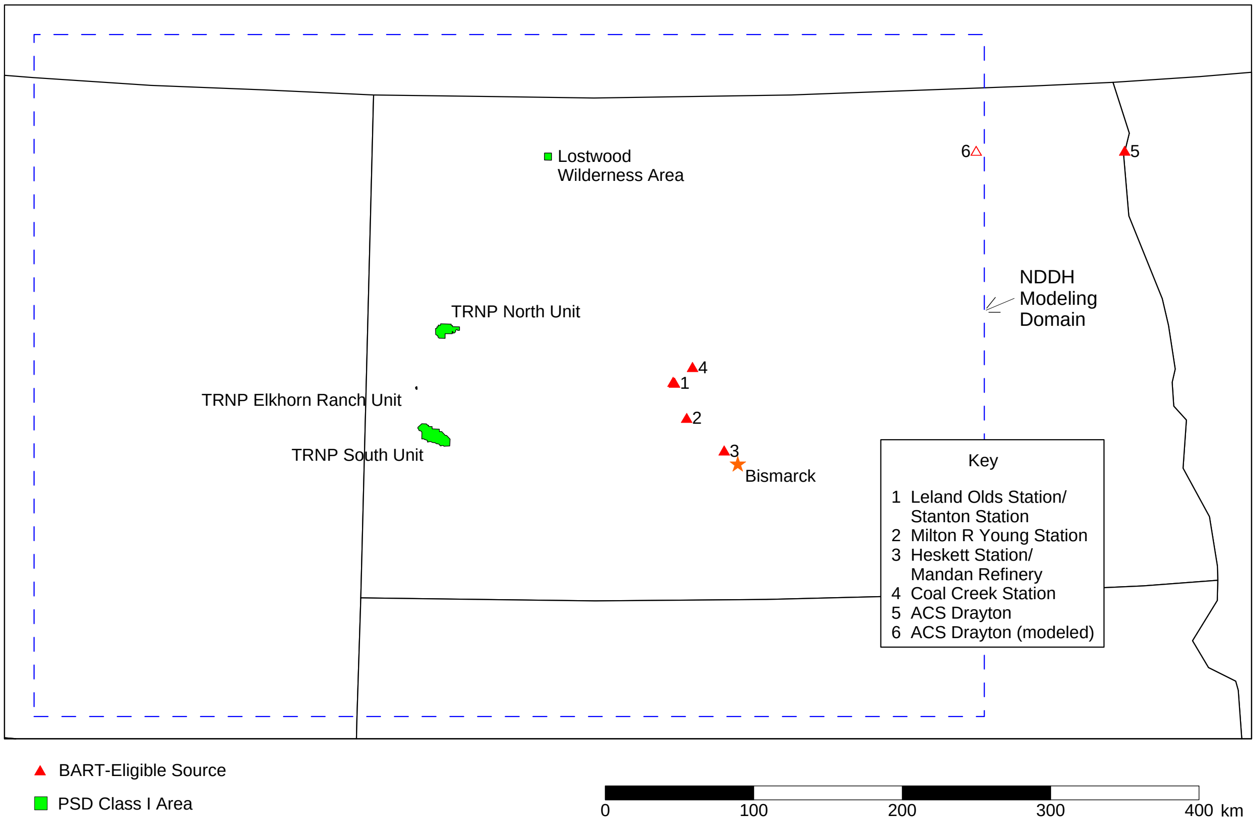
7.2 BART - Eligible Sources in North Dakota

The ten BART-eligible sources in the State of North Dakota and their locations are listed in Table 7.1. The locations of the BART-eligible sources with respect to Class I areas in North Dakota are illustrated in Figure 7.1.

Table 7.1
BART-Eligible Sources in North Dakota

Source and Unit	Location
American Crystal Sugar Company Main Boiler and Lime Kiln	Drayton, Pembina County
Basin Electric Power Cooperative Leland Olds Station Unit 1	Stanton, Mercer County
Basin Electric Power Cooperative Leland Olds Station Unit 2	Stanton, Mercer County
Great River Energy Coal Creek Station Unit 1	Falkirk, McLean County
Great River Energy Coal Creek Station Unit 2	Falkirk, McLean County
Great River Energy Stanton Station Unit 1	Stanton, Mercer County
Minnkota Power Cooperative Milton R. Young Station Unit 1	Center, Oliver County
Minnkota Power Cooperative Milton R. Young Station Unit 2	Center, Oliver County
MDU Resources Group, Inc. R. M. Heskett Station Unit 2	Mandan, Morton County
Tesoro Petroleum Corporation Mandan Refinery Carbon Monoxide Furnace	Mandan, Morton County

Figure 7.1
BART-Eligible Sources and Class I Areas in North Dakota



The BART-eligible sources were identified using the methodology in the Guidelines for BART Determinations Under the Regional Haze Rule, 40 CFR Part 51, Appendix Y, and summarized in 7.1.3.

Eight of the BART-eligible sources are fossil-fuel fired steam electric plants of more than 250 million British thermal units per hour heat input. One is a fossil-fuel fired boiler of more than 250 million British thermal units per hour heat input and a lime plant (the main boiler and the lime kiln at the American Crystal Sugar Company sugar beet processing plant at Drayton) and one is a process unit at a petroleum refinery (the carbon monoxide furnace at the Tesoro Petroleum Corporation refinery at Mandan).

7.3 Determination of BART-Eligible Sources Subject to BART

7.3.1 Sources Subject to BART

The modeled visibility impact of each of the ten BART-eligible sources listed in Table 7.1 on the Class I areas in North Dakota is shown in Table 7.2. The maximum 24-hour 98th percentile deciview represents the result for the worst year of the three years modeled (2000-2002).

The visibility impact of each BART-eligible source is considered significant if the projected change in the maximum 24-hour impact at a Class I area compared against natural conditions is equal to or greater than 0.5 deciviews. The source is then subject to BART. If the impact is less than 0.5 deciviews, the source is exempt from BART.

The modeling to determine if each BART-eligible source has a significant impact on visibility was performed by the Department using the CALPUFF model following EPA's Interagency Workgroup on Air Quality Modeling (IWAQM) Phase 2 Summary Report and Recommendations for Modeling Long Range Transport Impacts specified in the Guidelines for BART Determinations Under the Regional Haze Rule, 40 CFR Part 51, Appendix Y. The modeling protocol is included in Appendix A as Appendix A.1.

After completion of the subject-to-BART screening modeling, the eight subject-to-BART sources were notified they were subject-to-BART by letters dated November 30, 2005. These letters are attached as Appendix A.3.

The Department was contacted by Montana Dakota Utilities who requested approval to do a more refined CALPUFF screening analysis considering that the Department's results were slightly above the 0.5 deciview cutoff. MDU submitted a refined analysis in May 2006. This analysis is attached in Appendix A.2 and is discussed in 7.3.4 below.

Table 7.2
Individual BART-Eligible Source Visibility Impact on Class I Areas

Source and Unit	Class I Area	Maximum 24 Hour 98th Percentile Visibility Impact Value Deciview	Subject to BART or Exempt
American Crystal Sugar Company Main Boiler and Lime Kiln	Lostwood TRNP South Unit TRNP North Unit TRNP Elk. Ranch Unit	0.04 0.04 0.04 0.04	Exempt
Basin Electric Power Cooperative Leland Olds Station Unit 1 and Unit 2	Lostwood TRNP South Unit TRNP North Unit TRNP Elk. Ranch Unit	5.42 6.22 5.32 4.49	Subject to BART
Great River Energy Coal Creek Station Unit 1 and Unit 2	Lostwood TRNP South Unit TRNP North Unit TRNP Elk. Ranch Unit	4.04 4.48 3.56 3.04	Subject to BART
Great River Energy Stanton Station Unit 1	Lostwood TRNP South Unit TRNP North Unit TRNP Elk. Ranch Unit	1.35 1.68 1.54 1.43	Subject to BART
Minnkota Power Cooperative Milton R. Young Station Unit 1 and Unit 2	Lostwood TRNP South Unit TRNP North Unit TRNP Elk. Ranch Unit	4.88 6.69 5.58 6.10	Subject to BART
MDU Resources Group, Inc. R. M. Heskett Station Unit 2	Lostwood TRNP	0.23[1] 0.28[1]	Exempt
Tesoro Petroleum Corporation Mandan Refinery Carbon Monoxide Furnace	Lostwood TRNP South Unit TRNP North Unit TRNP Elk. Ranch Unit	0.04 0.05 0.04 0.04	Exempt

[1] MDU BART Screening Results (12/09)

Detailed descriptions of the seven subject-to-BART sources can be found in the Department BART Determinations in Appendix B and in the Company BART Analyses in Appendix C.

7.3.2 Exclusion of Tesoro Mandan Petroleum Refinery

The Department single-source modeling for the Tesoro Petroleum Corporation Mandan Refinery Carbon Monoxide Furnace predicted the highest maximum 24 hour 98th percentile visibility impact value to be 0.05 deciviews at Theodore Roosevelt National Park South Unit. This is a factor of 10 less than the 0.5 deciview threshold for determining whether a BART-eligible source causes or contributes to visibility impairment. Therefore, the unit is exempt and not subject to BART.

7.3.3 Exclusion of American Crystal Sugar Drayton Refinery

The Department single-source modeling for the American Crystal Sugar Company Drayton Plant Main Boiler and Lime Kiln predicted the highest maximum 24 hour 98th percentile visibility impact value to be 0.04 deciview at all four Class I areas. This is more than a factor of 10 less than the 0.5 deciview threshold for determining whether a BART-eligible source causes or contributes to visibility impairment. Therefore, the unit is exempt and not subject to BART.

As shown in Figure 7.1, the American Crystal Sugar Company Drayton Plant is located outside the Department's modeling domain. Even if the domain was extended eastward to incorporate the Drayton plant, the plant is located about 400 kilometers from the nearest North Dakota Class I area (Lostwood Wilderness Area), and this distance is beyond the accepted range of CALPUFF (about 300 kilometers). For modeling purposes, therefore, the Department repositioned the Drayton plant about 100 kilometers to the west, to create a virtual source located just inside the east boundary of the current modeling domain (represented by the "ACS Drayton (modeled)" source in Figure 7.1). This adjustment provided a source-receptor distance more consistent with the documented limits of CALPUFF, and should ensure results are conservative.

In addition, the Minnesota Pollution Control Agency modeled the American Crystal Sugar Company Drayton plant and found similar impact levels at the Class I areas in Minnesota, Voyagers National Park which is about 300 kilometers from the plant and Boundary Waters Canoe Area Wilderness which is about 350 kilometers from the plant.

7.3.4 Exclusion of Montana Dakota Utilities Heskett Unit No. 2

The Department single-source modeling for the Montana Dakota Utilities R.M. Heskett Station Unit 2 located near Mandan predicted the highest maximum 24 hour 98th percentile visibility impact value to be 0.82 deciview at the Theodore Roosevelt National Park South Unit, and 0.54 deciview at the North Unit, 0.61 deciview at the Elkhorn Ranch Unit and 0.58 deciview at Lost wood National Wilderness Area. Because these values were slightly above the threshold of 0.5 deciviews, Montana Dakota Utilities hired a consultant, ENSR Corporation, to perform a refined

CALPUFF modeling analysis. The ENSR analysis submitted June 9, 2006 is included as Appendix A.2.

The ENSR analysis made three refinements to the analysis performed by the Department:

- A 1 km grid size was used instead of 3 km,
- Particulate matter emissions were speciated into several components that have different light scattering potential, and
- The annual average background visibility was used instead of the annual 20 percent best day's background visibility (as per an EPA court settlement agreement).

The results of the refined ENSR analysis predicted the highest maximum 24 hour 98th percentile visibility impact value to be 0.436 deciviews at Lostwood National Wilderness area in 2001.

The Department had originally reviewed the ENSR analysis and found it acceptable. Additionally, MDU has committed to reduce the potential sulfur dioxide emissions from Heskett Unit 2 by a minimum of 70 percent within five years of EPA approval of this SIP. This would have reduced sulfur dioxide emissions to 1,847 tons per year from the 2000-2004 emissions of 2,400 tons per year, a 553 tons per year reduction. The Department had determined that Heskett Unit 2 was not subject to BART. See the Department's letter of May 8, 2007 in Appendix A.3. The FLMs and EPA have expressed concerns about the modeling that was conducted. MDU agreed to remodel using a revised modeling protocol approved by EPA. The Department reassessed the determination to exclude Heskett Station Unit 2 following review of the revised modeling. That reassessment shows that Heskett Unit 2 is not subject to the BART requirements. The results of the analysis using the protocol as approved by EPA indicated the highest maximum 24-hour 98th percentile visibility impact value to be 0.28 deciviews at TRNP and 0.23 deciviews at LWA. Based upon the refined analysis and the reassessment analysis, Heskett Unit 2 is exempt from the BART requirements.

7.4 Determination of BART Requirements for Subject-to-BART Sources

7.4.1 Company BART Analyses

The Department met individually with the seven subject-to-BART sources in December 2005 and requested they complete and submit BART analyses within nine months of the notification letters dated November 30, 2005 or by September 1, 2006. The nine month time was required by NDAC 33-15-25-02.1. This was agreed to by the seven sources. They were required to address BART for sulfur dioxide, nitrogen oxides, fine particulates and condensable particulates.

The Department also requested the sources follow requirements of Appendix Y to Part 51 - Guidelines for BART Determinations Under the Regional Haze Rule in conducting their analyses.

The seven BART analyses were submitted in final form in late 2007 to early 2008. The final company BART analyses are attached as Appendix C.

7.4.2 Department BART Determinations

The Department has reviewed the company BART determinations and conducted its own determinations for each source. The BART determinations followed the methodology of Section IV of Appendix Y to Part 51 - Guidelines for BART Determinations Under the Regional Haze Rule. This includes identifying the best system of continuous emission reduction taking into account:

1. The available retrofit control options,
2. Any pollution control equipment in use at the source (which affects the availability of options and their impacts),
3. The costs of compliance with control options,
4. The remaining useful life of the facility,
5. The energy and non-air quality environmental impacts of control options, and
6. The visibility impacts analysis.

A case-by-case top down BART analysis using the five basic steps was followed. The five steps are:

STEP 1 - Identify all available retrofit technologies,
STEP 2 - Eliminate technically infeasible options,
STEP 3 - Evaluate control effectiveness of remaining technologies,
STEP 4 - Evaluate impacts and document the results, and
STEP 5 - Evaluate Visibility impacts.

The Department BART determinations are included as Appendix B. Each BART determination includes a source description including the major boiler units and the minor sources such as auxiliary boilers, emergency generators, coal/materials handling dust controls, and coal storage piles; the site characteristics; BART evaluations for the major and minor sources; and a permit to construct description.

As detailed in Appendix B, Department BART determinations included an evaluation of visibility impacts. Single-source modeling was conducted by the companies to determine the degree of visibility improvement associated with various control options for individual units. This modeling was based on EPA guidance for BART determinations[1]. The Department asked companies to provide a 90th percentile 24-hr visibility modeling result (delta-deciview) along with the 98th percentile 24-hr value referenced in the guidance, because the 90th percentile would

---

[1] Federal Register, 2005. EPA Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations; Final Rule. Federal Register, July 6, 2005, Vol.70, No. 128, p. 39103-39172.

be more consistent with the *average of 20% worst days* metric utilized for assessing visibility improvement progress under the Regional Haze Rule.

Single-source visibility modeling as provided by the affected companies was reviewed by the Department, and results related to visibility improvement were considered in Department BART determinations. Because the Department had concerns regarding the viability of single-source modeling in representing actual visibility improvement, however, modeling was given less weight than other factors in the BART determination process.

Though single-source modeling is specified in the BART guidance for determining degree of visibility improvement, it is clear that this modeling overstates the real single-source visibility impact, given the complexity of multiple-source emissions and chemistry actually affecting visibility impairment in Class I areas. As suggested by the logarithmic relationship between deciview and light extinction (Section 5.1), an observer's perception of visibility change is affected by the total loading of visibility-affecting species in the atmosphere. The observer's perception of visibility change, due to a reduction (or increase) in visibility-affecting emissions from one source, depends on cumulative visibility impact due to all sources. For example, a unit reduction in visibility-affecting emissions (from one source) will have only half the visual impact on the observer (delta-deciview) if total light extinction is 80 Mm^{-1} compared to the impact if total light extinction is 40 Mm^{-1}. By excluding the impact of all other sources, therefore, single-source modeling is overstating the perceived (delta-deciview) change in visibility. Based on Department experience, single-source modeling results (delta-deciview) tend to be five to seven times larger than results obtained for the same source when it is combined with all other sources in a cumulative analysis.

It is because of this anomaly that the Department has been very cautious in the interpretation of single-source modeling results, and has focused BART determinations on factors other than visibility modeling. In some instances, as discussed in Appendix B, the Department has conducted supplemental cumulative modeling to more realistically assess the visibility impact of emissions reductions associated with optional control strategies for individual sources. Cumulative modeling is consistent with the procedure for determining status with respect to *uniform rate of progress* goals, which is discussed in Section 8.

BART determinations were made for sulfur dioxide, nitrogen oxides, filterable particulate matter, and condensable particulate matter for all seven sources. A summary of the BART determinations for the main boilers by pollutant follows.

Sulfur Dioxide

Three of the seven sources have existing sulfur dioxide removal equipment. Great River Energy Coal Creek Station Unit 1and Unit 2 and Minnkota Power Cooperative Milton R. Young Station Unit 2 are equipped with wet limestone scrubbers. The existing scrubbers at the Coal Creek Station employ a bypass for flue gas heat and achieve a 68 percent sulfur dioxide reduction. The lime/fly ash wet scrubber at Milton R. Young Unit 2 achieves a 65 percent sulfur dioxide reduction.

Great River Energy Coal Creek Station Unit 1 and Unit 2 - The BART selected by the Department for Unit 1 and Unit 2 is a 95 percent reduction efficiency or a limit of 0.15 pounds per million Btu of heat input on a 30-day rolling average basis to be achieved by modifying the existing wet scrubbers and the adding of a new coal dryer serving both units. Unit 1 and Unit 2 emissions may be averaged provided the average does not exceed the limit.

Minnkota Power Cooperative Milton R. Young Station Unit 2 - The BART for sulfur dioxide selected by the Department for Unit 2 is a 95 percent reduction efficiency or limit of 0.15 pounds per million Btu of heat input on a 30-day rolling average basis to be achieved by modifying the existing wet scrubber. The Consent Decree for Minnkota requires a minimum of 90 percent reduction of sulfur dioxide at Unit 2. The 90 percent reduction requirement will apply when Minnkota chooses to comply with the 0.15 lb/10^6 Btu limit. The 90 percent reduction requirement is included in the BART permit.

Minnkota Power Cooperative Milton R. Young Station Unit 1 - Unit 1 has no existing sulfur dioxide removal equipment. The BART selected by the Department for Unit 1 is a 95 percent reduction efficiency on a 30-day rolling average basis to be achieved by the installation of a new wet scrubber. The EPA/State Consent Decree states that if Minnkota installs a wet scrubber, they must comply with a 95 percent reduction requirement with no alternative pounds per million Btu of heat input limit.

Basin Electric Power Cooperative Leland Olds Station Unit 1 and Unit 2 - Unit 1 and Unit 2 have no existing sulfur dioxide removal equipment. The BART selected by the Department for Unit 1 and for Unit 2 is a 95 percent reduction efficiency or a limit of 0.15 pounds per million Btu of heat input on a 30-day rolling average basis to be achieved by the installation of new wet scrubbing system.

Great River Energy Stanton Station Unit 1 - Unit 1 has no existing sulfur dioxide removal equipment. Unit 1 burns either lignite coal or subbituminous coal. Because these coals have different average sulfur contents, Btu contents and chemical characteristics, the Department will issue BART limits appropriate to each coal. The BART selected by the Department for Unit 1 is a 90 percent reduction on a 30-day rolling average basis burning either coal or a limit of 0.24 pounds per million Btu of heat input on a 30-day rolling average basis when burning only lignite coal, a limit of 0.16 pounds per million Btu of heat input on a 30-day rolling average basis when burning subbituminous coal, and weighted average emission limit when burning a combination of lignite and subbituminous coal.

The sulfur dioxide emissions before and after BART control, the BART controls, and the sulfur dioxide emission limits for each of the seven sources are summarized in Table 7.3.

Table 7.3
BART-Level Emissions Reductions From the 2000-2004 Sulfur Dioxide Average

Source and Unit	2000-2004 Average Emissions Tons per Year	Baseline Level of Control % Reduction	BART Level of Control % Reduction*	Control Device	Emissions after Controls Tons per Year**	Emission Reduction Tons per Year**	Emission Limit
Basin Electric Power Cooperative Leland Olds Station Unit 1	16,666	0%	95%	New Wet Scrubber	1,376	15,290	95% reduction or 0.15 lb/10^6 Btu 30 day rolling average
Basin Electric Power Cooperative Leland Olds Station Unit 2	30,828	0%	95%	New Wet Scrubber	2,530	28,298	95% reduction or 0.15 lb/10^6 Btu 30 day rolling average
Great River Energy Coal Creek Station Unit 1	14,086	68%	95%	Modified Existing Wet Scrubber and Coal Dryer	3,781	10,305	95% reduction or 0.15 lb/10^6 Btu 30 day rolling average
Great River Energy Coal Creek Station Unit 2	12,407	68%	95%	Modified Existing Wet Scrubber and Coal Dryer	3,621	8,786	95% reduction or 0.15 lb/10^6 Btu 30 day rolling average
Great River Energy Stanton Station Unit 1	8,312	0%	90%	New Spray Dryer and Fabric Filter	1,179	7,133	90% reduction or 0.24 lb/10^6 Btu (lignite) or 0.16 lb/10^6 Btu (PRB) 30 day rolling average
Minnkota Power Cooperative Milton R. Young Station Unit 1	20,148	0%	95%	New Wet Scrubber	1,007	19,141	95% reduction 30 day rolling average
Minnkota Power Cooperative Milton R. Young Station Unit 2	12,404	65%	95%	Modified Existing Wet Scrubber	2,739	9,665	95% reduction; or 90% reduction and 0.15 lb/10^6 Btu 30 day rolling average
Total	114,851	----	----	----	16,233	98,618	----

*Based on the two year baseline emission rate for BART.
** Based on the average 2000-2004 operating rate and emission rates.

Nitrogen Oxides

There are many different technologies available for controlling nitrogen oxides emissions from coal fired boilers. The technical feasibility for a particular technology is dependent on the type and size of the boiler and the type of coal being combusted. The types of boiler used at the seven BART sources in the state are cyclone (3), tangentially-fired pulverized coal (2), and wall-fired pulverized coal (2). The types of coal burned in the state are lignite coal with varying characteristics from several different mines near the plants and subbituminous coal from the Powder River Basin (PRB) in Wyoming and Montana.

The nitrogen oxides control technologies that are applicable to a particular boiler are listed in the Company BART Analyses in Appendix C and in the Department BART Determinations in Appendix B.

One technology, selective catalytic reduction (SCR), has one of the highest nitrogen oxides removal rates (in the range of 90 percent) and has been commercially installed on many different types of boilers burning different types of coal. However, it has never been installed on any type of boiler burning North Dakota lignite. The only pilot scale testing conducted on North Dakota lignite failed after two months. The seven BART sources determined SCR is not technically feasible for installation on boilers in North Dakota burning lignite coal. The Department agrees that high dust SCR is not technically feasible; however, low dust and tail end SCR are considered technically feasible. A detailed discussion on the technical feasibility of SCR is provided in Appendix B.5. The BART for nitrogen oxides for each source follows:

Basin Electric Power Cooperative Leland Olds Station Unit 1 - This unit is a wall-fired pulverized coal boiler combusting primarily lignite coal (80-100%) and PRB subbituminous coal (20-0%). The existing nitrogen oxides control equipment is low NO_x burners installed in 1995. The BART selected by the Department is a limit of 0.19 pounds per million Btu of heat input on a 30-day rolling average basis. This limit is to be achieved by the installation of selective noncatalytic reduction (SNCR) and basic separated overfire air (SOFA).

Basin Electric Power Cooperative Leland Olds Station Unit 2 - This unit is a cyclone boiler combusting primarily lignite coal (80-100%) and PRB subbituminous coal (20-0%). The unit has no existing nitrogen oxides control equipment. The BART selected by the Department is a limit of 0.35 pounds per million Btu of heat input on a 30-day rolling average basis. This limit is to be achieved by the installation of selective noncatalytic reduction (SNCR) and advanced separated overfire air (ASOFA).

Great River Energy Coal Creek Station Unit 1 and Unit 2 - Unit 1 and Unit 2 are identical tangentially-fired pulverized coal boilers combusting lignite coal. The existing nitrogen oxides control equipment is low NO_x burners (LNB) and separated overfire air (SOFA). The BART selected by the Department for each unit is a limit of 0.17 pounds per million Btu of heat input on a 30-day rolling average basis. This limit is to be achieved by the use of the existing low NO_x burners (LNB) and modified/additional separated overfire air (SOFA).

Great River Energy Stanton Station Unit 1 - Unit 1 is a wall-fired pulverized coal boiler combusting PRB subbituminous coal and lignite coal. The existing nitrogen oxides control equipment is low NO_x burners. The BART selected by the Department is a limit of 0.29 pounds per million Btu of heat input on a 30-day rolling average basis when burning only lignite coal, a limit of 0.23 pounds per million Btu of heat input on a 30-day rolling average basis when burning subbituminous coal, and a weighted average emission limit when burning a combination of lignite and subbituminous coal. These limits are to be achieved by the installation of low NO_x burners (LNB), overfire air (OFA), and selective noncatalytic reduction (SNCR).

Minnkota Power Cooperative Milton R. Young Station Unit 1 and Unit 2 - Unit 1 and Unit 2 are both cyclone boilers burning lignite coal. The units have no existing nitrogen oxides control equipment. The BART selected by the Department for Unit 1 is a limit of 0.36 pounds per million Btu of heat input on a 30-day rolling average basis and for Unit 2 is a limit of 0.35 pounds per million Btu of heat input on a 30-day rolling average basis. These limits will be achieved by the installation of selective noncatalytic reduction (SNCR) and advanced separated overfire air (ASOFA). These limits do not apply during startup. During startup, NO_x emissions from Unit 1 shall not exceed 2070.1 pounds per hour on a 24-hour rolling average basis and 3995.6 pounds per hour from Unit 2 on a 24-hour rolling average basis.

The nitrogen oxides emissions before and after BART control, the BART controls, and the nitrogen oxide emission limits for each of the seven sources are summarized in Table 7.4.

Table 7.4
BART-Level Emissions Reductions From the 2000-2004 Nitrogen Oxides Average

Source and Unit	2000-2004 Average Emissions Tons per Year	Baseline Level of Control % Reduction	BART Level of Control % Reduction*	Control Device	Emissions after Controls Tons per Year**	Emission Reduction Tons per Year**	Emission Limit
Basin Electric Power Cooperative Leland Olds Station Unit 1	2,501	0%	42%	SOFA and SNCR	1,744	757	0.19 lb/10^6 Btu 30 day rolling average

Minnkota Power Cooperative Milton R. Young Station Unit 2	14,705	0%	58.0%	ASOFA and SNCR	6,392	8,313	0.35 lb/10^6 Btu 30 day rolling average
Total	48,848	----	----	----	27,711	21,137	----

*Based on the two year baseline emission rate for BART.
** Based on the average 2000-2004 average operating rate.

Filterable Particulate Matter

Filterable particulate matter is solid and liquid (non-condensable) matter that is captured in the front half of EPA test method five, the standard test method for determining particulate emissions from boilers.

The existing control devices for filterable particulate matter on all seven boilers are dry electrostatic precipitators (ESPs) with control efficiencies of 99+ percent. Each unit has an existing particulate emission limit of 0.1 pounds per million Btu of heat input.

Recent test results submitted to the Department show the actual emissions from the seven units average 0.03 to 0.05 pounds per million Btu of heat input with occasional values approaching 0.07 pounds per million Btu of heat input.

Upgrading or replacing existing ESPs could reduce the particulate emission rates to 0.013 to 0.015 pounds per million Btu of heat input. However, the BART analyses conducted by the sources indicate the cost effectiveness in dollars per ton is unreasonable and there is very little benefit to visibility in the federal Class I areas.

The existing particulate emissions from all seven boilers are very low, ranging from 74 tons per year, 2000-2004 average, at Stanton Station Unit 1 to 589 tons per year, 2000-2004 average, at Coal Creek Station Unit 2. The BART screening modeling indicates the maximum visibility impact improvement from reducing actual existing emissions levels of approximately 0.03 pounds per million Btu of heat input to 0.015 pounds per million Btu of heat input at any Class I area from any of the seven sources was 0.037 deciviews 98th percentile or less. Detailed particulate emissions data and modeling visibility impact improvement data for each source can be found in the Department BART determinations in Appendix B.

The Department has determined that the BART for filterable particulate matter for all seven sources is no additional controls and allowable particulate emission rate of 0.1 pounds per million Btu of heat input be reduced to 0.07 pounds per million Btu of heat input for five of the seven units. The Minnkota Power Cooperative Milton R. Young Station Unit 1 and Unit 2 are subject to an EPA/State consent decree for New Source Review violations. The consent decree requires filterable particulate emissions not to exceed 0.030 pounds per million Btu of heat input. Therefore 0.030 pounds per million Btu of heat input will be the BART limit for these two units.

Condensable Particulate Matter (PM_{10})

Condensable particulate matter is made up of both organic and inorganic substances. Organic condensable particulate matter will be made up of organic substances, such as volatile organic compounds, which are in a gaseous state through the air pollution control devices but will eventually turn to a solid or liquid state. The primary inorganic substance expected from the boiler is sulfuric acid mist, with lesser amounts of hydrogen fluoride and ammonium sulfate.

Since sulfuric acid mist is the largest component of condensable particulate matter, controlling it will control most of the condensable particulate matter. The options for controlling sulfuric acid mist are the same options for controlling sulfur dioxide. These include wet and dry scrubbers. Three of the sources have existing wet scrubbers that will be upgraded. Three of the remaining four units will be equipped with new wet scrubbers and one with a dry scrubber/baghouse system. These technologies will achieve greater than 40-60 percent reduction of sulfuric acid mist emissions. Changes that would provide additional reductions are economically infeasible considering the minimal improvement in visibility that could be achieved.

The control of volatile organic compounds at power plants is generally achieved through good combustion practices. The Department is not aware of any BACT determination at a power plant that resulted in any control technology being used. BACT has been found to be good combustion practices which are already in use since it minimizes the amount of fuel to generate electricity.

EPA document AP-42, Compilation of Air Pollutant Emission Factors, indicates the emission rate of condensable particulate matter could be expected to be 0.02 pounds per million Btu. This emission rate is less than the current emissions of filterable particulate matter and the emissions of filterable particulate matter were determined to have a negligible impact on visibility.

Having considered all the factors, the Department has determined that BART for condensable particulate matter is represented by good sulfur dioxide control and good combustion control. Since the primary constituent of condensable particulate matter is sulfuric acid mist which is controlled proportionately to the sulfur dioxide controlled, the BART limit for sulfur dioxide can act as a surrogate for condensable particulate matter along with a requirement for good combustion practices.

BART Modifications Description

A summary description of the BART modifications proposed at each of the seven subject-to-BART sources follows:

Basin Electric Power Cooperative Leland Olds Station Unit 1 and Unit 2 - A wet scrubbing system will be installed to remove sulfur dioxide from the flue gas of each unit. Nitrogen oxides emissions from Unit 1 will be controlled by basic separated overfire air (SOFA) and selective noncatalytic reduction (SNCR). Nitrogen oxides from Unit 2 will be controlled by advanced separated overfire air (ASOFA) and selective noncatalytic reduction (SNCR).

Great River Energy Coal Creek Station Unit 1 and Unit 2 - Sulfur dioxide emissions will be controlled by the installation of a coal drying system; the installation of trays or new liquid distribution rings (LDRs) and high flow mist eliminators (MEs) in the existing wet scrubbers; the elimination of the bypass of the wet scrubbers and the modification of the existing stacks for wet operating conditions. Nitrogen oxides emissions will be controlled by the installation of an additional level of separated overfire air (SOFA) in each boiler.

Great River Energy Stanton Station Unit 1 - Sulfur dioxide emissions will be controlled by the installation of a spray dryer and fabric filter system (dry scrubber). Nitrogen oxides emissions will be controlled by the installation of low-NO_x burners plus overfire air plus selective noncatalytic reduction (SNCR) technology.

Minnkota Power Cooperative Milton R. Young Station Unit 1 and Unit 2 - Sulfur dioxide emissions will be controlled by the installation of a new wet scrubber on Unit 1 and by upgrading the existing wet scrubber on Unit 2. Nitrogen oxides emissions from both units will be reduced using advanced separated overfire air (ASOFA) and selective noncatalytic reduction (SNCR).

The control technology to be installed on each source unit is described in more detail in the company BART determinations in Appendix C and the Department BART determinations in Appendix B.

7.4.3 Summary of Emission Reductions

BART for the BART-eligible sources in the State of North Dakota that are significant contributors to visibility impairment in a Class I area are shown in Tables 7.3 and 7.4 for sulfur dioxide and nitrogen oxides. BART is the emission limit for each pollutant based on the degree of reduction achievable through the application of the best system of continuous emission reduction, taking into consideration the technology available, the costs of compliance, the energy and the non-air quality environmental impacts of compliance, any pollution control equipment in use or in existence at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology. The Department BART determination analysis for each BART-eligible source is included in Appendix B.

The application of BART to all BART-eligible sources provides an estimated emission reduction from the 2000-2004 average baseline emissions of 98,618 tons per year of sulfur dioxide and 21,137 tons per year of nitrogen oxides. These reductions are shown in Tables 7.3 and 7.4 for each source and in total.

BART for each BART-eligible source was determined using the methodology in the Guidelines for BART Determinations Under the Regional Haze Rule. 40 CFR Part 51, Appendix Y.

7.5 Air Pollution Control Permit to Construct for Subject-to-BART Sources

Section V of Appendix Y to Part 51 - Guidelines for BART Determinations Under the Regional Haze Rule requires the State establish enforceable emission limits that reflect the BART determinations and require compliance within a given period of time. In particular, the State must establish an enforceable emission limit for each subject emission unit at the source and for each pollutant subject to review that is emitted from the source. The Department worked closely with the staff of the EPA Region 8 Air Programs office to ensure the permit template contents and language were acceptable to meet the requirements of Section V.

The emission limits, monitoring, recordkeeping and reporting requirements specified in the Department BART determination for each subject-to-BART source are included in a federally enforceable Air Pollution Control Permit to Construct that will be issued by the Department to the owner/operator of the facility before the SIP is submitted to EPA. The permits are issued by the Department under existing authority pursuant to NDAC Chapter 33-15-14 and Chapter 33-15-25.

There are four Permits to Construct, one for both Unit 1 and Unit 2 at the Basin Electric Power Cooperative Leland Olds Station, one for both Unit 1 and Unit 2 at the Great River Energy Coal Creek Station, one for Unit 1 at the Great River Energy Stanton Station, and one for Unit 1 and Unit 2 at the Minnkota Power Cooperative Milton R. Young Station. The four permits are included in Appendix D.

7.5.1 Enforceable Emission Limits

Enforceable emission limits that reflect the BART determinations are included in each Air Pollution Control Permit to Construct as permit condition II.A.1. Conditions for sulfur dioxide are in II.A.1.a., nitrogen oxides in II.A.1.b., and filterable (non-condensable) particulate matter in II.A.1.c. Each Air Pollution Control Permit to Construct is incorporated as a part of this Regional Haze SIP.

As required by Section V of Appendix Y, the limitations for sulfur dioxide and nitrogen oxides specify an averaging time of a 30-day rolling average, and contain a definition of “boiler operating day” which is any 24-hour period between 12:00 midnight and the following midnight during which any fuel is combusted at any time at the steam generating unit.

7.5.2 Monitoring, Recordkeeping, and Reporting Requirements

Monitoring, recordkeeping, and reporting requirements have been included in each Air Pollution Control Permit to Construct. The owner/operator is required to conduct monitoring, recordkeeping and reporting as required by NDAC Chapter 33-15-14-06, Title V Permit to Operate and NDAC 33-15-21, Acid Rain Program (40 CFR 72, 75, and 76). The conditions in each source’s existing Title V operating permit will be revised as necessary to cover the new BART emissions limits as they are included these permits. Monitoring requirements are found in permit condition II. A. 4, recordkeeping requirements are found in II.A.5, and reporting requirements are found in II. A. 6.

7.5.3 Operating and Maintenance Requirements

Item 51.308(e)(1)(v) of the EPA BART rule requires that each source subject to BART maintain the control equipment and establish procedures to ensure such equipment is properly operated. This requirement is also included in the state rules at NDAC 33-15-25-02.3.

Each Air Pollution Control Permit to Construct has condition II. B. 4 which requires that the owner shall at all times, including periods of startup, shutdown, and malfunction, maintain and operate the BART unit(s) and all other emission units including associated air pollution equipment and fugitive dust suppression operations in a manner consistent with good air pollution control practices for minimizing emissions.

7.5.4 Compliance Date

The Department is requiring that each source subject to BART shall install and operate BART as expeditiously as practicable but in no event later than five years after approval of the implementation plan revision by EPA as required by Section V of Appendix Y to 40 CFR Part 51 and Item 51.308(e)(1)(iv) of the EPA BART Rule. This requirement is also included in the State rule as NDAC 33-15-25-02.2.

This requirement is included as Condition II.A.2 in the Air Pollution Control Permit to Construct issued for each source subject to BART. When this implementation plan is approved by EPA, a Title V operating permit will be issued for each source incorporating the conditions of the Permits to Construct.

8. Visibility Modeling

8.1 Introduction

Computer modeling to determine progress with respect to visibility improvement goals was conducted in support of this North Dakota Regional Haze SIP. The Regional Haze Rule[2] (Rule) specifies that modeling must be applied to demonstrate reasonable progress toward the goal of achieving natural visibility conditions in each PSD Class I area by 2064. As discussed in Section 5.4, the *uniform rate of progress* defines the visibility improvement which would be needed for each planning period to achieve natural visibility conditions by 2064. The first planning period begins at the end of the baseline (2004) and terminates in 2018. The visibility improvement progress needed by 2018 (or 2018 target) is determined by interpolating from the uniform rate of progress glide path, as illustrated in Figure 5.5.

Modeling analyses completed in support of the North Dakota SIP and discussed here address the first planning period, and the 2018 target. These analyses assume that the 2018 goal for each Class I area is the uniform rate of progress (glide path) target for 2018. The Regional Haze Rule, however, gives states the option of establishing *reasonable progress goals* which are independent of the uniform rate of progress. The reasonable progress goals established by a state for 2018 will not necessarily equal the uniform rate of progress target for 2018 (see Section 10).

To demonstrate reasonable progress with respect to visibility goals for the first planning period, the Rule specifies that visibility on the 20 percent worst (most impaired) days must improve, while visibility on the 20 percent best (least impaired) days must not deteriorate, between the base period (2000-2004) and 2018. Computer modeling was used to project future visibility, accounting for proposed BART controls and other visibility-affecting emissions increases/decreases. Modeling was applied in a relative sense. Baseline and projected future emission inventories were modeled to develop a future/baseline prediction ratio (relative response factor). The ratio was then applied to baseline monitoring data for visibility-affecting species to project future visibility.

The Western Regional Air Partnership (WRAP) regional planning organization has established a Regional Modeling Center (RMC) to assist member states, including North Dakota, with modeling to determine status with respect to the 2018 goals. The RMC has applied a chemically sophisticated grid model (CMAQ), on a regional basis, to project future visibility in Class I areas in the WRAP region[3]. The RMC has developed comprehensive base period and future period visibility-affecting emission inventories to use with CMAQ, and has performed numerous studies

---

[3] Tonnesen, G., R. Morris, Z. Adelman, et. al., 2006. 2006 Report for the Western Regional Air Partnership (WRAP) Regional Modeling Center (RMC). Western Regional Air Partnership, Denver, CO 80202.

using base period model and monitoring data to evaluate CMAQ performance[4]. Finally, the RMC has applied CMAQ to project 2018 visibility for each Class I area in the WRAP region, including the Theodore Roosevelt National Park and Lostwood Wilderness Class I areas in North Dakota.

To supplement work done by the WRAP RMC, the North Dakota Department of Health (NDDoH) has conducted further modeling analysis to address 2018 visibility goals for North Dakota Class I areas. Though the NDDoH utilized WRAP RMC results in assessing progress with respect to visibility goals in North Dakota Class I areas, the NDDoH also recognized it would have to develop further modeling capability for visibility projection in order to address weight of evidence issues not included in WRAP modeling, such as discounting the impact of international sources. In addition, the NDDoH had concerns regarding the spatial resolution of the WRAP CMAQ simulations, particularly for large point sources.

The RMC is applying CMAQ on a national basis using a grid resolution of 36 km, with no plume-in-grid treatment. This means that emissions from point sources are immediately mixed uniformly throughout a 36 km (square) grid cell volume, which may overstate the dilution of the plume, and the speed of chemical reactions for species contained in the plume. This may be problematic, especially for sources located relatively near Class I areas. Consequently, the contribution of visibility-affecting species from these sources may be misrepresented for both base period and future period modeling. This limitation in treatment of point sources is recognized in CMAQ documentation[5].

The NDDoH utilized a hybrid modeling approach for determining status with respect to the visibility goals. This approach involved nesting the local NDDoH CALPUFF domain within the WRAP National CMAQ domain, and applying the Lagrangian CALPUFF model in a retrospective sense to more realistically define plume geometry for local point sources. To implement the nesting, hourly output concentrations from WRAP CMAQ were used to set hourly boundary conditions for CALPUFF. The use of CMAQ output to set CALPUFF boundary conditions has been suggested by Escoffier-Czaja and Scire[6]. Location of the NDDoH CALPUFF domain within the National CMAQ domain is illustrated in Figure 8.1.

Given limitations in the CALPUFF chemistry for other species, the NDDoH hybrid modeling system was used for simulation of SO_2-SO_4-NO_X-HNO_3-NO_3 chemistry and transport, and thus sulfate (SO_4) and nitrate (NO_3) predictions, only. Results for all other visibility-affecting

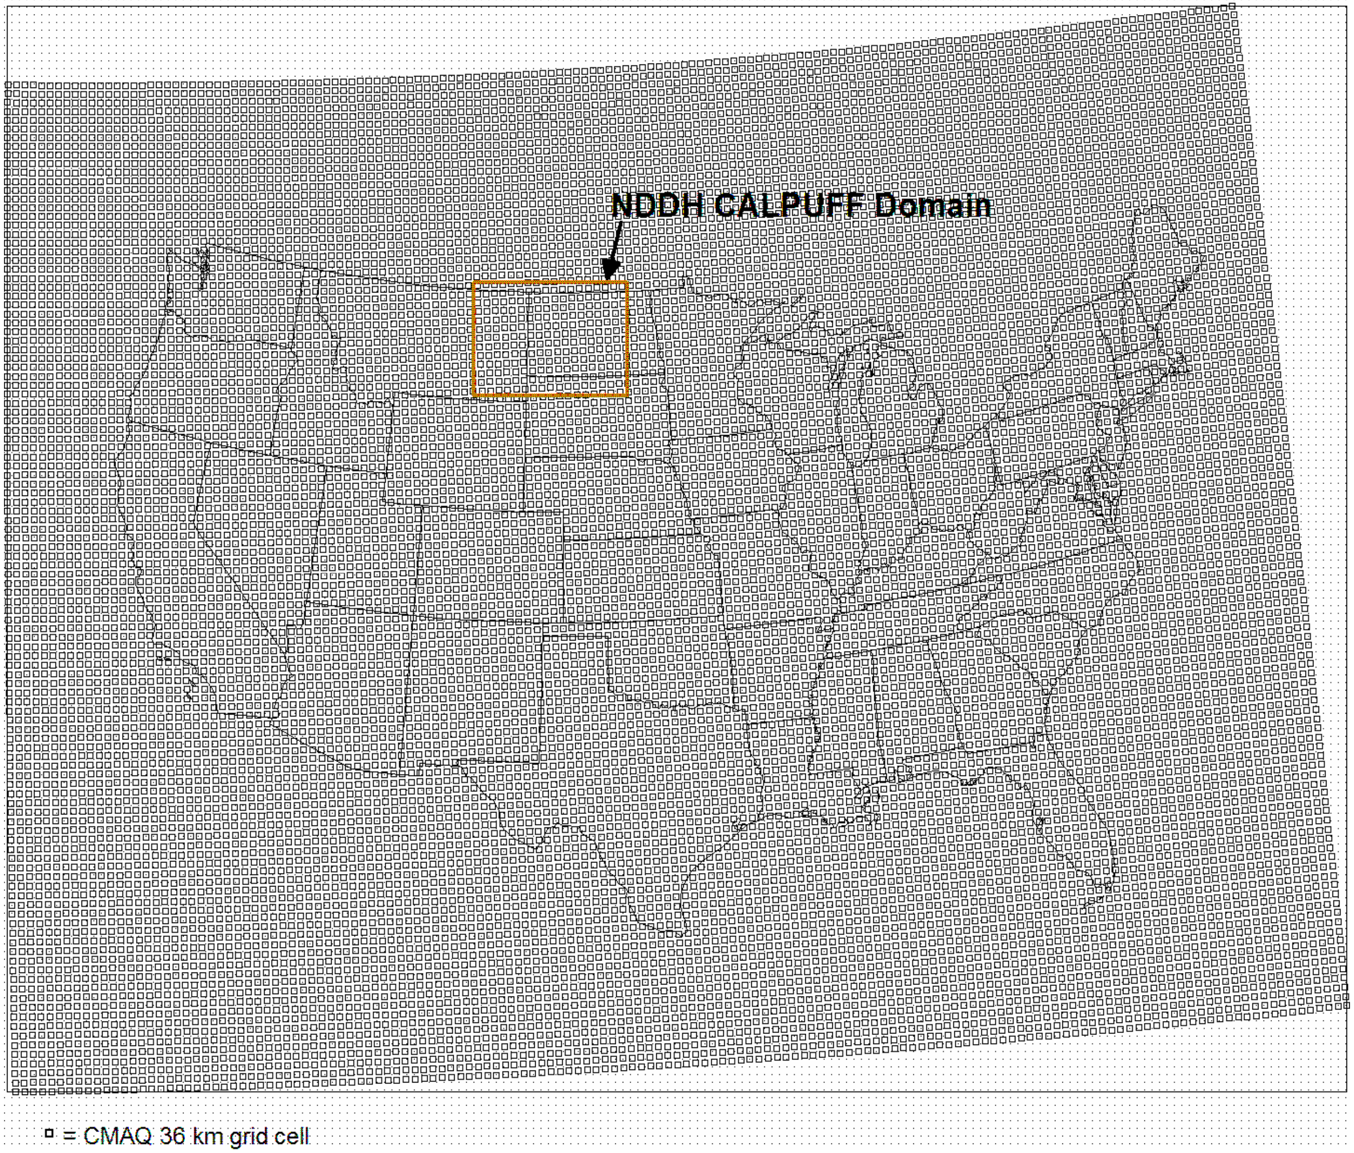
Figure 8.1
WRAP CMAQ Domain and NDDoH CALPUFF Domain



species, including organic carbon mass (OMC), elemental carbon (EC), fine particulate (Soil), and coarse particulate (CM), were obtained directly from the CMAQ output for the grid cell containing each subject Class I area IMPROVE monitor. CMAQ output was combined with CALPUFF results for sulfate and nitrate in order to perform necessary light extinction calculations. In this way, the NDDoH benefits from the sophistication of the RMC approach for other particulate components, which reflect a very small percentage of emissions from the local point sources of concern.

WRAP and NDDoH protocols for modeling visibility progress goals generally adhere to EPA *Guidance on the Use of Models and Other Analyses for Demonstrating Attainment of Air Quality Goals for Ozone*, *$PM_{2.5}$, and Regional Haze*[7]. An evaluation of modeling system performance was conducted first. Then baseline (2000-2004) and future (2018) emission scenarios were modeled in order to develop relative response factors (RRFs). Finally, RRFs were applied to baseline IMPROVE monitoring data to project future visibility in North Dakota Class I areas.

Class I areas in North Dakota include the three units of Theodore Roosevelt National Park (TRNP), and the Lostwood Wilderness Area (LWA). IMPROVE monitors are located at the TRNP South Unit and LWA, only. Therefore, these two Class I areas were the focus of the modeling analyses. Locations of North Dakota Class I areas, IMPROVE monitor sites, and larger visibility-affecting sources are depicted in Figure 8.2.

While this presentation (Section 8) addresses both WRAP and NDDoH visibility modeling analyses, focus is on the NDDoH modeling as WRAP procedures are extensively documented elsewhere. The WRAP protocol for regional haze visibility modeling is summarized in *2006 Report for the Western Regional Air Partnership (WRAP) Regional Modeling Center (RMC)*[8]. The NDDoH protocol for regional haze progress goal modeling is attached as Appendix E to this document.

8.2 Regional Haze Metrics

To address progress in visibility improvement, modeling is used to provide mass concentrations of visibility-affecting species. These concentrations are translated into light extinction using the IMPROVE algorithm. Finally, light extinction is converted to deciviews to accommodate comparison with visibility goals. Use of the deciview metric to assess baseline visibility, natural visibility, and improvement in visibility was discussed in Section 5.

Calculation of light extinction from visibility-affecting aerosol concentrations for the WRAP

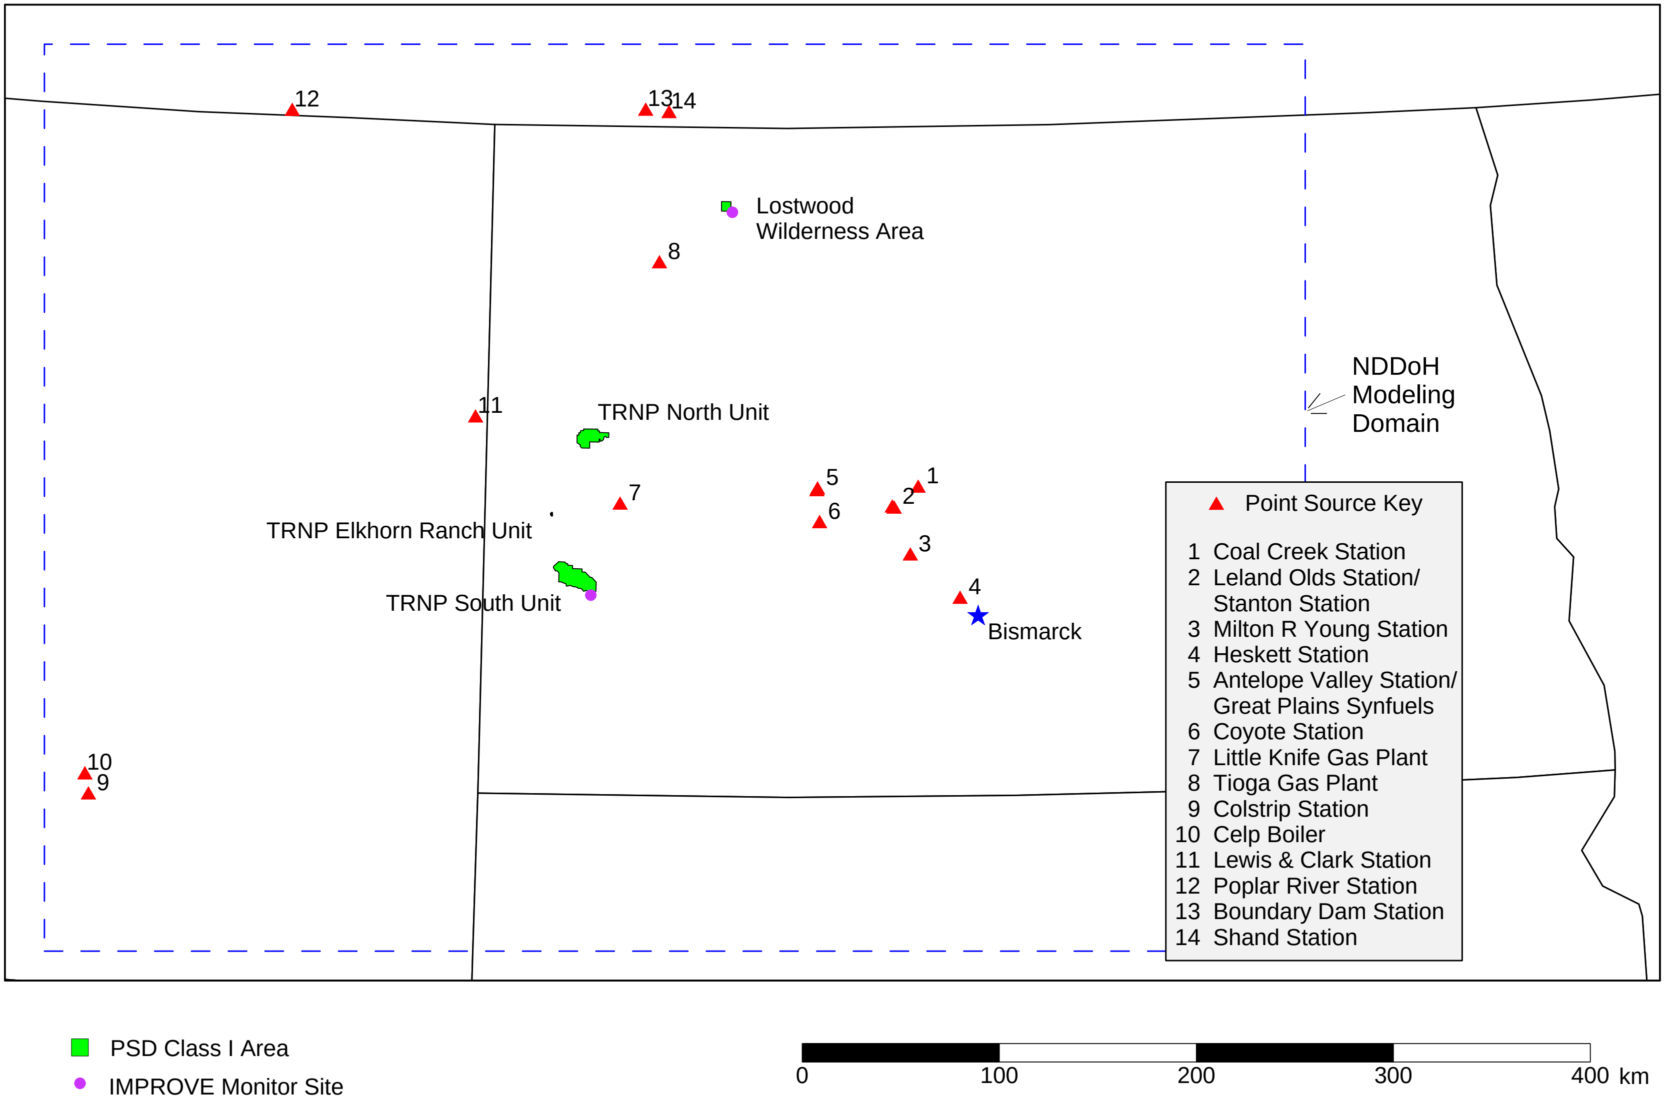
[7] EPA, 2007. Guidance on the Use of Models and Other Analyses for Demonstrating Attainment of Air Quality Goals for Ozone, PM2.5, and Regional Haze. Publication No. EPA 454/B-07-002, Office of Air Quality Planning and Standards, Research Triangle Park, NC 27711.

[8] See supra note 3.

Figure 8.2
Larger Point Sources and PSD Class I Areas



RMC and NDDoH regional haze analyses is based on the "new" IMPROVE algorithm[9]. This new system was seen to reduce bias associated with use of the "old" IMPROVE algorithm, and was adopted as an alternative by the IMPROVE Steering Committee in December 2005. The new algorithm splits ammonium sulfate, ammonium nitrate, and organic mass concentrations into two fractions: small and large. The new algorithm for light extinction is:

$$
\begin{aligned}
b_{ext} = {} & 2.2 \times f_s(RH) \times [\text{small amm. sulfate}] + 4.8 \times f_L(RH) \times [\text{large amm. sulfate}] \\
& + 2.4 \times f_s(RH) \times [\text{small amm. nitrate}] + 5.1 \times f_L(RH) \times [\text{large amm. nitrate}] \\
& + 2.8 \times [\text{small organic mass}] + 6.1 \times [\text{large organic mass}] \\
& + 10.0 \times [\text{elemental carbon}] \\
& + 1.0 \times [\text{fine soil}] \\
& + 1.7 \times f_{ss}(RH) \times [\text{sea salt}] \\
& + 0.6 \times [\text{coarse mass}] \\
& + \text{Rayleigh scattering (site-specific)} \\
& + 0.33 \times [NO_2\ (\text{ppb})]
\end{aligned}
$$

where

b_{ext} = light extinction in units of inverse megameters (Mm^{-1}),
$f_s(RH)$ = function of relative humidity for small size fraction,
$f_L(RH)$ = function of relative humidity for large size fraction,
$f_{ss}(RH)$ = function of relative humidity for sea salt,
all species concentrations (with exception of NO_2) are provided in ug/m^3,
amm. sulfate / amm. nitrate means ammonium sulfate / ammonium nitrate.

Apportionment of total sulfate concentrations into small and large size fractions is defined:

$$[\text{large amm. sulfate}] = \frac{[\text{total amm. sulfate}]^2}{20\ ug/m^3}, \text{ for } [\text{total amm. sulfate}] < 20\ ug/m^3$$

$$[\text{large amm. sulfate}] = [\text{total amm. sulfate}], \text{ for } [\text{total amm. sulfate}] \geq 20\ ug/m^3$$

$$[\text{small amm. sulfate}] = [\text{total amm. sulfate}] - [\text{large amm. sulfate}]$$

Similar equations are used to apportion total ammonium nitrate and total organic matter concentrations into small and large size fractions.

A solution for the NO_2 term in the extinction algorithm is problematic as the IMPROVE network does not include NO_2 sampling. However, WRAP and the NDDoH have determined that the NO_2 term has very little impact on total light extinction. A review of observational NO_2 data from an NDDoH monitoring site in Theodore Roosevelt National Park revealed that readings were less than the minimum detectable level of 2.0 ppb more than 80% of the time in 2002.

---

[9] IMPROVE, 2005. New IMPROVE algorithm for estimating light extinction approved for use. The IMPROVE Newsletter, Volume 14, Number 4. Air Resource Specialists, Inc., Fort Collins, CO 80525.

Accordingly, both WRAP and the NDDoH have omitted the NO_2 term in analyses for future visibility.

The IMPROVE network does include sampling for sea salt. But monitored values are very low in North Dakota Class I areas. Further, the WRAP RMC found that the CMAQ model was not a reliable predictor for sea salt. Therefore, WRAP has omitted sea salt as a modeled species, and both WRAP and the NDDoH are assuming a relative response factor of 1.0.

Light extinction is converted to deciview using the following relationship:

$$dv = 10 \times \ln(b_{ext} / 10)$$

where

dv = deciview,
b_{ext} = light extinction in units of inverse megameters (Mm^{-1}).

Visibility goals are generally expressed as deciviews.

8.3 Projection of Future Visibility

Methodology for WRAP and NDDoH projection of future visibility is based on EPA *Guidance on the Use of Models and Other Analyses for Demonstrating Attainment of Air Quality Goals for Ozone, $PM_{2.5}$, and Regional Haze*[10]. The guidance proposes a relative modeling approach to project future (2018) visibility, in order to determine compliance status with respect to visibility goals at Class I areas. Implementation of the relative modeling approach relies on relative response factors (RRFs) which represent the modeled impact of the future (visibility affecting) source emissions inventory divided by the modeled impact of the baseline source inventory at Class I areas. These RRFs are applied to baseline IMPROVE monitoring data to project future visibility for each Class I area.

Per the Regional Haze Rule, projection of future visibility is needed for the 20% worst and 20% best visibility days at each Class I area. The 20% worst days and 20% best days are determined from Class I area IMPROVE monitoring data for each year for the 5-year baseline period 2000-2004. Because IMPROVE sampling occurs once every three days, the maximum number of monitored days per year would be 122, and the maximum number of 20% worst or best days per year would be 24.

According to the EPA guidance, worst-day RRFs are developed by comparing the future average predicted mass concentration for 20% worst days to the baseline average predicted mass concentration for 20% worst days, for each visibility affecting species. The 20% worst modeled days are temporally consistent with the worst monitored days, which requires that modeling is

---

[10] See supra note 7.

based on 2000-2004 meteorological data (i.e., meteorological data used for modeling represents the same period as baseline monitoring), if all five years are modeled[11]. For each visibility affecting species (SO_4, NO_3, OMC, EC, Soil, CM), a single RRF is developed for each Class I area. The RRF is calculated by dividing the predicted future concentration averaged over all worst days by the predicted baseline concentration averaged over all worst days. Then, future concentrations for each species are projected by multiplying the RRF by the observed species concentration on each of the baseline worst days. The same process is used to develop best-day RRFs, and project best-day concentrations.

The RRF approach can be expressed mathematically:

$$X^{i,j}_{of} = X^{i,j}_{ob}\,(RRF^{i}) = X^{i,j}_{ob}\,(\overline{X}^{i}_{pf}/\overline{X}^{i}_{pb})$$

where

$X^{i,j}_{of}$ represents projected observed future concentration for species i on day j (each of 20% worst days for each baseline year),

$X^{i,j}_{ob}$ represents **o**bserved baseline (IMPROVE data) concentration for species i on day j (each of 20% worst days for each baseline year),

$\overline{X}^{i}_{pf}$ represents average predicted future concentration for species i (average of 20% worst days),

$\overline{X}^{i}_{pb}$ represents average predicted baseline concentration for species i (average of 20% worst days),

RRF^{i} represents the relative response factor for species i.

The same system is applied to project 20% best day concentrations.

The set of projected future worst-day concentrations (including all species above) is converted to light extinction through application of the IMPROVE equation (Section 8.2) for each day, then daily light extinction is converted to deciview for each day. Finally, projected daily deciview is averaged over all worst-case days for each year, then averaged over all years to produce the single future value needed to address visibility goals for each Class I area. This procedure is repeated for projected future best-day concentrations.

Both the WRAP RMC and the NDDoH followed this general methodology for projecting future visibility-affecting species concentrations, and subsequently, worst day and best day future deciview.

---

[11] Because of the resource demands of the CMAQ model, the WRAP RMC limited their visibility modeling analysis to the use of 2002 meteorology, only. Consequently, the NDDoH analysis was likewise limited to 2002 meteorology. The RRFs developed from modeling based on 2002 meteorology were then applied to all five years of monitoring data for future projection.

8.4 WRAP Visibility Modeling Methodology

The Western Regional Air Partnership (WRAP) is a Regional Planning Organization (RPO) representing the western states, including North Dakota. WRAP is one of five RPOs which together cover all states in the country. These RPOs are responsible for assisting states in the development of State Implementation Plans (SIPs) and Tribal Implementation Plans (TIPs) to address requirements of the Regional Haze Rule, and to assist with other air quality issues.

WRAP has established a Regional Modeling Center (RMC) to conduct visibility modeling and provide technical modeling guidance to support regional haze SIPs and TIPs for western states. This RMC reflects a consortium of technical expertise from University of California Riverside, University of North Carolina, and ENVIRON International Corporation. With funding from the western states, the RMC conducted an extensive modeling effort to project future visibility for each Class I area in the western United States, including the Class I areas in North Dakota.

WRAP RMC visibility modeling methodology is largely described in *Final Report for the Western Regional Air Partnership (WRAP) Regional Modeling Center (RMC) for the Project Period March 1, 2004 through February 28, 2005*[12] and *2006 Report for the Western Regional Air Partnership (WRAP) Regional Modeling Center (RMC)*[13]. Specific documentation for most recent baseline and future modeling cases is provided in *2002 Planning Simulation Version D*[14] and *2018 Preliminary Reasonable Progress Simulation Version A*[15], respectively. These and other resources can be obtained from the WRAP web site at http://pah.cert.ucr.edu/rmc.

Primary modeling tools used by the WRAP RMC include:

- the Fifth-Generation Pennsylvania State University/National Center for Atmospheric Research (PSU/NCAR) Mesoscale Model (MM5) meteorological modeling system,
- the Sparse Matrix Operator Kernel Emissions (SMOKE) emissions modeling system,
- the Community Multiscale Air Quality (CMAQ) air quality modeling system, and

- the PM Source Apportionment Technology extension (PSAT) of the Comprehensive Air Quality Model (CAMx).

The modeling domain established by the RMC includes all of the contiguous United States, and parts of Mexico and Canada (see Figure 8.1). The RMC used the MM5 model to develop the meteorological fields necessary for execution of CMAQ and PSAT within the domain. Grid cell size was specified as 36 kilometers in the horizontal direction, and vertical structure was defined by 19 layers of varying depth. Because of resource and time constraints (primarily related to CMAQ and PSAT), preparation of meteorological data was limited to Year 2002 of the baseline period.

Emissions inventory development for WRAP RMC visibility modeling relied primarily on the EPA National Emissions Inventory (NEI), and information collected from states and other RPOs. County emissions data for visibility affecting species, as well as all other species necessary to execute the chemistry in CMAQ and PSAT, were collected and processed into the format required by SMOKE. Then SMOKE was executed to apportion emissions to the appropriate grid cell and vertical layer within the modeling domain, on an hourly basis. Where appropriate, temporal emissions patterns were applied during the execution of SMOKE. All source categories shown in Table 8.1 were accounted for in the processing of emissions data in SMOKE.

Table 8.1

The WRAP RMC has included three basic emissions cases in their visibility modeling, for performance evaluation and the development of relative response factors.

- Case BASE02b reflects year 2002 emissions which are concurrent with the year 2002 meteorology. WRAP used this case for performance evaluations.

- Case PLAN02d reflects a composite interpretation of emissions for the 2000-2004 period. WRAP used this case for the baseline period to generate relative response factors.

- Case PRP18a (Preliminary Reasonable Progress 2018 Scenario A) reflects projected year 2018 emissions. Case PRP18a represents base period emissions projected to 2018, accounting for estimates of the effect of BART controls, and assuming other growth and control factors. WRAP used this case for the future period to generate relative response factors.

Note that WRAP recently completed modeling for an updated Case PRP18b future emissions scenario, as discussed in Section 6. Because NDDoH visibility modeling was initiated and largely completed well before the WRAP PRP18b emissions inventory and modeling results were available, however, Case PRP18b is not included in the visibility modeling results discussed in this SIP. For North Dakota sources, Case PRP18b reflects only a slight decrease in emissions relative to Case PRP18a. Therefore, results and conclusions of the visibility analyses reported here would not be meaningfully changed with the use of Case PRP18b emissions.

To define boundary conditions for the WRAP modeling domain, species concentrations for the perimeter of the domain were derived from the global GEOS-CHEM model.

Before beginning production modeling for development of RRFs, the WRAP RMC conducted extensive performance evaluations for both CMAQ and CAMx/PSAT. These performance evaluations were used to refine emissions inventories and other input conditions. CMAQ was subsequently applied to baseline (PLAN02d) and future (PRP18a) emissions inventories to generate RRFs and project future visibility in Class I areas. Development of RRFs and projection of future visibility followed default EPA methodology[16], as outlined in Section 8.3. Finally, PSAT was applied to assess source and species attribution for projected visibility impacts.

Results of WRAP RMC modeling for North Dakota Class I areas are reviewed in Section 8.6.2.

8.5 NDDoH Visibility Modeling Methodology

In support of the North Dakota Regional Haze SIP, the North Dakota Department of Health (NDDoH) conducted refined progress goal visibility modeling to supplement and update the modeling conducted by WRAP RMC. The NDDoH developed an in-house modeling capability to address weight of evidence issues, and concerns regarding the resolution of the WRAP CMAQ simulations, particularly as applied to large point sources located near Class I areas. As discussed in Section 8.4, WRAP RMC modeling focused on the default EPA methodology for regional haze[17], and did not address weight of evidence issues such as discounting the effect of

---

[16] See supra note 7.

[17] See supra note 7.

international source emissions. The RMC applied CMAQ on a regional basis using a grid resolution of 36 km, with no plume-in-grid treatment.

The NDDoH regional haze modeling constitutes a hybrid approach as it involved nesting the local NDDoH CALPUFF domain within the WRAP National CMAQ domain, and applying the Lagrangian CALPUFF model in a retrospective sense to more realistically define plume-receptor geometry for local point sources. To implement the nesting, hourly output concentrations from WRAP CMAQ modeling were used to set hourly boundary conditions for CALPUFF. CMAQ output used to set CALPUFF boundary conditions reflects corresponding WRAP cases for baseline and future emission inventories.

The hybrid modeling approach was used for simulation of SO_2-SO_4-NO_X-HNO_3-NO_3 chemistry and transport and, thus, sulfate and nitrate predictions, only. RRFs and projected future concentrations for other visibility affecting species, including organic carbon (OMC), elemental carbon (EC), fine particulate (Soil), and coarse mass (CM), were taken directly from the WRAP RMC results for North Dakota Class I areas. The deferral to WRAP CMAQ results for these species is based on limitations in the CALPUFF chemistry, and the fact that larger point sources located relatively near North Dakota Class I areas, where CMAQ resolution is a concern, are primarily emitters of SO_2 and NO_X. Further, IMPROVE measurements at North Dakota Class I areas indicate that sulfate and nitrate are primary contributors to light extinction on most worst-case days. Individual species contribution to light extinction for worst-case days at Theodore Roosevelt National Park is illustrated in Figure 8.3. Therefore, weight of evidence assessments should be most affected by changes in sulfate and nitrate concentrations.

The NDDoH used the hybrid modeling system in a supportive sense to add value to the original WRAP CMAQ modeling results for sulfate and nitrate. The hybrid system was used to adjust WRAP CMAQ results in order to offset coarseness in the CMAQ resolution for large local point sources, and in order to discount the effect of international (Canadian) sources. Procedures for adjusting WRAP CMAQ results are discussed in Section 8.5.6.

For hybrid modeling, the NDDoH used the State's point source inventory for SO_2 and NO_X, and has imported WRAP RMC data for all other source categories (and for point source SO_4 and NO_3) to apportion emissions within the CALPUFF domain. WRAP used the SMOKE emissions model[18] to develop the emissions inventory for CMAQ. The NDDoH has obtained and processed WRAP SMOKE output to define area source emissions for the CALPUFF domain. The CALPUFF area source emissions inventory includes the species SO_2, SO_4, NO_X, and NO_3. In addition, primary SO_4 and NO_3 emissions data were extracted from the SMOKE inventory for point sources, and apportioned to the CALPUFF domain as area sources. WRAP CMAQ source categories included in the CALPUFF emissions inventory are outlined in Table 8.2. Note that WRAP SMOKE output did not contain all four species for some source categories.

Point	SO_4, NO_3

The interfacing of CMAQ and CALPUFF modeling systems for the NDDoH hybrid approach is illustrated in the flow diagram in Figure 8.4. Necessary software for processing input data and projecting future visibility has been developed by the NDDoH.

To confirm effectiveness of the hybrid CMAQ-CALPUFF modeling system, the NDDoH conducted a performance evaluation prior to commencing production modeling. The evaluation focused on performance of the hybrid system for sulfate and nitrate concentrations, and prompted changes to some model inputs to improve performance relative to observations. CMAQ performance evaluations conducted by WRAP RMC for OMC, EC, Soil, and CM species are also relevant. The NDDoH Performance evaluation is discussed in Section 8.6.1.

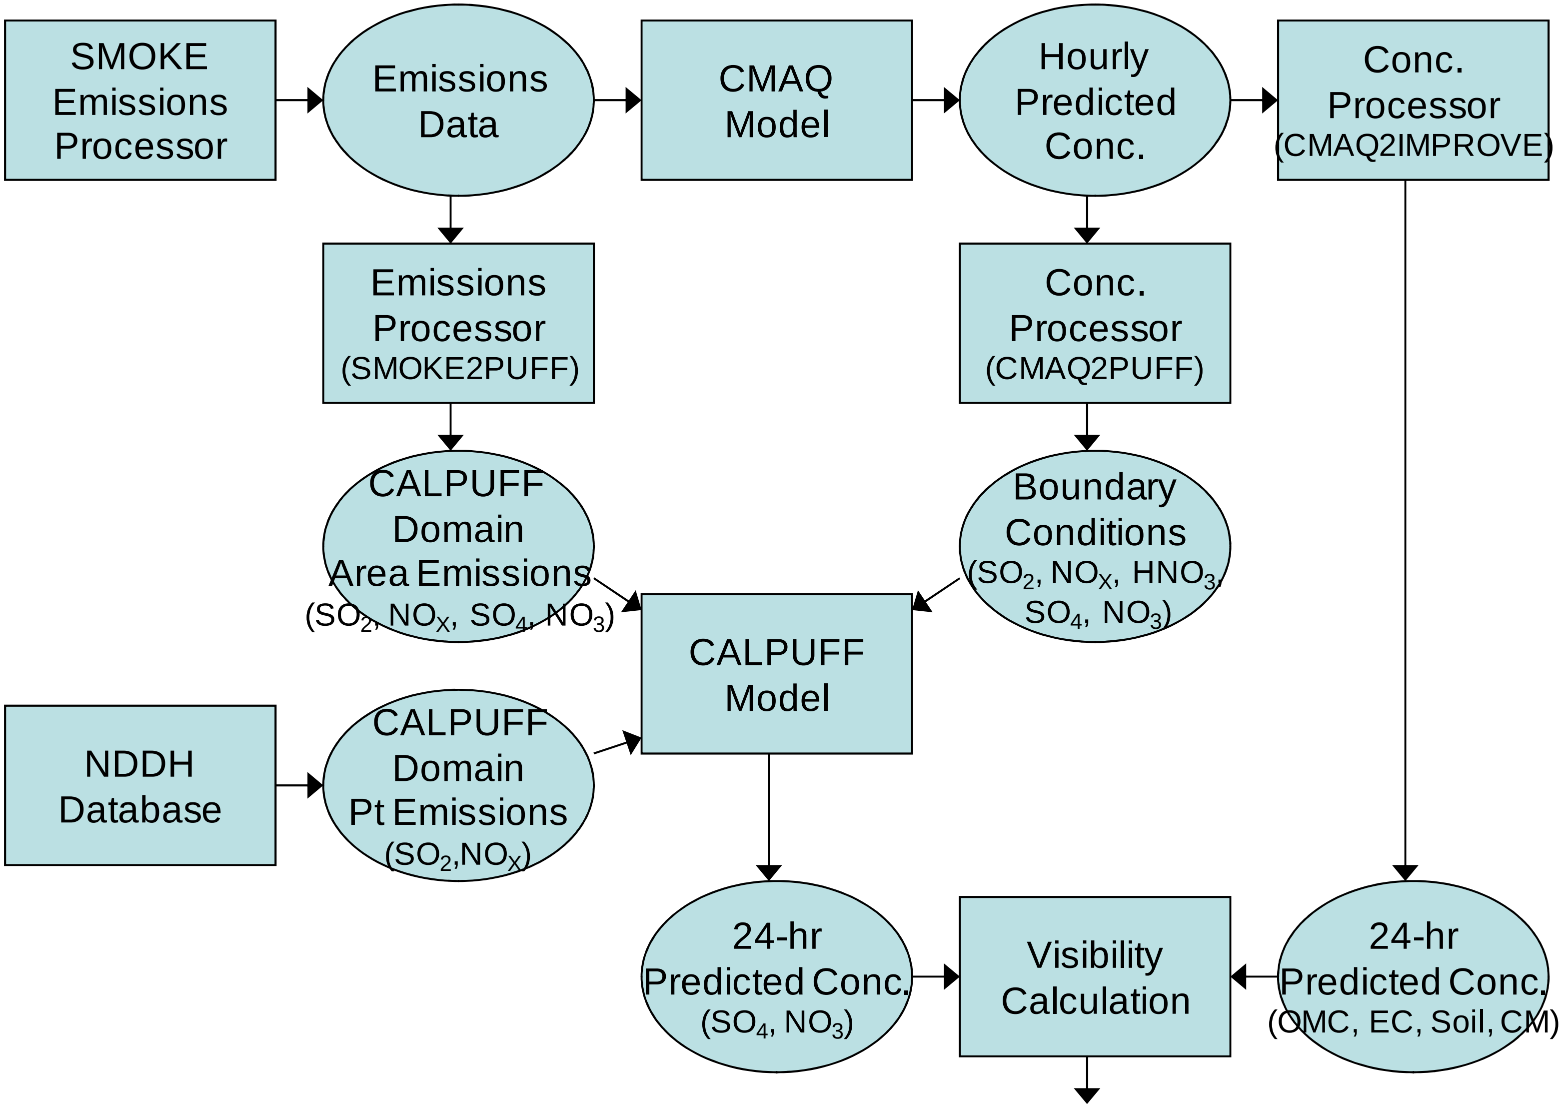
The NDDoH has obtained CMAQ emissions input data (SMOKE output) and hourly concentration output files from the WRAP RMC. CMAQ data used to set CALPUFF boundary conditions and develop the CALPUFF area source inventory will be based on WRAP cases BASE02b, PLAN02d, and PRP18a, for performance evaluation, baseline case, and future case modeling, respectively. These WRAP scenarios are described as follows.

- Case BASE02b reflects CMAQ modeling using year 2002 emissions with year 2002 meteorology. The NDDoH used this case for performance evaluations.

- Case PLAN02d reflects CMAQ modeling using composite 2000-2004 emissions with 2002 meteorology. The NDDoH used this case for the base period to generate relative response factors.

- Case PRP18a (Preliminary Reasonable Progress 2018 Scenario A) reflects CMAQ modeling using projected year 2018 emissions with 2002 meteorology. Case PRP18a represents base period emissions projected to 2018, accounting for estimates of the effect of BART controls, and assuming other growth and control factors. The NDDH used this case for the future period to generate relative response factors.

Figure 8.4
Hybrid Interfacing of CMAQ and CALPUFF Modeling Systems



Again, WRAP recently completed modeling for an updated Case PRP18b future emissions scenario, as discussed in Section 6. Because NDDoH visibility modeling was initiated and largely completed well before the WRAP PRP18b emissions inventory and modeling results were available, however, Case PRP18b is not included in the visibility modeling results discussed in this SIP. For North Dakota sources, Case PRP18b reflects only a slight decrease in emissions relative to Case PRP18a. Therefore, results and conclusions of the visibility analyses reported here, although conservative, would not be meaningfully changed with the use of Case PRP18b emissions.

The modeling system, emissions inventory, other model inputs, and procedures for the NDDoH regional haze modeling analysis are discussed in following Sections 8.5.1 through 8.5.6. A detailed, step-by-step outline of NDDoH visibility modeling procedure is also provided in Appendix E of this report.

Results of the NDDoH hybrid visibility modeling for North Dakota Class I areas are reviewed in Section 8.6.

8.5.1 Hybrid Modeling System

For sulfate and nitrate predictions, the NDDoH applied the CALPUFF model, using regional WRAP CMAQ output concentrations to set boundary conditions for the CALPUFF domain. The CALPUFF computer modeling system includes the CALMET meteorological model[19], the CALPUFF dispersion/chemistry model[20], and the POSTUTIL and CALPOST post processing programs. POSTUTIL implements the ammonia limiting method, which provides an adjustment to avoid overstating available ammonia for NO_x to NO_3 conversion chemistry in CALPUFF. In the NDDoH implementation of the CALPUFF system for production visibility modeling, the CALPOST processor was replaced with CALHAZE, a module which directly processes relative response factors and projects future visibility, using hourly output from CALPUFF (POSTUTIL) baseline and future model runs.

With the exception of CALHAZE (developed by NDDoH), CALPUFF and associated software was developed and is maintained by TRC Corporation (previously by Earth Tech, Inc.). The versions of CALPUFF and associated programs which the NDDoH utilized for regional haze modeling are summarized in Table 8.3.

Table 8.3
CALPUFF System Versions
Applicable For Regional Haze Modeling

Program	**Version**	**Level**
CALMET	5.8	70623
CALPUFF	5.8	70623
POSTUTIL	1.56	70627

The meteorological/computational modeling domain used by the NDDoH for CALPUFF visibility modeling is illustrated in Figure 8.5. Dimensions of the domain are 639 kilometers east-west by 459 kilometers north-south, with a horizontal grid cell size of 3 kilometers. In the vertical, the domain is defined by twelve vertical layers. The domain is sized and positioned to encompass all large visibility-affecting point sources located within 250 km of North Dakota Class I areas. Because the domain is relatively large for CALPUFF modeling, all location coordinates are based on the Lambert Conformal map projection to mitigate distortions due to the earth's curvature.

8.5.2 CALMET Input

Input requirements for the CALMET model include various meteorological and geophysical data sets, and a control input file with appropriate settings. Required meteorological data include surface, upper-air, and precipitation observations, and mesoscale model output data fields. Geophysical input data include terrain elevation and land-use data. Though CALMET may be run with mesoscale model meteorological data, alone (i.e., no observations), the EPA modeling guideline[21] recommends "blending" observations with the mesoscale model fields. Therefore, the NDDoH included surface and upper-air observations in a blended approach.

Because WRAP RMC modeling was limited to the single year 2002 meteorology due to resource limitations, the NDDoH hybrid approach was necessarily limited to the same single year of meteorology.

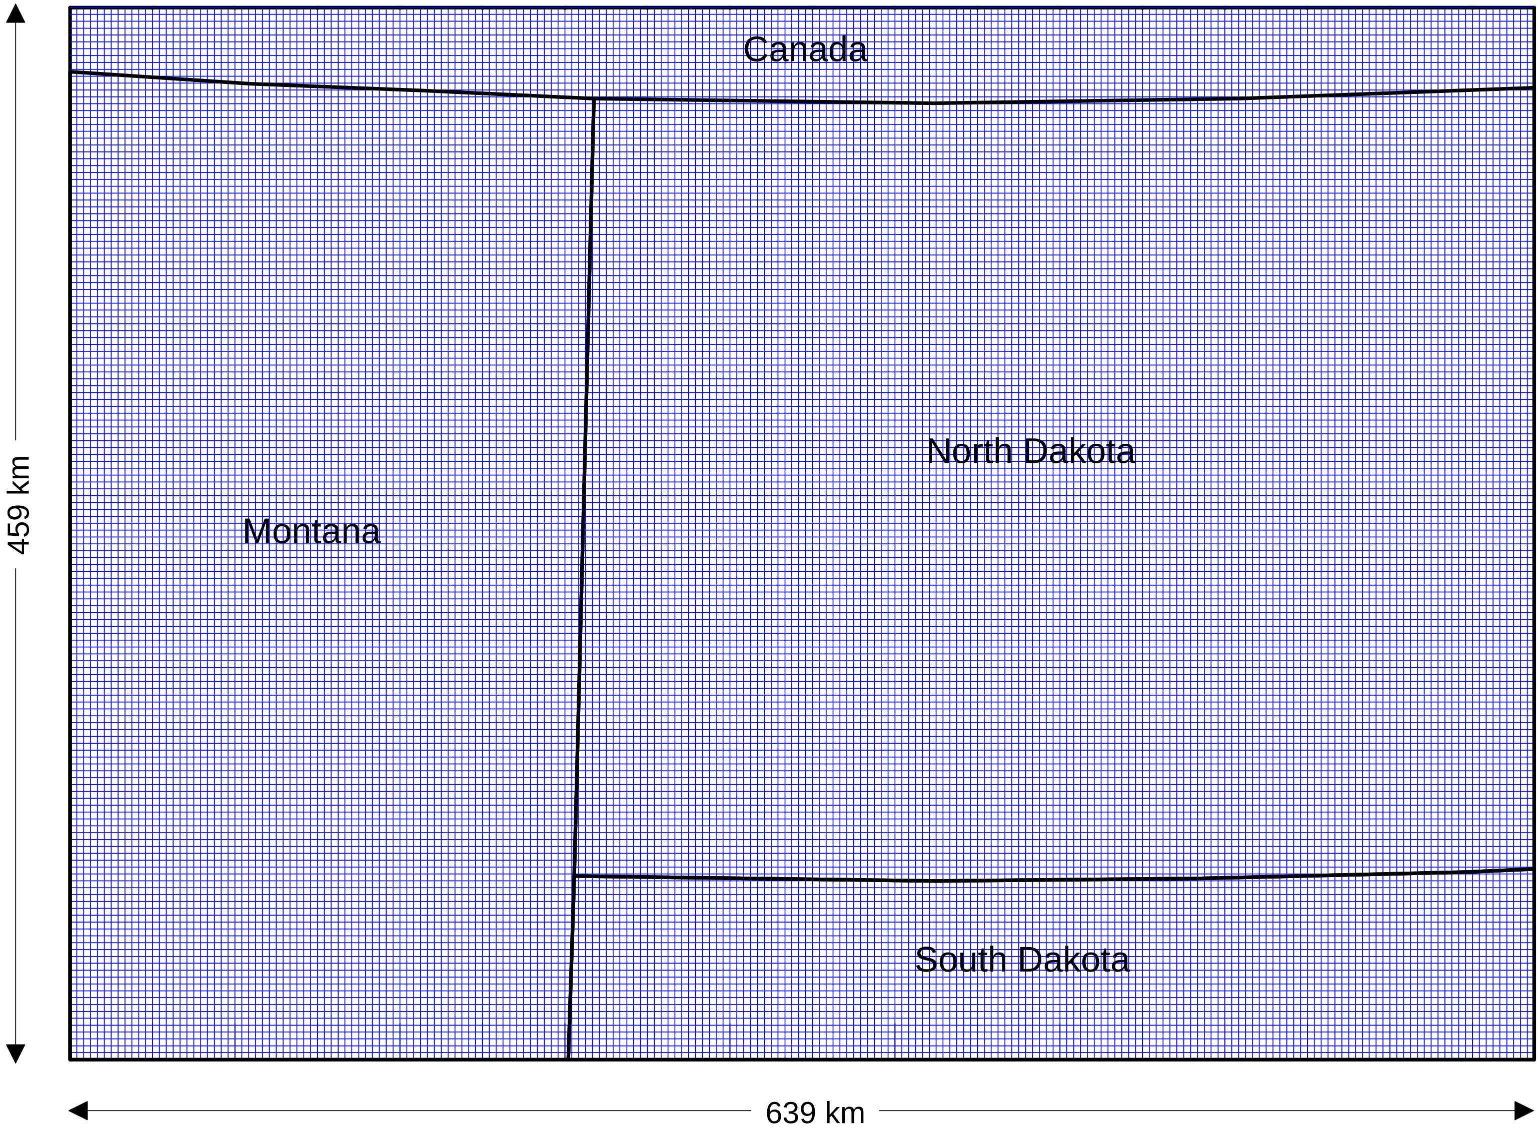
Figure 8.5
CALPUFF 3-km Meteorological/Computational Grid



8.5.2.1 Meteorological Data

8.5.2.1.1 Mesoscale Model Data

NDDoH mesoscale model wind fields used with CALMET are based on the National Center for Environmental Predictions (NCEP) Rapid Update Cycle (RUC) forecast model. Mesoscale model fields in the MM5.DAT format required by CALMET were developed by a contractor[22]. The contractor obtained and archived RUC hourly initial analyses from NCEP for years 2000 through 2002. Resolution of these initial analyses was 40 km. The contractor used the ARPS Data Assimilation System (ADAS) to enhance resolution to 10 km, and converted the resultant hourly wind fields to the MM5.DAT format recognized by CALMET. The domain of these hourly wind fields is consistent with the CALMET/CALPUFF domain used by NDDoH (Section 8.5.1).

In the process of model performance evaluation, the NDDoH also tested the hybrid modeling system with the 2002 36-km MM5 data set prepared by the WRAP RMC for CMAQ modeling. Hybrid model performance was similar using either MM5 or RUC mesoscale data.

8.5.2.1.2 Surface Observations

Concurrent surface observations for 2002 were obtained in surface hourly abbreviated format from the National Climatic Data Center (NCDC). Data were obtained for 40 ASOS and manual stations located within or near the NDDoH CALMET/CALPUFF domain. The ASOS/manual observations reflect data from stations operated by the National Weather Service, Federal Aviation Administration, U.S. Air Force, and Environment Canada. Locations of these stations are shown in Figure 8.6.

To compensate for well-documented deficiencies in ASOS cloud data above 12,000 feet, NDDoH also obtained concurrent GOES ASOS satellite cloud data for all selected surface stations. The satellite hourly observations included cloud amount (sky cover) and cloud height (ceiling height) data above 12,000 feet, and were therefore used to supplement the ASOS observations.

NDDoH prepared custom software to merge the ASOS and satellite data. Earth Tech utility software was then used to quality assure merged data, and convert to the format required by CALMET (SURF.DAT). Standard methods were applied to provide substitutions for missing

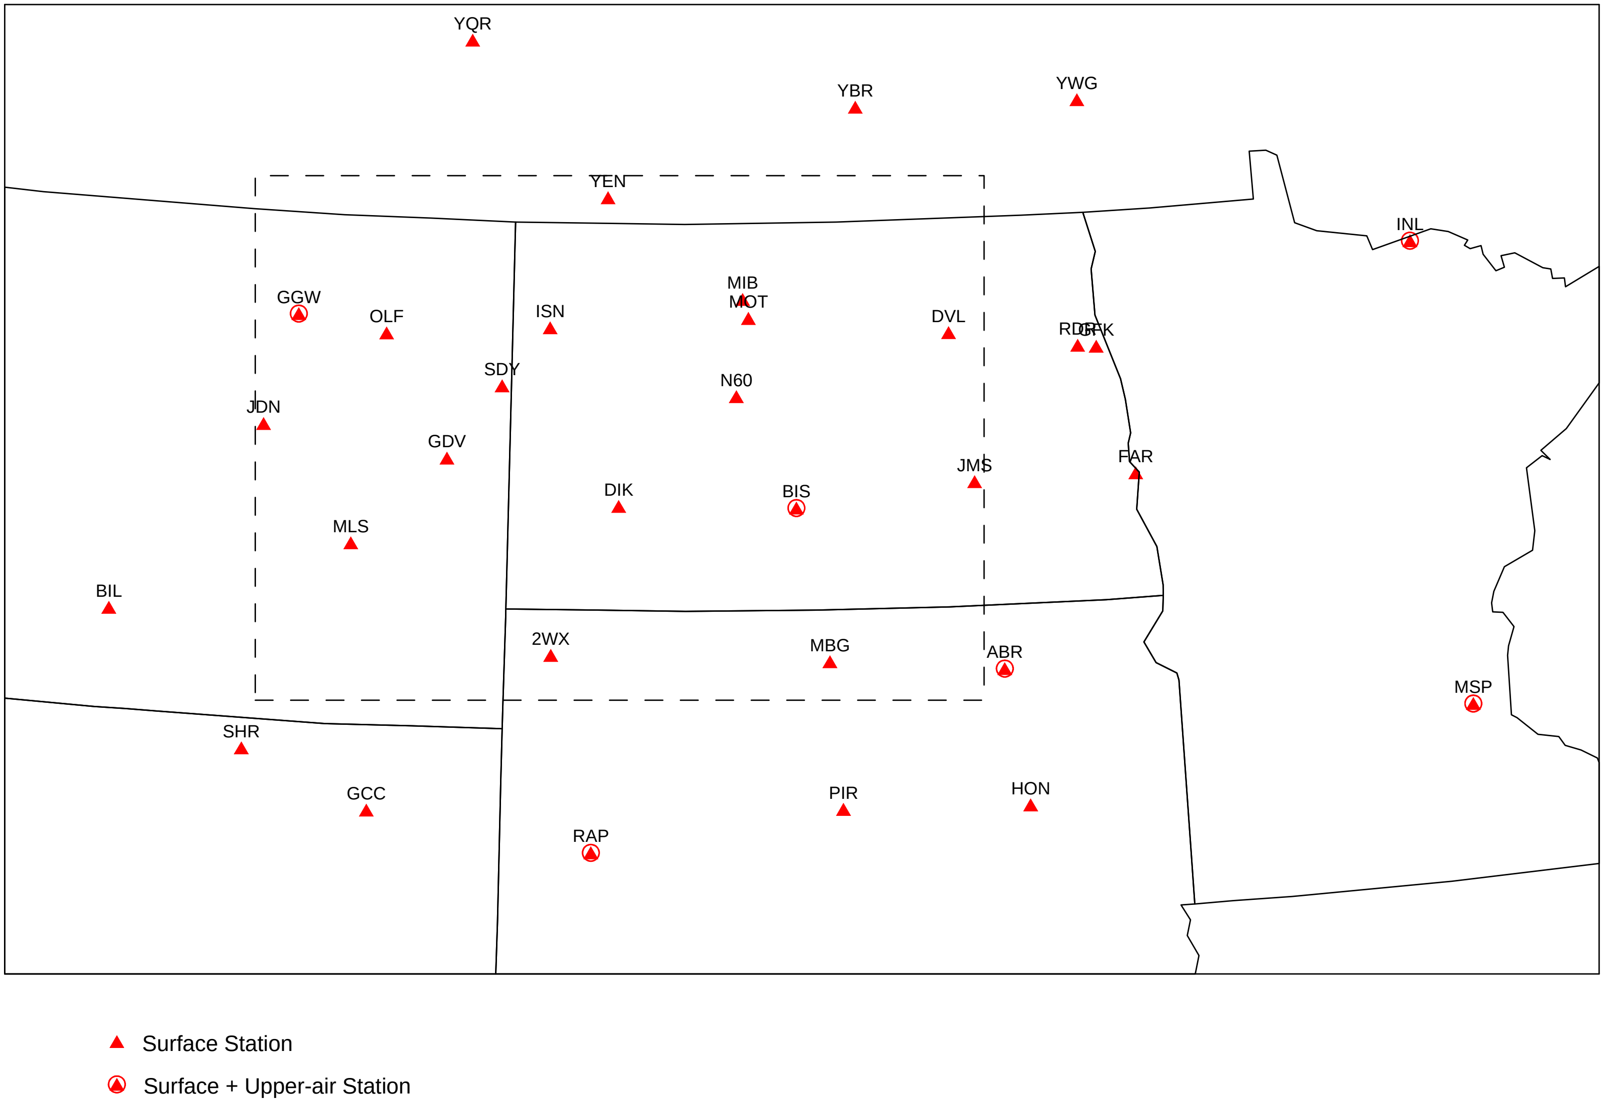
Figure 8.6
CALMET Surface / Upper Air Meteorological Stations



data.[23,24] The occurrence of missing data elements in the surface observations was generally very limited, and within the tolerances suggested by EPA.

8.5.2.1.3 Upper-Air Observations

Upper-air observations for 2002 were obtained from NOAA's Earth Systems Research Laboratories (ESRL) in Boulder, Colorado. Upper-air sounding files were downloaded from the website (www.fsl.noaa.gov) in the original FSL format, which is accepted for CALMET input as the option "NCDC CD-ROM". Data were obtained for six upper-air stations (NWS) located within or near the NDDoH CALMET/CALPUFF domain. Locations of these stations are also shown in Figure 8.6.

Processing of the upper-air data for CALMET input involved using Earth Tech utility software, running custom software written by NDDoH staff, and manual editing of data files. The main Earth Tech program quality checked the upper-air data files, output error messages to identify problems in the data to be corrected by the user, and converted the data to the format required by CALMET. The NDDoH custom software performed additional quality checks, and, combined with manual editing of data files, corrected additional errors or problems in the data and filled in for missing data when necessary. Substitutions for missing data generally followed standard EPA guidance. [22,23] Upper-air soundings were processed up to the 500-mb level to accommodate mixing heights up to 4000 meters above ground level at Rapid City, South Dakota. In addition, the main Earth Tech processing program had to be modified slightly (corrected) to correctly read longitude for Glasgow, Montana.

8.5.2.1.4 Precipitation Data

Hourly precipitation data for 2002 were obtained from NCDC in TD-3240 format. Data were included for 93 NWS hourly recording stations located within or near the NDDoH CALMET/CALPUFF modeling domain. Location of these stations is shown in Figure 8.7.

Earth Tech utility software was employed to quality assure the TD-3240 data, and process it into the format required by CALMET (PRECIP.DAT). No substitutions were made for missing data, because CALMET substitutes internally from the nearest available station, and the station resolution was relatively good (Figure 8.7).

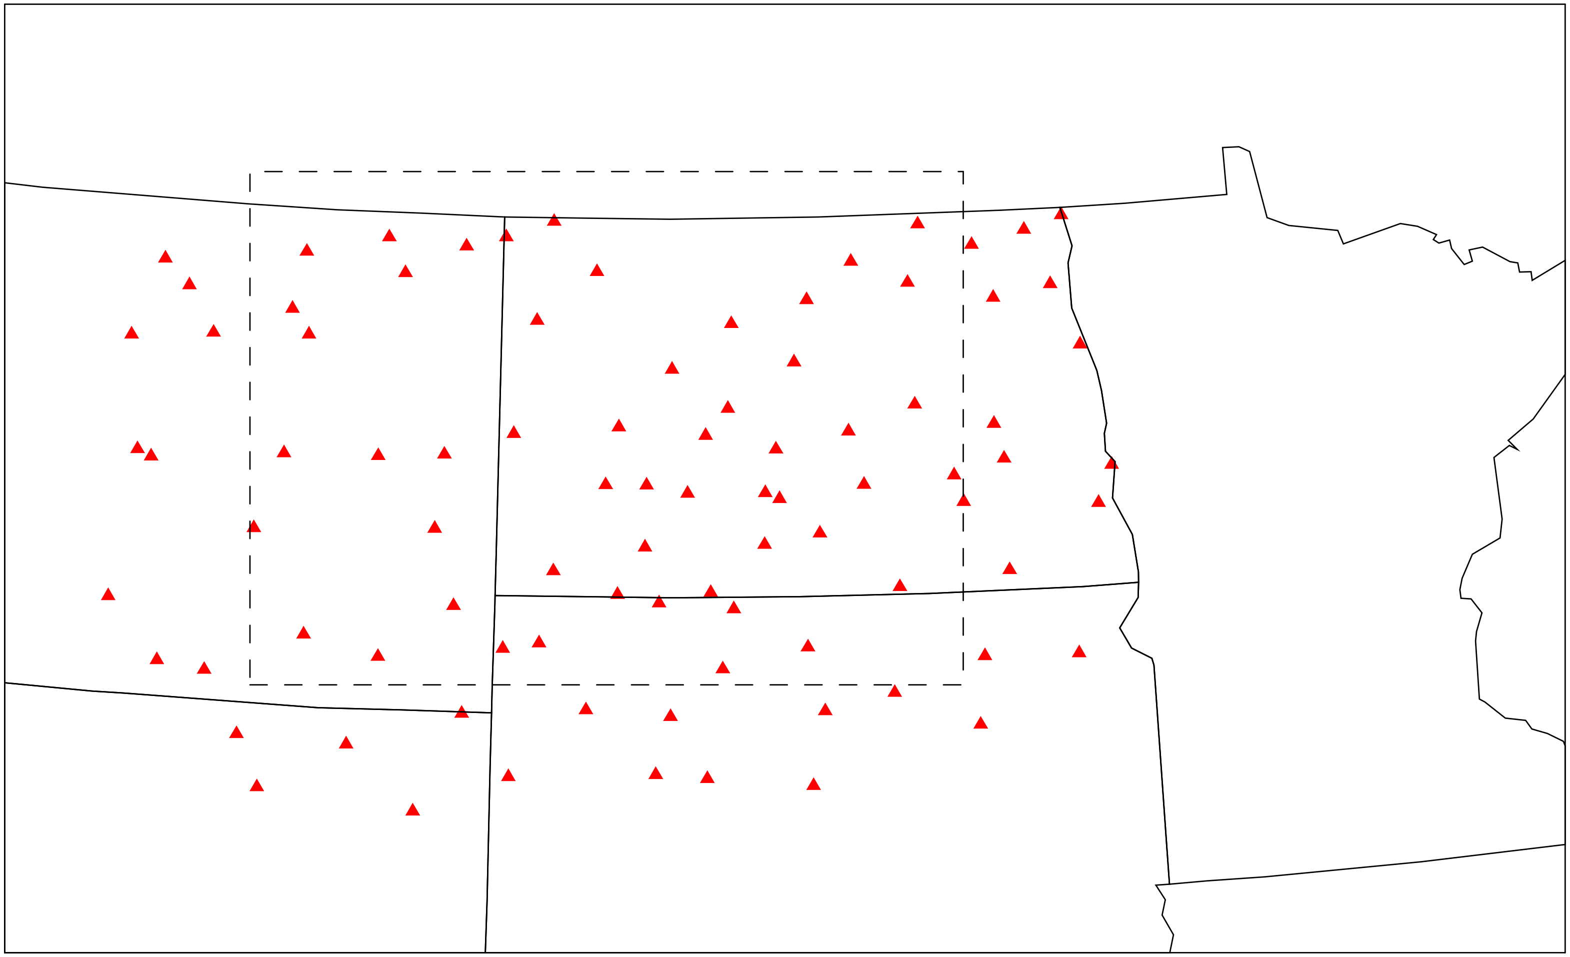
[24] EPA, 1987. On-Site Meteorological Program Guidance for Regulatory Modeling Application. Office of Air Quality Planning and Standards, Research Triangle Park, NC 27711.

Figure 8.7
CALMET Precipitation Stations



8.5.2.2 Geophysical Data

CALMET requires specification of terrain elevation, and parameters related to the land-use profile, for each grid cell in the modeling domain. The NDDoH derived terrain elevations from United States Geological Survey (USGS) GTOPO30 data sets for North America central and mountain zones. Land-use profiles were derived from the USGS Global Data Set for North America.

Using CALMET utility software, all gridded terrain and land-use data were processed into the single geophysical file (GEO.DAT) required by CALMET. NDDoH assumed default values relating surface roughness length, albedo, Bowen ratio, soil heat flux, and leaf area index to land-use type.

8.5.2.3 CALMET Control File Settings

CALMET control file settings used for processing year 2002 meteorological data for visibility analyses are generally consistent with guidance from the Interagency Workgroup on Air Quality Modeling (IWAQM)[25]. To the extent applicable, the settings are also consistent with the North Dakota alternative protocol for PSD Class I increment analyses[26].

IWAQM recommendations for CALMET control file variable settings fall into two categories. IWAQM-defined variables are those for which IWAQM provides a default value as a general recommendation for all analyses. User-defined variables are those where IWAQM recognizes the input value will need to be tailored for a given application, and default values are therefore not provided.

For visibility analyses, the NDDoH has established appropriate settings for user-defined variables, and has determined the need to adjust a limited number of IWAQM-defined variables from recommended values, as discussed below. The CALMET control file user-defined settings, as well as the IWAQM-defined settings which have been adjusted by NDDoH, are summarized in Table 8.4. IWAQM-defined settings adjusted by NDDoH have a shaded background in the Table.

---

[25] EPA, 1998. IWAQM Phase 2 Summary Report and Recommendations for Modeling Long Range Transport Impacts. Publication No. EPA-454/R-98-019, Office of Air Quality Planning and Standards, Research Triangle Park, NC 27711.

[26] NDDoH, 2005. A Proposed Alternative Air Quality Modeling Protocol to Examine the Status of Attainment of PSD Class I Increment. North Dakota Department of Health, Bismarck, ND 58506.

Most of the user-defined settings are intuitive, related to parameterization of the meteorological grid used with CALMET, as previously discussed. The remaining user-defined variables, (RMAX1, RMAX2, RMAX3, TERRAD, R1, R2) control the influence of mesoscale model data, station observations, and terrain features in development of the final wind field. Settings for these variables are based on the NDDoH alternative protocol for PSD Class I increment analyses.

NDDoH settings for IWAQM-defined variables are consistent with IWAQM recommendations, with limited exceptions as established in the alternative protocol for PSD Class I increment analyses. Because the use of mesoscale meteorological data is now being generally recommended for long-range modeling analyses, the IPROG variable has been changed from 0 to 14, which reflects use of MM5 format data (in this case RUC data) as the initial guess wind field. The ZUPWND setting has been changed for consistency with default values in recent versions of CALMET (the IWAQM setting reflected defaults for an older version of CALMET). Based on visual feedback testing, IWAQM settings for variables related to spatial averaging of mixing heights, MNMDAV and ILEVZI, were adjusted to provide averaging over a larger area.

Because the NDDoH CALMET/CALPUFF modeling domain extends into the western part of the upper Great Plains, maximum mixing height settings (ZIMAX/ZIMAXW) were increased from 3000 to 4000 meters to be consistent with maximum mixing heights reported for this region.[27] Note that the CALMET BIAS factors have no effect when mesoscale data are used as the initial guess wind field.

8.5.3 CALPUFF Input

Along with the CALMET-processed meteorological data, CALPUFF input requirements for NDDoH hybrid visibility modeling include emissions and stack data, background ozone data, background ammonia data, receptor locations, boundary conditions, and input control file settings. These CALPUFF input requirements are discussed here.

Table 8.4
User-Defined and Non-IWAQM Settings for CALMET Control File*

Variable	**Description**	**Value**
NSSTA	No. of surface stations	40
NUSTA	No. of upper-air stations	5
NPSTA	No. of precipitation stations	93
IBTZ	Base time zone	7
PMAP	Map projection (LCC=Lambert Conformal Conic)	LCC
FEAST	False easting at origin	0.0
FNORTH	False northing at origin	0.0
RLAT0	Origin latitude of projection	44.0N
RLON0	Central meridian of projection	102.0W
XLAT1	Latitude of 1st standard parallel for projection	46.0N
XLAT2	Latitude of 2nd standard parallel for projection	48.5N
DATUM	Datum-region for output coordinates	NWS-27
NX	No. of X grid cells	213
NY	No. of Y grid cells	153
DGRIDM	Grid spacing (km)	3.0
XORIGKM	Southwest grid cell X coordinate	-380
YORIGKM	Southwest grid cell Y coordinate	140
NZ	No. vertical layers	12
ZFACE	Cell face heights (m)	0.,20.,50.,90.,140.,200., 270.,370.,500.,1000., 1700.,2500.,4200.
NOOBS	No observation mode (0 = no)	0
IPROG	Use MM5.DAT file as initial guess wind field (14=yes)	14

Variable	**Description**	**Value**
RMAX1	Max. radius of influence of surface observation (km)	100
RMAX2	Max. radius of influence of upper-air observation (km)	200
RMAX3	Max. radius of influence over water (km)	200
TERRAD	Radius of influence of terrain features (km)	10
R1	Distance from a surface observation station at which the wind observation and the first guess field are equally weighted (km)	10
R2	Distance from an upper-air observation station at which the wind observation and the first guess field are equally weighted (km)	10
ISURFT	Surface station number used for the surface temperature for the diagnostic wind field module (Bismarck)	17
IUPT	Upper-air station number used to compute the domain-scale temperature lapse rate for the diagnostic wind field module (Bismarck)	1
ZUPWND	Bottom and top of layer through which the domain-scale winds are computed (m)	1.,2500.
MNMDAV	Max. search distance (in grid cells) for spatial averaging of mixing ht. and temperature	7
ILEVZI	Layer of winds used in upwind averaging of mixing heights	3
ZIMAX	Maximum over land mixing height (m)	4000.
ZIMAXW	Maximum over water mixing height (m)	4000.

*Shaded background indicates IWAQM-defined setting adjusted by NDDoH

8.5.3.1 Emissions Inventory

The emissions inventory utilized in the NDDoH hybrid visibility modeling analysis accounted for all SO_2-SO_4-NO_X-HNO_3-NO_3 emission sources located within and outside of the NDDoH CALPUFF domain. The impact of emission sources located outside of the domain was accounted for using the boundary condition feature of CALPUFF, with WRAP CMAQ output concentrations used to set appropriate boundary concentrations. Within the CALPUFF domain, all SO_2-SO_4-NO_X-NO_3 emissions were configured as conventional point and area sources.

Note that HNO_3 is not directly emitted by any visibility affecting source. However, HNO_3 is an important component of nitrate chemistry (both CMAQ and CALPUFF), and is provided as an output species in CMAQ. Therefore, HNO_3 is included as a boundary concentration for CALPUFF boundary conditions, but it is not directly emitted by any of the visibility affecting sources configured within the CALPUFF domain.

For SO_2-SO_4-NO_X-NO_3 sources located within the NDDoH CALPUFF domain and within the North Dakota border, stack data for point sources, including stack operating parameters and SO_2 and NO_X emission rates, were obtained from an internal Department database. Point source data were reviewed by NDDoH to confirm viability of all stack parameters, and emission rates were updated, if necessary, to reflect values representative of the 2000-2004 period.

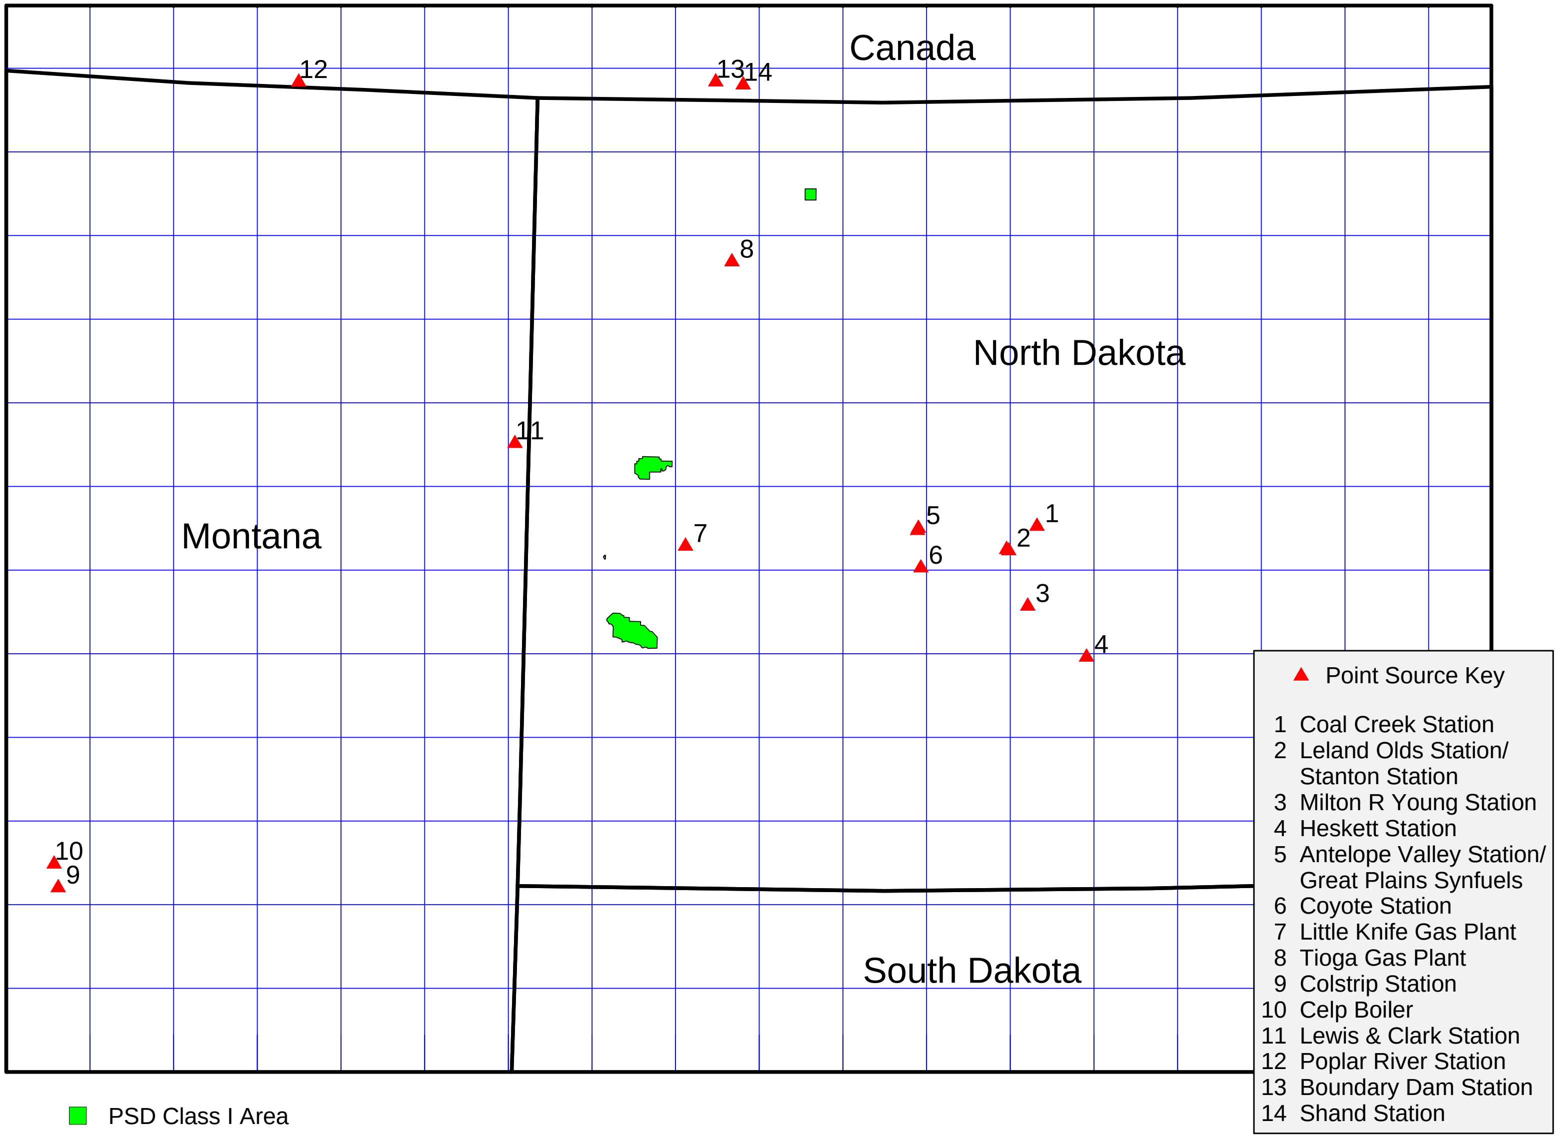
For SO_2 and NO_X point sources located within the NDDoH CALPUFF domain, but outside of North Dakota (South Dakota, Montana, Canada), the NDDoH obtained appropriate stack parameters and emission rates from governing agencies representing these jurisdictions. Most Montana data was obtained directly from the facility operators. Data representing the 2000-2004 period were requested. Data were reviewed by NDDoH to confirm viability of all stack parameters.

Note that the size threshold for configuring visibility-affecting sources as point versus area is generally connected to the availability of point source data in the National Emissions Inventory (NEI). All point sources included in the NEI (and located within the NDDoH CALPUFF domain) were configured as point sources for the visibility analysis. The exception is oil and gas related SO_2 sources for which the NDDoH maintains a separate database. These oil and gas related sources, though not included in the NEI, were also configured as point sources for the visibility analysis.

The location of larger visibility-affecting point sources within the CALPUFF domain is depicted in Figure 8.8.

All remaining SO_2-SO_4-NO_X-NO_3 sources located within the NDDoH CALPUFF domain, but not included in the North Dakota or adjoining jurisdiction's point source inventories, were configured as 36-kilometer area sources using a predefined grid structure in CALPUFF. The area-source grid is illustrated in Figure 8.8. Emission rates for the CALPUFF area source grid were developed using WRAP CMAQ input (SMOKE output) for the CMAQ grid cells located within the NDDoH CALPUFF domain. The NDDoH obtained the SMOKE output data from WRAP RMC. Because the location and orientation of the CMAQ and CALPUFF grids are not

Figure 8.8
NDDoH Domain - Locations of Larger Point Sources and 36-km Area Source Grid



consistent, software was developed by NDDoH to accurately apportion emissions from 36-kilometer CMAQ grid cells to the 36-kilometer CALPUFF area source grid.

Based on availability in WRAP SMOKE output, the CALPUFF area source emissions inventory included the source categories and species summarized in Table 8.2 . Note that SMOKE output did not include all four species (SO_2-SO_4-NO_X-NO_3) for some source categories. Although NDDoH developed a conventional point source inventory for SO_2 and NO_X, the NDDoH database did not include primary SO_4 and NO_3 emissions for point sources. Therefore, SO_4 and NO_3 emissions for the point source category were obtained from WRAP SMOKE output, and these components of point source emissions were configured as area sources in CALPUFF.

Based on testing during the performance evaluation, and on consultation with Joe Scire (TRC)[28,29], area sources in CALPUFF were configured for best model performance, and to be more consistent with the grid cell treatment in CMAQ. This involved proper settings for the CALPUFF "release height" and "initial sigma z" input parameters for area sources.

Emission rates used for both point and area sources reflect total actual tons per year. CALPUFF apportions these total emissions, on a temporal basis, equally to each hour of the year. The NDDoH tested the use of temporal profiles to vary emission rates on a seasonal, monthly, or hourly basis, but found that such adjustments made little difference in the hybrid model performance evaluation (see Section 8.6.1). For example, North Dakota electrical generating stations (EGUs) were modeled using an annual profile of actual hourly emissions for SO_2 and NO_X, and results (compared to default total tons per year modeling) were unchanged for most of the metrics included in the comparison. The NDDoH attributes this finding to the fact that the characterization of model output used for developing RRFs is the *average* of the 20 percent worst or best day predictions, and this longer-term average was also the focus of the performance evaluation. Using the average of 20 percent of the days in a year serves to dampen out differences attributable to shorter-term temporal variations in emissions.

To address hybrid model performance and the development of RRFs, the NDDoH prepared separate emissions inventories for base period, future period, and performance evaluation scenarios. SMOKE data used to apportion area source emissions was based on WRAP cases BASE02b, PLAN02d, and PRP18a for performance evaluation, base period, and future period modeling, respectively. These WRAP cases are described as follows.

- Case BASE02b reflects use of year 2002 emissions with year 2002 meteorology. NDDoH used this case for performance evaluations.

- Case PLAN02d reflects use of composite 2000-2004 emissions with 2002 meteorology. NDDH used this case for base period modeling to generate relative response factors.

[29] Joe Scire previously affiliated with Earth Tech, Inc.

- Case PRP18a (Preliminary Reasonable Progress 2018 Scenario A) reflects use of projected year 2018 emissions with 2002 meteorology. Case PRP18a represents base period emissions projected to 2018, accounting for estimates of the effect of BART controls, and assuming other growth and control factors. NDDoH used this case for future period modeling to generate relative response factors.

To complete emission inventories for the three modeling scenarios, the NDDoH developed point source inventories (SO_2 and NO_X) consistent with the WRAP cases. For EGUs, the inventory for performance evaluation was based on actual emissions for 2002, while the base period inventory assumed the five-year average of 2000-2004 actual emissions. The future period inventory for EGUs included emission reductions consistent with BART controls (see Section 6.2), but remained consistent with base period emissions for non-BART facilities. The possible addition of new EGUs was also accounted for in the future inventory (e.g., the potential “Gascoyne 500” EGU was added to the future inventory).

For point sources other than EGUs (reflecting generally small sources), the source inventory for performance evaluation was based on 2002 actual emissions, and the inventory for base period and future period modeling was relatively consistent with that used for the performance evaluation. For non-EGU point sources, little change in the emissions inventory is expected between base and future periods. Emissions increases associated with new sources will be no greater (and likely less) than emissions decreases associated with retiring sources.

When considering weight of evidence options in the NDDoH hybrid visibility modeling analysis, emissions inventories as described above were adjusted to eliminate sources. For example, when exercising the option to discount the impact of international sources, all Canadian sources of visibility affecting emissions (SO_2-SO_4-NO_X-NO_3) were eliminated from the base and future period inventories (see Section 8.6.3.1). Weight of evidence assumptions are discussed in Section 8.6.3.

In developing its emission inventories for hybrid modeling using the default EPA methodology, as well as weight of evidence options, the NDDoH adjusted WRAP future period emissions (PRP18a) for NO_X associated with oil and gas related sources. The total North Dakota oil and gas NO_X emissions estimated by WRAP for the future inventory was about 4.5 times higher than the total estimate for the baseline inventory. Based on recent projections from the North Dakota Department of Mineral Resources, oil and gas activity in 2018 is expected to be about 2 to 2.5 times higher than the 2002 level.[30] Moreover, in a subsequent telephone consultation, WRAP representatives admitted that 2018 estimates of NO_X related to oil and gas activity in North Dakota may have been overstated[31]. Therefore, the NDDoH applied a constant correction to WRAP future oil and gas NO_X emissions for all area sources in North Dakota, such that total 2018 emissions are 2.5 times higher than total baseline emissions for oil and gas related NO_X.

[30] ND Department of Mineral Resources, 2008. December 2, 2008 Electronic Communication from Lynn Helms to Terry O’Clair.

[31] WRAP, 2008. December 12, 2008 Telephone Communication between representatives of WRAP and NDDoH.

The NDDoH also had concerns regarding WRAP estimates of future Soil (fine particulate) emissions. Because the NDDoH is not directly modeling the Soil species, this concern was related to the RRF developed by WRAP for North Dakota Class I areas. The Soil RRFs applied by WRAP are 1.13 for TRNP and 1.11 for LWA. Both values imply some significant increase in future Soil emissions (or precursors). Given recent increases in the practice of conservation tillage farming in North Dakota and adjoining states, and recent decreases in the existence of summer fallow (retiring a portion of cultivated land for one growing season), an increase in Soil emissions between the baseline and 2018 seems unlikely, with a decrease probable. This issue is discussed in more detail in Section 9.5.2. The NDDoH addressed the Soil inconsistency by adjusting the TRNP and LWA RRFs to 1.0 to implement the default EPA methodology, as well as weight of evidence options. This value is probably still conservative, but more in line with current and predicted future farming practices than RRFs developed by WRAP.

8.5.3.2 Boundary Conditions

Boundary conditions account for the additive impact of all emission sources located outside of the CALPUFF domain. Out-of-domain source emissions generally constitute a large component of total predicted concentrations for sulfate and nitrate species.

The NDDoH is using the boundary condition feature of CALPUFF to effectively nest the CALPUFF domain within the WRAP CMAQ domain to facilitate its hybrid modeling approach. The use of CMAQ output to set CALPUFF boundary conditions has been suggested by Escoffier-Czaja and Scire[32]. Location of the NDDoH CALPUFF domain within the WRAP CMAQ domain was illustrated in Figure 8.1.

To implement the feature in CALPUFF, a supplemental boundary condition data file must be provided as part of the CALPUFF input conditions. In this file, the user provides the length and location of boundary segments which follow the perimeter of the Calpuff domain. For each segment, the concentration of each species being modeled is provided, and an air mass depth is assigned. Species concentrations for boundary segments can be updated as frequently as hourly.

For NDDoH hybrid visibility modeling, the length of boundary segments was set to match the resolution of the CALPUFF meteorological/computational grid, which is 3 kilometers. Accordingly, a boundary segment was placed adjacent to each computational grid cell along the perimeter of the domain. Boundary segment hourly concentrations for SO_2-SO_4-NO_X-HNO_3-NO_3 species were taken from CMAQ hourly output concentration files provided by WRAP RMC. For each segment, concentrations from the 36-km CMAQ grid cell containing the largest part of the segment were utilized. A constant air mass depth of 3000 meters was assumed for all boundary segments. (Though air mass depth of 1000-2000 meters is nominally suggested in

---

[32] See supra note 6.

guidance for CALPUFF boundary conditions[33], the NDDoH found the use of 3000 meters provided better agreement with observations in performance evaluations.)

Separate boundary condition files were prepared for cases BASE02b, PLAN02d, and PRP18a for performance evaluation, baseline, and future hybrid modeling, respectively.

8.5.3.3 Ozone Background

CALPUFF utilizes background ozone values in its chemistry module. The model accepts either a single constant background ozone value, or an input file of hourly ozone values commensurate with the period of meteorological data. The NDDoH uses the hourly ozone file option with CALPUFF, and would regard this as the appropriate implementation for visibility modeling (this is also the IWAQM default option). The hourly ozone file was constructed using year 2002 hourly ozone data obtained from four NDDoH monitoring sites located within the corridor of primary plume transport between major electric generating stations and Theodore Roosevelt National Park (TRNP). These monitoring sites include Hannover, Beulah, Dunn Center and TRNP South Unit. As indicated in Section 8.5.3.6, a constant ozone background value (30 ppb) is also provided in the CALPUFF control file, so that it can be substituted when the hourly value is missing. This value represents the approximate annual average for North Dakota ozone monitoring sites.

8.5.3.4 Ammonia Background

The need for ammonia background concentrations in CALPUFF is also related to chemistry processing. CALPUFF accepts either a single annual value, or twelve monthly averages from a single site. To achieve a more realistic seasonal progression of sulfate and nitrate predictions, the NDDoH used monthly average ammonia background values for CALPUFF hybrid visibility modeling input (note that temporal ammonia resolution is improved to hourly in the POSTUTIL processing step described in Section 8.5.4).

Monthly average ammonia concentrations suitable for visibility modeling in North Dakota are provided in Table 8.5. These values were derived from data collected at the State’s ammonia monitor located near Beulah. Hourly monitor data from years 2001-2002 (data not available for year 2000) were filtered to eliminate data from wind directions associated with sources causing a local bias, then remaining data were processed to produce the monthly averages. The Table 8.5 values should be generally representative of background ammonia concentrations in western North Dakota.

8.5.3.5 Receptors

Receptors for NDDoH visibility progress goal modeling are located at the TRNP and Lostwood NWA IMPROVE monitoring sites. In its guidance for regional haze modeling[34], EPA recommends including nearby receptors or grid cells in order to provide spatial averaging of the design concentration. Use of a spatial average addresses possible “migration” of the predicted peak, and some uncertainties in the formulation of the model and model inputs. Therefore, the NDDoH used a 3 by 3 receptor grid (9 receptors) which is centered on the IMPROVE site, at each Class I area. Receptor spacing in the grid is 5 kilometers. Receptor elevation was set to the ground elevation of the IMPROVE monitor site for all 9 receptors in the grid.

Recognizing that visibility is not necessarily a “ground level” concept, the NDDoH also tested the effect of elevated or “flag pole” receptors. A sensitivity test was conducted using a flag pole elevation of 18 meters, which is one-half the height of the surface layer used in WRAP CMAQ modeling. Results of this test showed a negligible difference compared to predictions for ground level receptors.

---

[34] See supra note 7.

8.5.3.6 CALPUFF Control File Settings

CALPUFF control file settings used for NDDoH hybrid visibility analyses are generally consistent with IWAQM guidance[35]. To the extent applicable, the settings are also consistent with the North Dakota alternative protocol for PSD Class I increment analyses[36].

IWAQM recommendations for CALPUFF control file settings fall into two categories. IWAQM-defined variables are those for which IWAQM provides a default value as a general recommendation for all analyses. User-defined variables are those where IWAQM recognizes the input value will need to be tailored for a given application, and default values are therefore not provided.

For visibility analyses, the NDDoH has established appropriate settings for user-defined variables, and has determined the need to adjust a limited number of IWAQM-defined variables from recommended values, as discussed below. The CALPUFF control file user-defined settings, as well as the IWAQM-defined settings which have been adjusted by NDDoH, are summarized in Table 8.6. IWAQM-defined settings adjusted by NDDoH have a shaded background in the table.

Most of the user-defined settings are intuitive, involving variables related to defining the meteorological/computational grid, variables related to the Lambert map projection, and the use of default values for dry and wet deposition parameterization. The variable IRESPLIT was set such that puffs are eligible for splitting on any hour of the day.

NDDoH settings for IWAQM-defined variables are equivalent to IWAQM recommendations, with exception of settings for a limited number of variables related to puff splitting, dispersion, and mixing height. Variable MSPLIT was set to allow puff splitting, as this option is generally recommended when modeling source-receptor distances of 200 km or more. Based on performance testing of the CALPUFF model for PSD Class I increment modeling[37], the NDDoH used adjusted settings for dispersion-related variables MDISP and MPDF, and for variables IVEG and ROLDMAX, as these adjustments provided better model performance. NDDoH settings for MDISP and MPDF, reflecting the use of micrometeorological variables in calculating dispersion, are also more consistent with dispersion treatment in the local-scale model AERMOD[38]. Values for background ozone and ammonia (variables BCKO3 and

**Use same value for each month.

BCKNH3, respectively) were set to be consistent with local monitoring data. Maximum mixing height (XMAXZI) was set to 4000 meters for consistency with CALMET settings.

8.5.4 POSTUTIL Input

Because CALPUFF allows the full amount of the specified background concentration of ammonia to be available to each puff for forming nitrate, the same ammonia may be used multiple times, resulting in an overestimate of nitrate formation. The POSTUTIL processor provides repartitioning of total nitrate at the *receptor* location to adjust for over-counting of ammonia in the CALPUFF chemistry. This repartitioning in POSTUTIL is commonly referred to as the ammonia limiting method[39]. The repartitioning process in POSTUTIL generates a modified hourly concentration file in the same format as the input CALPUFF hourly concentration file. Species HNO_3 and NO_3, only, are modified in the repartitioning process. Concentrations for all other species remain unchanged.

To implement the ammonia limiting method, POSTUTIL requires an input control file, the hourly concentration output file from CALPUFF, and (optionally) an hourly file of ammonia background concentrations. Among other intuitive input assignments (file names and carryover of settings from CALPUFF), the POSTUTIL input control file specifies the setting for the MNITRATE parameter, which is related to the method of nitrate repartitioning. The control file also provides the source and temporal resolution for ammonia background concentrations to be used in nitrate repartitioning. POSTUTIL provides for the use of annual, monthly, or hourly ammonia background concentrations from a single site. By allowing use of hourly ammonia background, POSTUTIL improves on the maximum temporal resolution available in CALPUFF (monthly).

The POSTUTIL processor also accommodates the 3-step ammonia limiting method, which is used to determine the contribution of a subgroup of sources (from the complete source inventory) to total nitrate formation. Effectively, the 3-step method allows consideration of the effect of excluded sources on the model chemistry (e.g., excluded sources still "use up" some of the available ammonia). The MNITRATE parameter is used to control processing for each step of the 3-step sequence. The 3-step ammonia limiting method requires three separate executions of POSTUTIL. Input/output for the 3 steps, along with appropriate MNITRATE settings, is outlined in Table 8.7.

---

[39] Escoffier-Czaja, C., and J. Scire, 2002. The Effects of Ammonia Limitation on Nitrate Aerosol Formation and Visibility Impacts in Class I Areas. Earth Tech, Inc., Extended Abstract. 12th Joint Conference on the Applications of Air Pollution Meteorology with the Air and Waste Management Association, American Meteorological Society, J5.13.

Table 8.7
3-Step Ammonia Limiting Method

Step	**MNITRATE Setting**	**Description**
1	1	Using CALPUFF hourly concentration file for entire source inventory as input, repartitioning is performed based on entire source inventory. Modified hourly concentration file is created (affects HNO_3 and NO_3 species).
2	0	Using Step 1 modified hourly file as input, new species names are assigned to HNO_3 and NO_3 (HNO3ALL and NO3ALL). Hourly concentration file containing only renamed species is created.
3	2	Using both CALPUFF new hourly concentration file for source group (subset of entire source inventory in Step 1) and Step 2 hourly concentration output file (HNO3ALL and NO3ALL species representing entire source inventory), repartitioning is performed based on the source group contribution to the entire source inventory. Modified hourly concentration file is created (affects HNO_3 and NO_3 species).

The NDDoH utilized POSTUTIL and the ammonia limiting method in its hybrid modeling analysis. The NDDoH developed an hourly ammonia background concentration file to use with POSTUTIL repartitioning. To create the hourly file, observed hourly ammonia concentrations were obtained from the State's Beulah monitoring site (the only ammonia site in North Dakota) for the three-year period 2001-2003. Hourly data for the three years were filtered to eliminate data from wind directions associated with sources causing a local bias. Then the three years were averaged together, on a temporally consistent basis, to produce a single hourly file considered representative of 2002, and appropriate for use with 2002 meteorological data modeling. Years 2001 and 2003 were incorporated in an averaging scheme because year 2002 contained missing periods of hourly data, and some additional data were lost due to filtering as described above. Finally, smoothing was applied to the resultant hourly data set, in the form of a 24-hour running average, to dampen the effect of discontinuities in the ammonia data.

The resultant background hourly ammonia file was tested during the performance evaluation of the hybrid modeling system (Section 8.6.1). While the adjusted Beulah data provided good modeled comparisons with TRNP observed nitrate, the LWA nitrate observations were consistently under predicted. The NDDoH found that agreement with LWA nitrate observations was significantly improved if hourly values in the ammonia file are approximately doubled. Moreover, the NDDoH found empirical evidence (discussed below) that ammonia levels in the vicinity of LWA would be typically higher than ammonia levels at TRNP. Therefore, the

NDDoH applied the original hourly ammonia file (above) for all POSTUTIL processing associated with TRNP, and doubled the hourly ammonia profile for all POSTUTIL processing associated with LWA.

In addition to performance evaluation results, there is empirical support for the assumption of higher ammonia background at LWA than at TRNP and Beulah. Figure 8.9 provides an illustration of ammonia emissions density (tons/year/square mile) for North Dakota counties and adjoining Canadian provinces. These data were obtained from the WRAP RMC 2004/2005 report[40], and represent ammonia input conditions for CMAQ modeling. As shown in the figure, the TRNP and LWA IMPROVE sites, and the Beulah monitoring site, are all located in counties with the lowest ammonia emissions density (0.000-0.001 tons/year/square mile). However, the proximity of the LWA site is such that prevailing local winds (northwest and southeast wind direction) will likely direct higher density ammonia emissions from Saskatchewan (0.075-0.25 tons/year/square mile) and Ward county (0.005-0.025 tons/year/square mile) toward the LWA site.

For comparing predicted visibility progress with respect to the default (EPA) glide path, the NDDoH applied the basic ammonia limiting method, presented as Step 1 in Table 8.7. In order to determine progress in the context of weight of evidence arguments, such as discounting the effect of Canadian emissions, it was necessary to apply the 3-step ammonia limiting method (Section 8.6.3).

POSTUTIL output was subsequently processed with the NDDoH CALHAZE program to project future visibility (Section 8.5.5).

8.5.5 CALHAZE

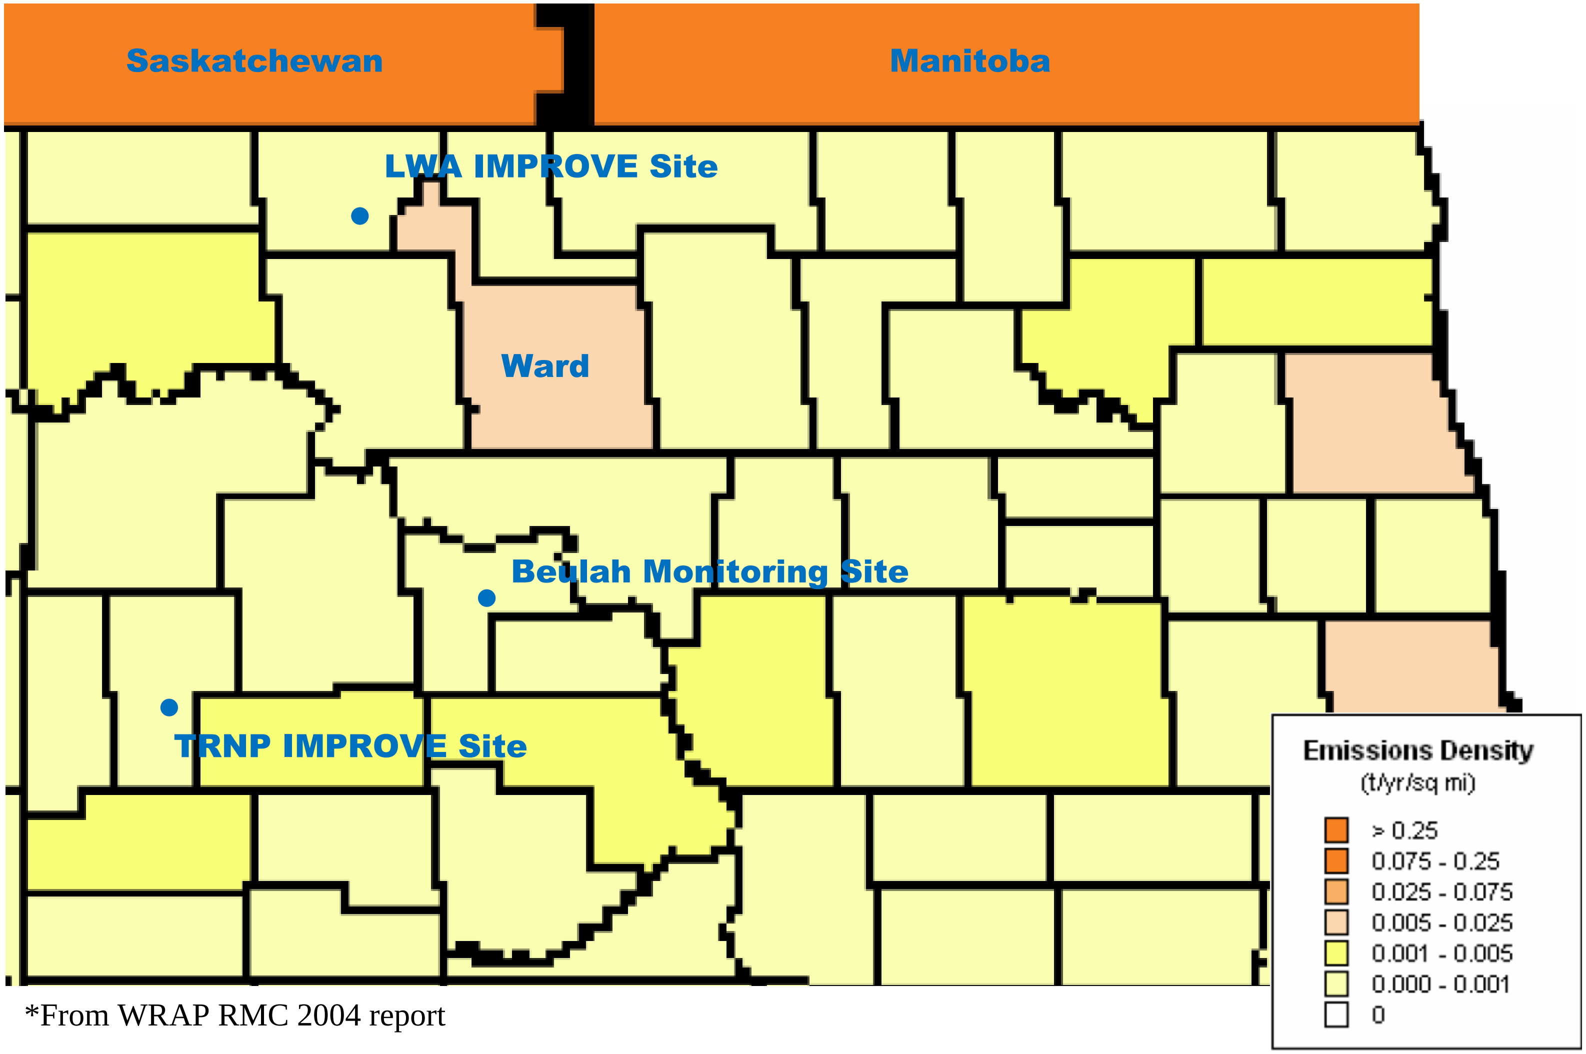
The NDDoH has developed a software system to generate relative response factors (RRFs) from WRAP CMAQ and NDDoH CALPUFF (POSTUTIL) hourly concentration output files for baseline and future scenarios, project future concentrations of visibility affecting aerosols by applying RRFs to baseline IMPROVE data, and convert projected future concentrations to visibility (deciview). This system is informally known as CALHAZE. CALHAZE represents the final step in the NDDoH hybrid visibility modeling sequence (CALMET-CALPUFF-POSTUTIL-CALHAZE). Effectively, CALHAZE replaces CALPOST.

CALHAZE accesses NDDoH CALPUFF (POSTUTIL) hourly concentration files for baseline and future scenarios to generate 20 percent worst/best day RRFs for sulfate and nitrate. CALHAZE accesses WRAP CMAQ hourly concentration files (provided by WRAP RMC) for baseline and future scenarios to generate 20 percent worst/best day RRFs for all other visibility

---

[40] Tonnesen, G., R. Morris, Z. Adelman, et. al., 2005. Final Report for the Western Regional Air Partnership (WRAP) Regional Modeling Center (RMC) for the Project Period March 1, 2004, through February 28, 2005, Appendices A Through E. Western Regional Air Partnership, Denver, CO 80202.

Figure 8.9
NH_3 Emissions Density for North Dakota Counties and Adjoining Canadian Provinces*



*From WRAP RMC 2004 report

affecting species. RRFs are applied to IMPROVE baseline monitoring (2000-2004) data files, obtained from the WRAP TSS (Technical Support System) internet site (http://vista.cira.colostate.edu/tss/), to project future concentrations of each visibility affecting species for each worst/best day for each year. Next, CALHAZE applies the new IMPROVE algorithm to calculate light extinction (using projected future concentrations) for each worst/best day for each year. Finally, deciview is calculated for each worst/best day, and averaged across all worst/best days and all years. CALHAZE repeats this procedure for each Class I area. CALHAZE incorporates the default EPA methodology to calculate RRFs and future deciview (Section 8.3).

Input files required by CALHAZE, as applied by NDDoH, are summarized:

1) WRAP CMAQ hourly concentration output file for baseline scenario (2002),

2) WRAP CMAQ hourly concentration output file for future scenario (2018),

3) NDDoH CALPUFF (POSTUTIL) hourly concentration output file for baseline scenario (2002 results for both TRNP and LWA receptors),

4) NDDoH CALPUFF (POSTUTIL) hourly concentration output file for future scenario (2018 results for both TRNP and LWA receptors),

5) IMPROVE daily baseline monitoring data for TRNP (2000-2004),

6) IMPROVE daily baseline monitoring data for LWA (2000-2004).

CMAQ hourly concentrations are taken from the grid cell containing the North Dakota Class I area. Note that all additional parameters necessary for calculating light extinction, via the new IMPROVE algorithm, are provided in the IMPROVE baseline monitoring data files. This includes function of relative humidity for sea salt and small and large size fractions, and the Rayleigh scattering coefficient. Consistent with WRAP RMC conclusions addressing the viability of CMAQ coarse mass predictions, CALHAZE forces a RRF of 1.0 for the coarse mass species. As discussed in Section 8.2, a constant RRF of 1.0 is also applied for sea salt.

As an option, the CALHAZE system also accepts a control input file which allows the user to set RRF for each species, and set the visibility target (in deciviews), for each Class I area. Use of this feature was necessary when applying the normalization procedure described in Section 8.5.6.

The NDDoH has applied the CALHAZE software to complete the hybrid modeling procedure and visibility projections for North Dakota Class I areas. To address quality assurance issues with respect to the CALHAZE system, the NDDoH has successfully cross-checked CALHAZE output with data on the TSS internet site. For example, the worst-day RRFs generated by CALHAZE for elemental carbon, organic mass, fine soil, and coarse mass for North Dakota Class I areas agree exactly with the corresponding values obtained from the TSS site.

8.5.6 Hybrid System Used to Adjust WRAP CMAQ Modeling Results

Based on performance testing of direct hybrid model predictions (operational evaluation), as conducted by NDDoH (see Section 8.6.1), the hybrid CMAQ-CALPUFF modeling system performed well in replicating observed concentrations of SO_4 and NO_3. However, performance regarding sensitivity to changes in NO_X emissions (diagnostic evaluation) was not good, with the hybrid modeling system significantly overstating future case nitrate formation compared to predictions obtained by WRAP using CMAQ alone. The NDDoH concluded this anomaly is an artifact of the chemistry in CALPUFF, and acknowledges that CMAQ chemistry is superior.

For this reason, the NDDoH chose not to accept direct hybrid modeling system results to independently address progress with respect to regional haze goals. Rather, the NDDoH used the hybrid modeling system in a supportive sense to add value to the original WRAP CMAQ modeling results. The hybrid system was used to provide a "correction" to WRAP CMAQ results in order to offset coarseness in the CMAQ spatial resolution for large, local point sources. Similarly, the hybrid system was applied to adjust WRAP CMAQ results in order to discount the effect of international (Canadian) sources. (WRAP did not provide regional haze modeling results which discount the impact of international sources, a modeling interpretation which had been requested by EPA and others, and which the NDDoH wanted to include in its weight of evidence discussion.)

8.5.6.1 Adjusting WRAP CMAQ Modeling Results for Local Point Sources

To address the concern regarding spatial resolution of the WRAP CMAQ simulations for local point sources, the NDDoH concluded that the hybrid modeling system could be used in an indirect manner to apply a reasonable and conceptually simple "correction" to the WRAP CMAQ RRFs (relative response factors) for sulfate and nitrate. Given that CALPUFF has the capability of treating point sources as well as area sources, all point sources within the NDDoH CALPUFF domain can be allocated (converted) to area sources, or more specifically to a 36-km area source grid, in order to emulate the coarse treatment of point sources in CMAQ. Then a correction factor can be established which adjusts the WRAP CMAQ prediction based on the predicted difference between point sources treated as conventional point sources and point sources treated as area sources (i.e., CMAQ emulation) with the hybrid model. This adjustment can be expressed

$$\overline{\chi}_{NDDH} = \overline{\chi}_{CMAQ}\left(\frac{\overline{\chi}_{HybridPt}}{\overline{\chi}_{HybridArea}}\right) \qquad (8-1)$$

where

$\overline{\chi}_{NDDH}$ is the adjusted average concentration (sulfate or nitrate) for 20% worst days. Note that both WRAP and NDDoH were consistent in basing 20% worst days on IMPROVE monitoring data (2002),

$\overline{\chi}_{CMAQ}$ is the average concentration for 20% worst days obtained by WRAP using CMAQ,

$\overline{\chi}_{HybridPt}$ is the average concentration for 20% worst days predicted by the hybrid model when point sources (within the NDDoH CALPUFF domain) are treated as conventional point sources,

$\overline{\chi}_{HybridArea}$ is the average concentration for 20% worst days predicted by the hybrid model when point sources (within the NDDoH CALPUFF domain) are allocated as 36-km area sources.

The ratio $\overline{\chi}_{HybridPt}$ / $\overline{\chi}_{HybridArea}$ in the equation is effectively a correction factor to address the coarse resolution of local point sources in CMAQ. Equation 8-1 can be thought of as an emulation of the result CMAQ would have produced had the plume-in-grid feature been deployed for local point sources (WRAP did not deploy CMAQ plume-in-grid for regional haze modeling). The Equation 8-1 adjustment involves modifying only the point source component of the hybrid model emissions inventory. Boundary conditions and sources originally treated as area sources (Section 8.5.3.1) remain equivalent in *HybridPt* and *HybridArea* emissions inventories.

Equation 8-1 is applicable for both baseline and future period modeling. Recall that the RRF for each species is defined[41],

$$RRF = \left(\frac{\overline{\chi}_{Future}}{\overline{\chi}_{Baseline}}\right)$$

where $\overline{\chi}_{Future}$ is the future 20% worst day average concentration and $\overline{\chi}_{Baseline}$ is the baseline 20% worst day average concentration. Therefore, if the future period implementation of Equation 8-1 is divided by the baseline period implementation of Equation 8-1, it follows that the adjustment for CMAQ treatment of point sources can be specified in terms of RRF,

$$RRF_{NDDH} = RRF_{CMAQ}\left(\frac{RRF_{HybridPt}}{RRF_{HybridArea}}\right) \qquad (8-2)$$

where

RRF_{NDDH} is the adjusted relative response factor ultimately used by NDDoH to project future concentrations of sulfate and nitrate,

RRF_{CMAQ} is the relative response factor obtained by WRAP using CMAQ,

---

[41] See supra note 7.

$RRF_{HybridPt}$ is the relative response factor produced by the hybrid model when point sources (within NDDoH CALPUFF domain) are treated as conventional point sources,

$RRF_{HybridArea}$ is the relative response factor produced by the hybrid model when point sources (within NDDoH CALPUFF domain) are allocated as 36-km area sources.

Thus, Equation 8-2 was used by NDDoH to implement the adjustment for WRAP CMAQ treatment of point sources. The adjustment was utilized for 20% best days as well as 20% worst days, and was applied for each Class I area in North Dakota. It was applied directly to the RRFs from WRAP CMAQ modeling (specific day option[42]), which are shown in Table 8.8.

Table 8.8
WRAP CMAQ RRF

To develop the *HybridArea* CALPUFF input files, all point source emissions were allocated to the CALPUFF 36-km area source grid, which is discussed in Section 8.5.3.1 and shown in Figure 8.8. The CALPUFF "effective height" (plume height) and "initial sigma z" area source input parameters were used to assign point source emissions to discrete vertical "layers" which are consistent with the WRAP CMAQ layers. Effective height is based on stack height plus plume rise as calculated externally.

---

[42] In addition to the EPA-recommended specific day option for generating RRFs, WRAP also generated RRFs and projected future visibility based on monthly and quarterly weighting. The NDDoH used the specific day option exclusively in hybrid visibility modeling.

To complete emulation of the WRAP CMAQ 36-km grid resolution, receptor treatment was also addressed in the *HybridArea* input files. Effective "receptor" resolution in WRAP CMAQ is limited to the average concentration in the 36-km surface grid cell volume containing the Class I area IMPROVE site. To emulate WRAP CMAQ in *HybridArea* input files, the NDDoH averaged across a uniform receptor grid which filled the CALPUFF area-source 36-km grid cell containing each IMPROVE site (Figure 8.8). Receptors were spaced at 3 km for a total of 12 x 12 or 144 discrete receptors for each Class I area. Note that this type of receptor averaging was only applied in CALPUFF runs for CMAQ emulation (*HybridArea*), and not in runs for conventional point source treatment (*HybridPt*) or performance evaluation.

Given that the NDDoH hybrid modeling was limited to sulfate and nitrate species (and precursors), the Equation 8.2 adjustment was also limited to sulfate and nitrate species. The RRFs for all other light affecting species were taken directly from WRAP CMAQ modeling, as shown in Table 8.8. Therefore, it is likely that the correction for CMAQ resolution of point sources, in terms of the total projected future light extinction, is somewhat understated. However, the primary contributors to light extinction from the local point sources of concern in North Dakota are sulfate and nitrate.

The Equation 8.2 adjustment as applied by NDDoH also accounted for the WRAP overestimate of future oil and gas related NO_X emissions in North Dakota, as discussed in Section 8.5.3.1. This error affected the future period modeling only. Therefore, the *HybridArea* input file (CMAQ emulation) for the future period included WRAP estimated NO_X emissions for oil and gas, while the *HybridPt* input file for the future period included the NDDoH corrected future NO_X emissions for oil and gas. (The base period NO_X emissions in both cases were based on WRAP estimates for 2002.) This accounting for the WRAP error in future oil and gas NO_X emissions was not expected to make a significant difference in results.

When applying the Equation 8.2 adjustment, the NDDoH found the ratio $RRF_{HybridPt}$ to $RRF_{HybridArea}$ to be consistently less than 1.0, providing a resultant RRF_{NDDH} which was significantly lower than the WRAP CMAQ RRF, with subsequently lower projected future concentrations and greater projected visibility improvement than predicted by WRAP. This expected response is related primarily to the resolution of modeling systems as applied to local point sources. When local point sources are treated as conventional point sources, the higher density point-source plumes cause higher predictions at the IMPROVE monitor site (for both baseline and future periods) such that the future reduction in emissions from local point sources may cause a relatively large impact compared to the more static contribution of all other sources (area and boundary). When local point sources are configured as 36-km area sources, the associated diluted plumes cause lower predictions compared to the contribution of all other sources (other area and boundary), such that the future reduction in emissions may be overwhelmed by the more static contribution of other sources.

8.5.6.2 Discounting the Impact of Canadian Sources

In the process of analyzing progress with respect to visibility goals, it was necessary for the NDDoH to address the impact of Canadian sources north of the International border. This interpretation of modeling results was requested by EPA and others, and was an important element of the NDDoH weight of evidence discussion (see Section 8.6.3). No specific guidance is provided for this type of analysis. The method used by NDDoH was to eliminate Canadian sources from the baseline and future emissions inventories used to develop RRFs, and to develop a modified glide path which discounts the effect of Canadian sources. This approach is similar to methods proposed by CENRAP[43] and others.

Again, the NDDoH implemented its procedure for discounting Canadian sources in terms of an adjustment to WRAP CMAQ modeling results. If Canadian sources are eliminated from baseline and future emissions inventories for conventional point sources, Equation 8-2 becomes

$$RRF_{NDDH} = RRF_{CMAQ}\left(\frac{RRF_{HybridPt-C}}{RRF_{HybridArea}}\right) \qquad (8-3)$$

where

$RRF_{HybridPt-C}$ represents the resultant relative response factor after eliminating Canadian sources from the conventional point source baseline and future emissions inventories used with the hybrid modeling system.

Equation 8-3 was used by the NDDoH to develop adjusted RRFs for sulfate and nitrate. Note that with the implementation of Equation 8-3, the adjustment to discount the impact of Canadian sources is effectively “added on” to the adjustment for WRAP CMAQ point source resolution.

To complete the illustration, the impact of Canadian sources must also be discounted from the glide path used to assess progress with respect to visibility goals. In this case, the NDDoH applied the hybrid modeling system exclusively to estimate the baseline starting point (deciview) of the modified glide path. The estimation process involved adjusting the IMPROVE baseline concentration for each worst-case day for the five-year period 2000-2004, in order to approximate the daily observations without the impact of Canadian sources. The estimation procedure for each worst-case day can be expressed

$$\chi_{obs(us)} = \chi_{obs}\left(\frac{\overline{\chi}_{pred(us)}}{\overline{\chi}_{pred}}\right) \qquad (8-4)$$

where

$\chi_{obs(us)}$ is the estimated sulfate or nitrate concentration for one worst case day of IMPROVE monitoring data for all non-Canadian sources (plus natural background),

---

[43] CENRAP, 2007. CENRAP Policy Oversight Group (POG) - Summary of PM Source Apportionment Modeling and 2018 Projection Approaches. Power Point presentation, Joint Workgroup Meeting, Kansas City, Missouri, March 7, 2007.

χ_{obs} is the original IMPROVE observed sulfate or nitrate concentration for the worst case day,

$\overline{\chi}_{pred(us)}$ is the average prediction for 20% worst days when hybrid model is applied for non-Canadian sources only (Year 2002 baseline emissions inventory),

$\overline{\chi}_{pred}$ is the average prediction for 20% worst days when hybrid model is applied for the entire source inventory (Year 2002 baseline emissions inventory).

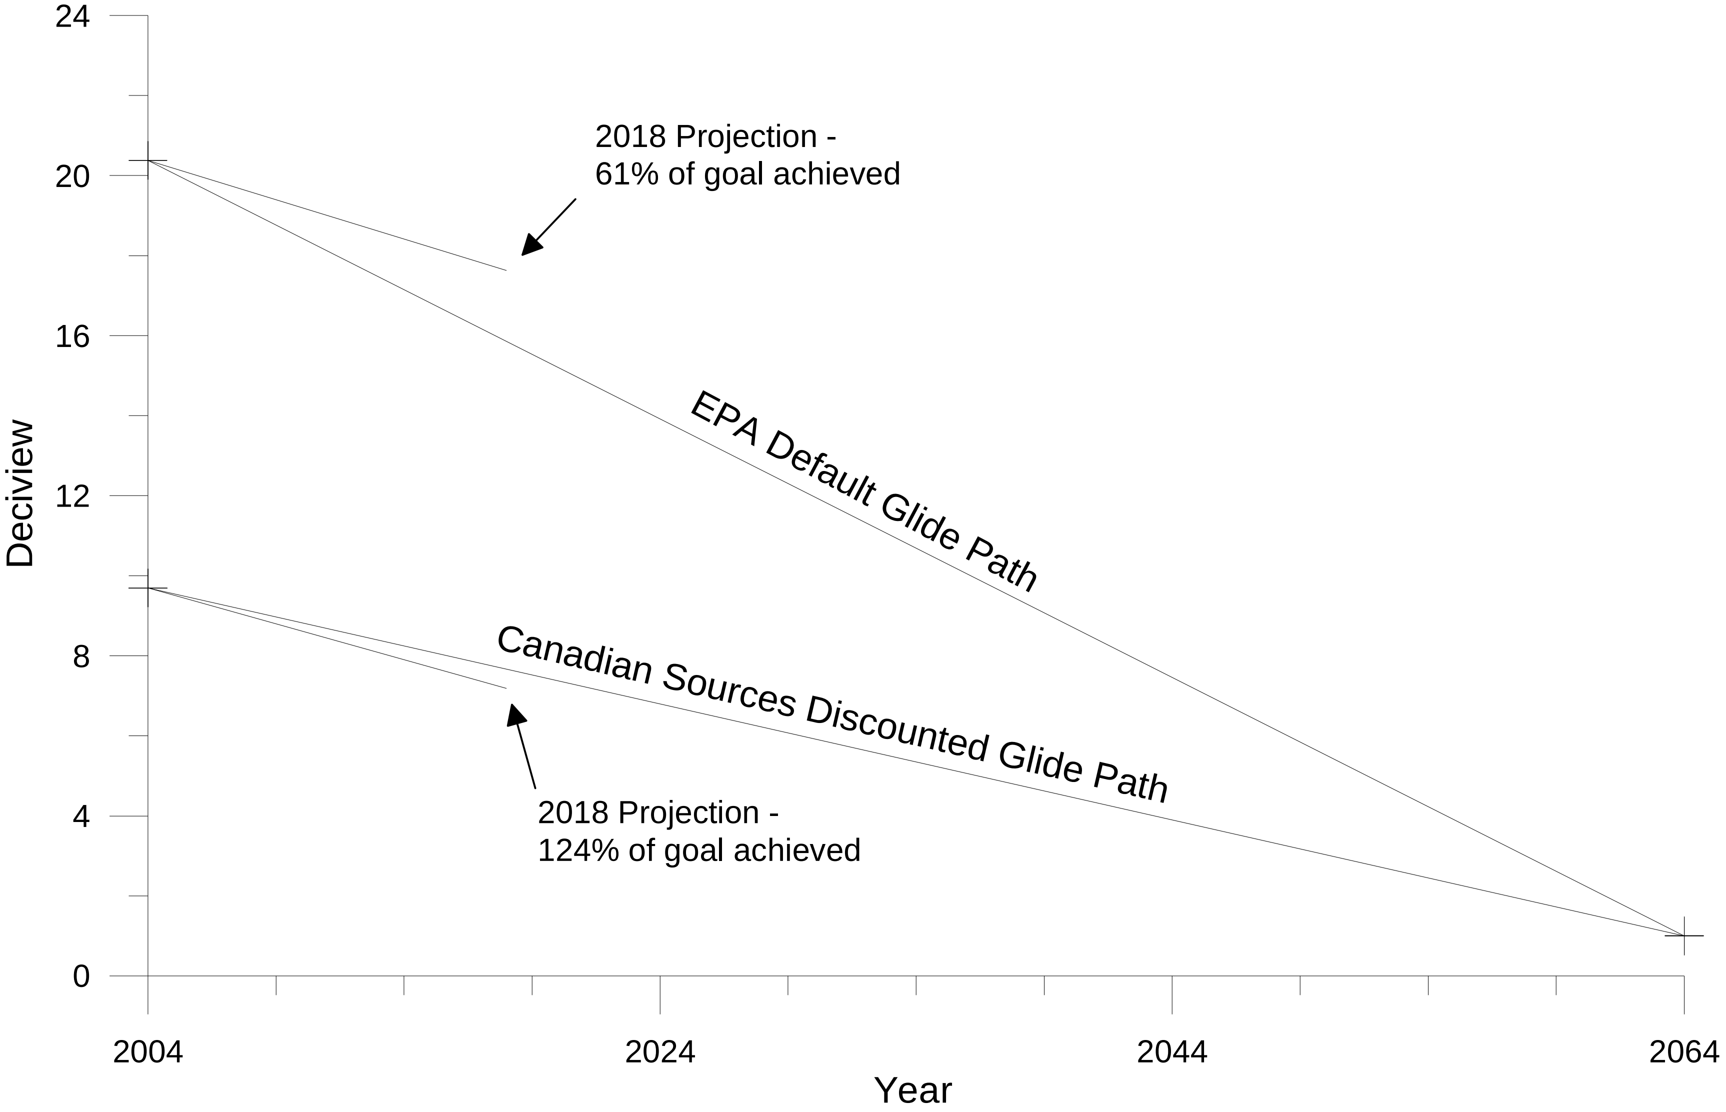
Using the adjusted worst day observations for sulfate and nitrate, along with the original IMPROVE worst day observations for all other visibility-affecting species, light extinction and deciview were calculated for each 20% worst day of the 2000-2004 period. Finally, the five-year average deciview was calculated to set the starting point for the “Canadian sources discounted” glide path for 20% worst days.

The NDDoH next considered the end point (2064) of the modified glide path. When adjusting baseline and future emissions inventories to exclude Canadian sources, the intent of NDDoH was to eliminate the impact of non-natural sources only, leaving the contribution of all other non-Canadian sources plus natural sources. Therefore, an adjustment was made to CALPUFF boundary conditions (baseline and future) to eliminate the contribution of Canadian source emissions, while retaining the impact of natural Canadian sources of sulfate and nitrate. This adjustment is described in Section 8.6.3.1. And recall that the NDDoH adjustment does not affect the impact of all other visibility-affecting species on the glide path. As such, the NDDoH concluded that it was not necessary or appropriate to change the end point (default natural conditions) of the modified glide path.

A modified glide path is illustrated in Figure 8.10, for a hypothetical case where Canadian source emissions contribute about one-half of total visibility degradation.

Using the modified glide path, the NDDoH applied RRFs generated using Equation 8-3 to the adjusted starting point to estimate visibility improvement progress by 2018 (see Section 8.6.3.1). As expected, visibility improvement increased significantly when Canadian sources were discounted. Canadian source emissions were discounted only for 20% worst days, as the impact of Canadian sources was not problematic in meeting visibility goals for best days.

Figure 8.10
Illustration of Visibility Improvement Using EPA Default Glide Path and Canadian Sources Discounted Glide Path



8.6 Modeling Process and Results

The NDDoH hybrid modeling system was applied to adjust WRAP CMAQ results, using input conditions and procedures as described in Section 8.5. A performance evaluation was conducted first to ensure that selected inputs were producing viable results relative to observed concentrations of sulfate and nitrate. (Note that the performance evaluation was based on predictions taken directly from hybrid model output, rather than adjusted WRAP CMAQ output described in Section 8.5.6.) Next, the hybrid modeling system was executed in default production mode to determine progress with respect to the glide path and URP target based on default EPA methodology. Finally, the hybrid modeling system was applied to test several weight of evidence scenarios. NDDoH hybrid results and WRAP CMAQ results were compared for the default EPA methodology.

8.6.1 Hybrid CMAQ-CALPUFF Performance Evaluation

The NDDoH conducted a limited operational evaluation to assess performance of the hybrid CMAQ-CALPUFF modeling system. The focus of the evaluation was to assess performance in reproducing observed concentrations of sulfate and nitrate at IMPROVE monitoring sites in North Dakota. These sites include the Theodore Roosevelt National Park South Unit (TRNP) and the Lostwood Wilderness Area (LWA). Alternative input options which might improve performance were also explored. To the extent applicable, the performance evaluation followed EPA guidance for Regional Haze modeling analyses[44].

An emissions inventory for the performance evaluation was developed by NDDoH. WRAP CMAQ hourly concentration output (SO_2-SO_4-NO_X-HNO_3-NO_3) for Case BASE02B was used to set hourly boundary conditions for CALPUFF. The emissions inventory (SO_2-NO_X) for the point source category was developed using data from the NDDoH emissions database for 2002, and sources were configured as conventional point sources in CALPUFF. This inventory included point sources located in adjacent parts of South Dakota, Montana, and Canada, which are included in the NDDoH CALPUFF domain (see Figure 8.5). This inventory also included SO_2 emissions associated with oil and gas production facilities (treaters and flares) in North Dakota, which did not appear to be accounted for in the WRAP inventory for BASE02B. Emission rates for the point source inventory reflect actual emissions for Year 2002.

All other source categories (see Table 8.2) were treated as area sources in CALPUFF, and the emissions inventory (SO_2-SO_4-NO_X-NO_3) for these categories was based on WRAP CMAQ input (SMOKE output) for all sources other than point sources. Software was prepared and implemented to apportion the gridded SMOKE output emissions for BASE02B into a 36-km area source grid structure developed for the NDDoH CALPUFF domain (Figure 8.8), on a consistent spatial basis. Emission rates for this area source inventory reflect annual averages for the SMOKE data.

---

[44] See supra note 7.

The CALPUFF modeling system (CALMET-CALPUFF-POSTUTIL-CALPOST) was applied for SO_2-SO_4-NO_X-NO_3 source inventories and boundary conditions as described above. All other input conditions were consistent with the description of the hybrid modeling system in Section 8.5. Single receptors were placed at the TRNP and LWA IMPROVE sites. Monthly average ammonia data were utilized from the Beulah monitoring site in both CALPUFF and POSTUTIL.

After initial application of CALPUFF for the performance evaluation, it was concluded that certain scientifically-defensible adjustments to CALPUFF input conditions may improve performance for the hybrid modeling system, and should be investigated. Thus, the performance evaluation evolved into a suite of tests which are described below.

1) Test 1 - Calpuff executed with default input conditions, as outlined above. Air mass depth for boundary conditions was set to 2000 meters.

2) Test 2 - CALPUFF as in Test 1, but using CEMS 2002 hourly emissions data (SO_2, NO_X) for point sources, where available.

3) Test 3 - CALPUFF as in Test 1, but using WRAP MM5 12 km 2002 mesoscale data in CALMET, rather than the default NDDoH RUC 2002 mesoscale data.

4) Test 4 - CALPUFF as in Test 1, but increasing air mass depth for boundary conditions from 2000 to 3000 meters.

5) Test 5 - CALPUFF as in Test 1, but with addition of SO_4 and NO_3 emissions from point sources. (Previous tests excluded this component, because SO_4 and NO_3 emissions are not included in the NDDoH point source inventory. For Test 5, an SO_4-NO_3 emissions inventory was derived from SMOKE gridded output for the point source category, and configured as area sources for CALPUFF.)

6) Test 6 - CALPUFF as in Tests 4 and 5 (air mass depth = 3000 meters, SO_4 and NO_3 emissions from point sources included), but area sources configured as 4 separate groups to account for varying release heights of different source types, and Beulah hourly profile used for background NH_3 in POSTUTIL. (Area sources were configured as a single CALPUFF group in previous tests.)

7) Test 7 - CALPUFF as in Test 6, but Beulah hourly NH_3 profile doubled for LWA.

Results of the performance evaluation are summarized in Tables 8.9 and 8.10. Table 8.9 compares predicted NO_3 and SO_4 concentrations to observed concentrations for both IMPROVE sites, while Table 8.10 provides predicted-to-observed ratios. Note that both tables include a column labeled “CMAQ only”, which provides the original WRAP CMAQ results for Case BASE02B.

As shown in Tables 8.9 and 8.10, the primary metrics selected to measure performance for this evaluation are 90th percentile day concentration (24-hour average), average of 20% worst days concentration, and annual average concentration. The first two metrics were selected for consistency with the time scale that applies to regional haze modeling, i.e., average of the 20% worst or 20% best days. The third metric, annual average concentration, is a measure of the model's ability to accurately conserve total annual mass. The comparison between predicted and observed concentrations for the first two metrics is unpaired in time.

Also shown in Tables 8.9 and 8.10 is the 98th percentile day prediction (24-hour average). This metric was included for completeness at the request of EPA. The 98th percentile prediction has relevance as the primary metric used in BART single-source modeling.

Results in Tables 8.9 and 8.10 indicate that the hybrid modeling system performed well, in general. Even for the initial Test 1, predictions were well within a factor of two of observations. In most cases, the hybrid system predictions were closer to observations than predictions from CMAQ, alone. Table 8.10 illustrates that the hybrid system slightly over-predicted observations for TRNP NO_3, and slightly under-predicted, otherwise.

A comparison of results for Tests 1 through 5 reveals very little difference in predictions. The implication is that the input changes reflected in Tests 2 through 5 did not add significant value to the hybrid model's ability to accurately reproduce observations. The increased temporal resolution obtained by using the CEMS hourly emissions for applicable point sources (Test 2) provided no consistent improvement. Test 3 results suggest that the NDDoH RUC mesoscale data is consistent with the WRAP MM5 mesoscale data. Test 4 results indicate that Calpuff is not very sensitive to boundary air mass depth. Even the addition of point source NO_3 and SO_4 emissions in Test 5 achieved no meaningful improvement in predictions, suggesting that sources configured as area sources in CALPUFF may have only a small contribution to the total prediction.

While the operational evaluation to compare predictions with observations was being conducted, the NDDoH also undertook a preliminary diagnostic evaluation[45] to assess the response of the hybrid modeling system to changes in NO_X and SO_2 emissions. In response to significant reductions in both SO_2 and NO_X emissions, the NDDoH found that the hybrid system responded reasonably well with correspondingly lower SO_4 predictions, but seemed to overstate NO_3 predictions for the reduced emission scenario. In fact, NO_3 concentrations actually increased under some assumptions, possibly an overreaction to the newly freed ammonia in the reduced SO_2 emissions scenario (SO_2 preferentially scavenges ammonia in the CALPUFF chemistry). This behavior was not as obvious in the WRAP CMAQ results for baseline versus future predictions.

---

[45] See supra note 7.

To address the problematic NO_3 response, the NDDoH discussed the issue with Joe Scire (TRC)[46], a recognized CALPUFF expert in the regulatory modeling community. Mr. Scire indicated that TRC testing has shown that the NO_3 response may improve if hourly background ammonia is used rather than monthly average values. Also, Mr. Scire provided some insight on configuring area sources in CALPUFF to be more consistent with the area source treatment in CMAQ. This involves proper settings for the CALPUFF "release height" and "initial sigma z" input parameters for area sources. The NDDoH retested after incorporating Mr. Scire's suggestions, i.e., using hourly ammonia background and reconfigured area sources. Although the NO_3 response improved, predicted reductions were still not consistent with CMAQ.

As a result of the initial diagnostic performance testing, the NDDoH concluded that the use of hourly ammonia background concentrations is preferable to the use of monthly averages, and that CALPUFF inputs for area sources should be reconfigured. Additional operational evaluation tests (Tests 6 and 7) were thus conducted to determine how these changes would affect the comparison with observations. Test 6 was conducted by first assuming a boundary air mass depth of 3000 meters (Test 4) and accounting for NO_3 and SO_4 emissions from point sources (Test 5). Then area sources were configured as suggested by Scire, including the use of 4 area source groups to account for varying release heights for different source categories (as opposed to one group in Tests 1-5). Finally, Test 6 included use of the Beulah hourly ammonia profile in POSTUTIL.

Results of Test 6, as shown in Tables 8.9 and 8.10, indicate significantly improved performance with respect to TRNP NO_3, but worse performance for LWA NO_3. Results for SO_4 were not significantly affected. This tendency for conflicting results for TRNP and LWA NO_3 was also exhibited in Tests 1 through 5, and led the NDDoH to conclude that the Beulah data may not be representative of ammonia background for both TRNP and LWA. Moreover, the actual ammonia background affecting LWA may be significantly higher than the background affecting TRNP.

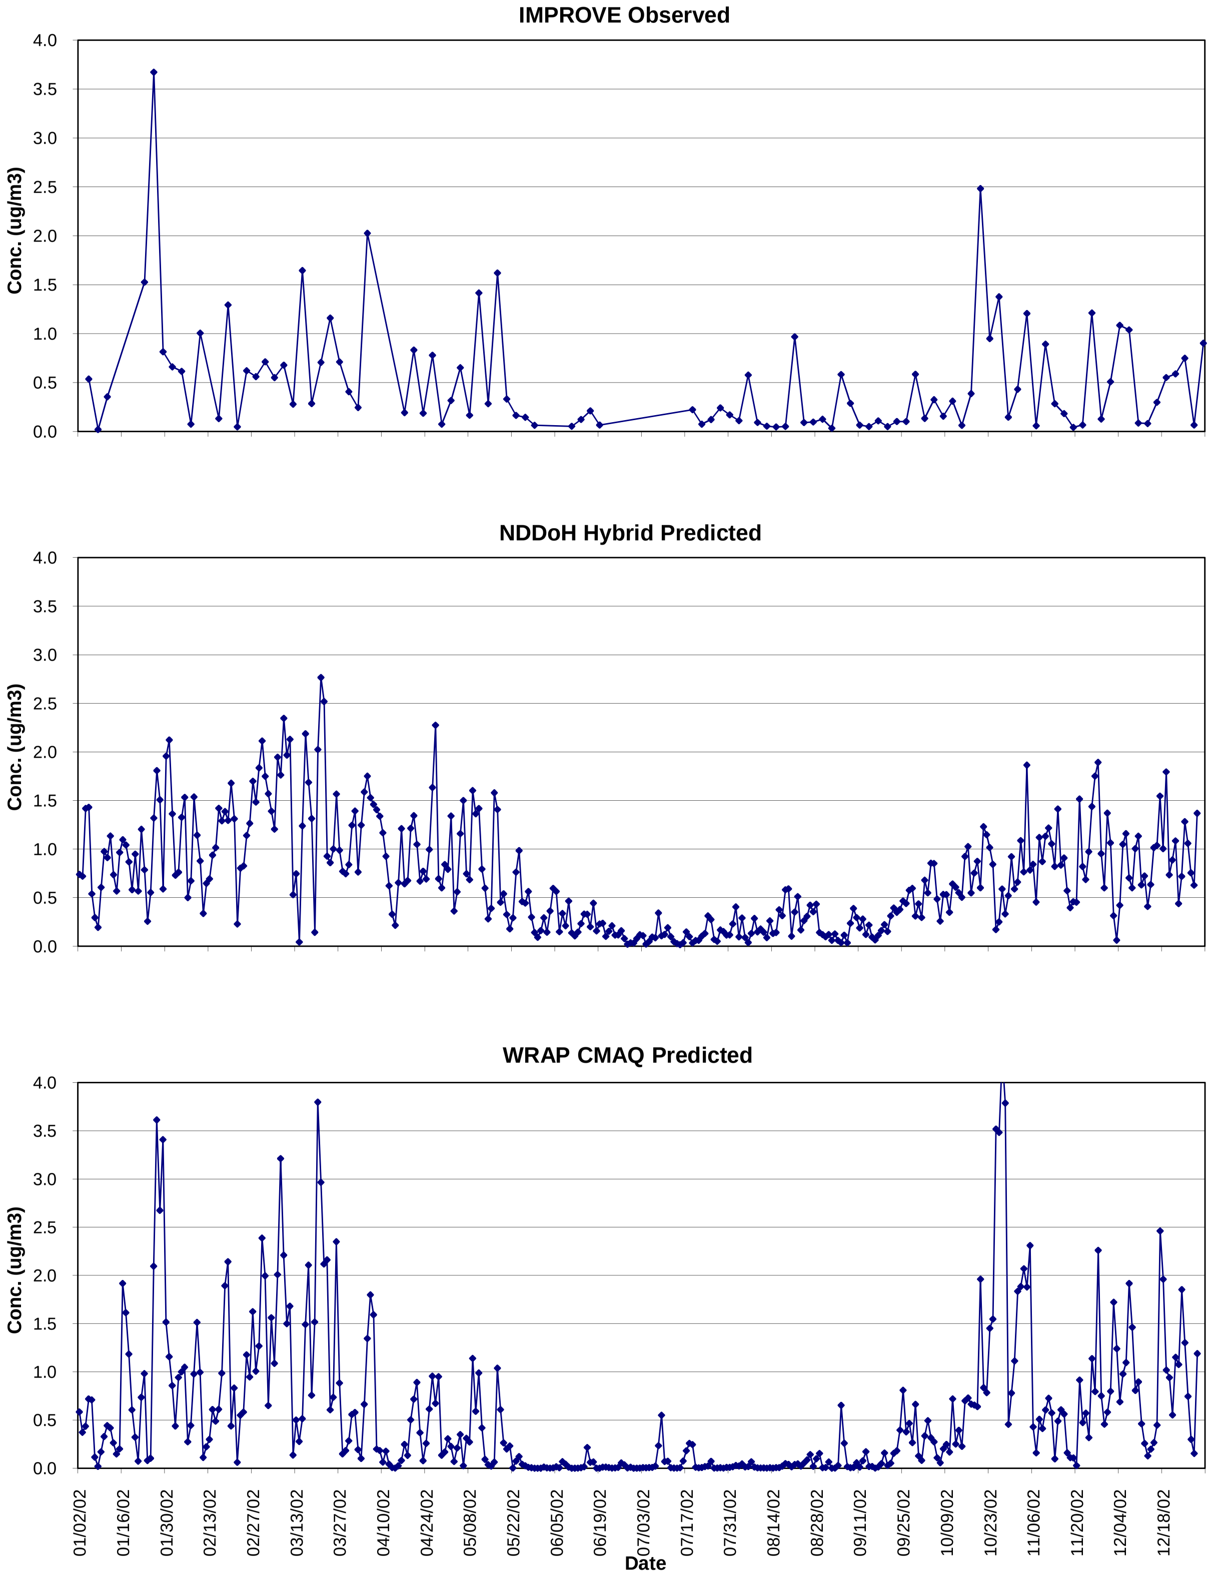
In Test 7, the NDDoH found that observational agreement for LWA NO_3 can be vastly improved if the ammonia hourly backgound values are approximately doubled (for LWA only). All other conditions for Test 7, including the ammonia background for TRNP, remain the same as in Test 6. NO_3 predictions for Test 7 in Tables 8.9 and 8.10 now show good agreement with observations at both TRNP and LWA.

Finally, the NDDoH developed time series plots (consistent with Test 1 assumptions) to compare temporal patterns of predictions with observations for year 2002. In Figure 8.11, daily model predictions for nitrate at TRNP are compared with IMPROVE observations for 2002 (note that observations are only available for every third day). Time series for both NDDoH hybrid predictions and WRAP CMAQ predictions are included. As shown in the figure, both modeling systems appear to reproduce the general seasonal pattern of nitrate observations, with significantly lower concentrations in the summer. When compared with observations, the overall magnitude of predictions for the hybrid modeling system appears better, as CMAQ seems to under predict in the summer (many daily values very close to 0.0) and over predict otherwise.

---

[46] See supra note 28.

Figure 8.11
Observed and Predicted Time Series TRNP NO_3 2002



CMAQ, however, may be more effective in reproducing some of the peak observed concentrations (paired in time).

In summary, the NDDoH concluded that the hybrid modeling system performs effectively, and may be used to adjust WRAP CMAQ modeling results. Further, agreement with sulfate and nitrate observations would be optimized using the following input conditions with the hybrid system:

- use RUC mesoscale data for CALMET,
- use boundary air mass depth of 3000 meters,
- include SO_4 and NO_3 emissions from point sources,
- configure area sources as four groups,
- use Beulah hourly background ammonia for TRNP, and
- use double Beulah hourly background ammonia for LWA.

8.6.2 Results for Default EPA Methodology

8.6.2.1 Cumulative Results

The NDDoH hybrid modeling system was applied to adjust WRAP CMAQ results, using input conditions and procedures consistent with optimal model performance, and described in Section 8.5. Hybrid modeling for the default EPA methodology included the entire emissions inventory. NDDoH projections for 2018 visibility are compared here with WRAP RMC projections for 2018 visibility, based on default EPA methodology.

Results of WRAP CMAQ and NDDoH hybrid visibility modeling for the default EPA scenario are summarized in Table 8.11. The table includes visibility projections for North Dakota Class I areas for 20% worst monitored days and 20% best monitored days. The table includes deciview values for baseline conditions, natural conditions, and the 2018 uniform rate of progress (URP) target. WRAP and NDDoH projections provided in the table include the absolute visibility projection in deciviews, and the percentage of the visibility target achieved by the projection. Note that the URP target and projected percentage of target are not included for best days, because the Regional Haze Rule specifies the URP target only for worst days. The requirement for best days is simply that the visibility projection for 2018 is no higher than the baseline monitored value.

Table 8.11
WRAP and NDDoH Visibility Modeling Results
Uniform Rate of Progress – Default EPA Methodology

Figure 8.12
TRNP Uniform Rate of Progress – EPA Default Methodology

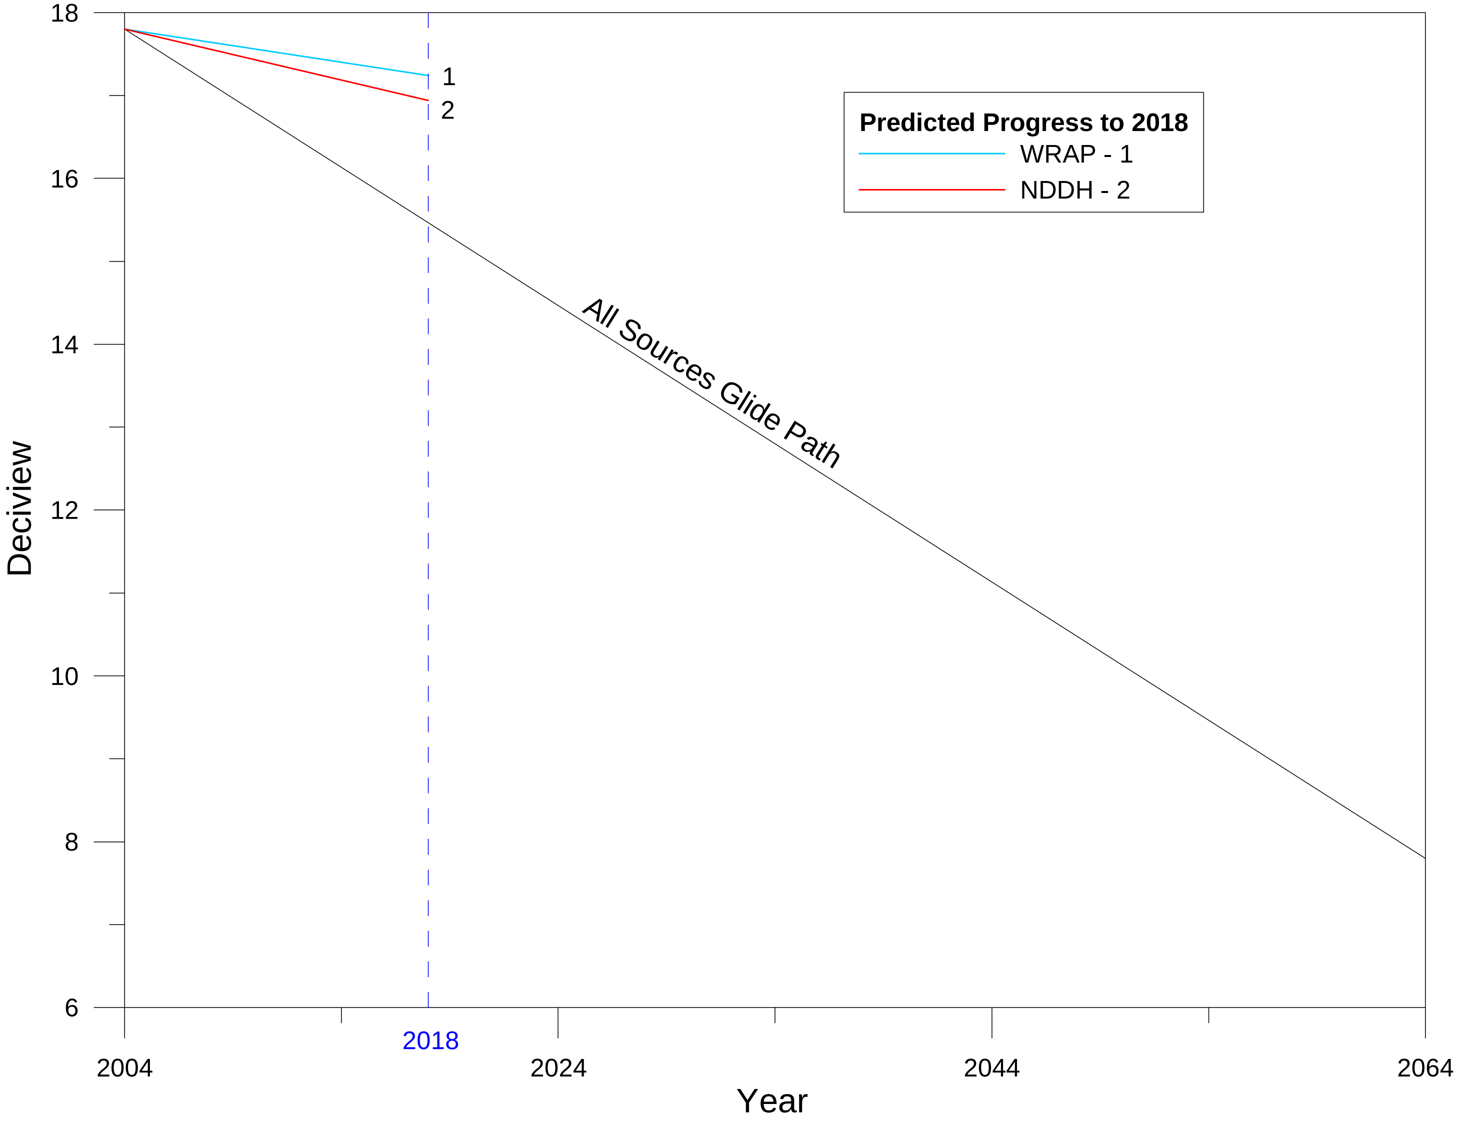

Figure 8.13
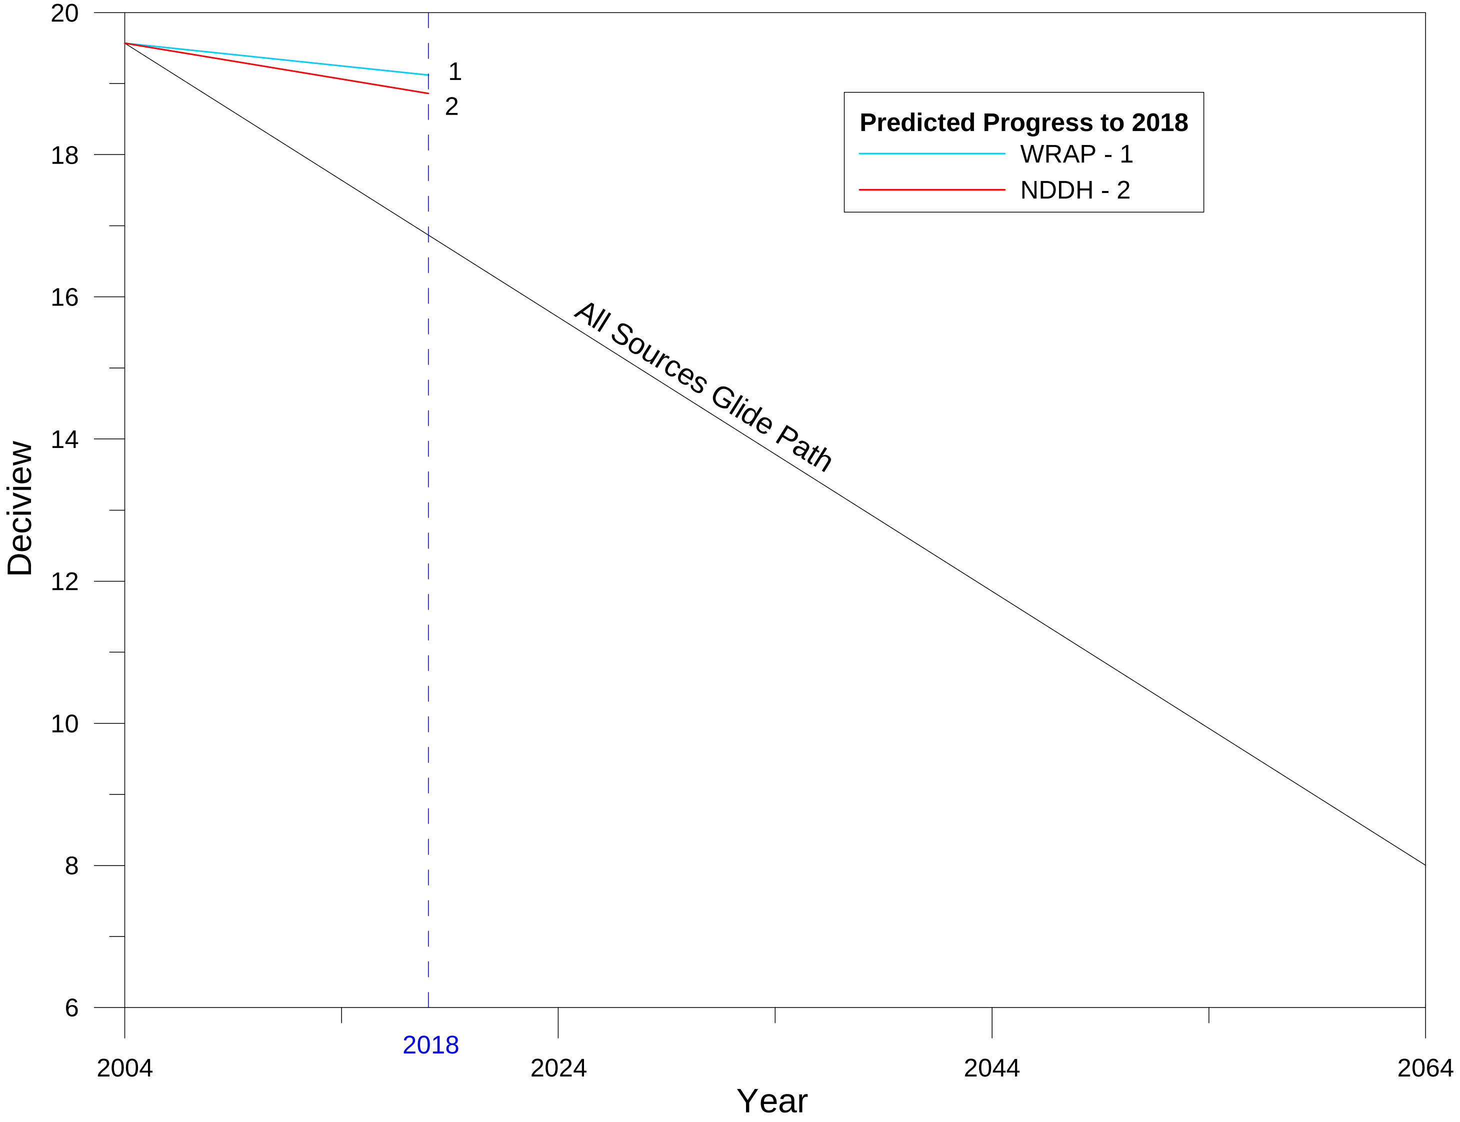
LWA Uniform Rate of Progress – EPA Default Methodology



As shown in Table 8.11, the NDDoH projections for 20% worst days indicate greater progress with respect to the 2018 goals than the WRAP projections, but both sets of projections fall well short of the URP targets. The WRAP projection constitutes 24.0 percent of the visibility goal at Theodore Roosevelt National Park (TRNP), while the NDDoH projection is 37.1 percent of the goal at that Class I area. For Lostwood Wilderness Area (LWA), WRAP projects 16.7 percent of the URP goal while the NDDoH projects that 26.3 percent of the goal will be achieved.

On the 20% best monitored days, both WRAP and NDDoH predictions in Table 8.11 illustrate that 2018 visibility will be better than baseline monitored values for both TRNP and LWA Class I areas. The WRAP 2018 projection of 7.67 deciviews and the NDDoH 2018 projection of 7.63 deciviews compare favorably with the baseline value of 7.76 deciviews for TRNP. At the LWA Class I area, the WRAP 2018 prediction of 8.06 deciviews and the NDDoH prediction of 8.10 deciviews both fall below the baseline value of 8.19 deciviews. Thus, requirements of the Regional Haze rule for the 20% best days will be satisfied.

Worst-day results of WRAP and NDDoH visibility modeling for the EPA default scenario are graphically interpreted with respect to the uniform rate of progress in Figure 8.12 and Figure 8.13 for TRNP and LWA, respectively. The “all sources” glide paths in Figures 8.12 and 8.13 originate with the monitored baseline deciview value in 2004, and terminate with the natural background deciview value in 2064. Using the same point of origination, the projected visibility progress is plotted against the glide path in each figure.

Figures 8.12 and 8.13 illustrate how NDDoH hybrid modeling projects better visibility improvement to 2018 than WRAP CMAQ modeling for both Class I areas. The figures also illustrate how far WRAP and NDDoH projections are from meeting the 2018 URP targets for 20% worst day visibility.

8.6.2.2 Apportionment by Species

The contribution of individual visibility-affecting species to total observed and projected light extinction for 20% worst/best days is discussed here. According to the IMPROVE algorithm, light affecting species include sulfate (SO_4), nitrate (NO_3), organic carbon (OMC), elemental carbon (EC), fine soil (Soil), coarse material (CM), and sea salt (SS). An additional component of light extinction which is included in the IMPROVE algorithm is Rayleigh scattering (Ray), which was also addressed in the projection of future visibility.

IMPROVE speciated monitoring data for 20% worst days at TRNP and LWA are summarized in the bar charts of Figures 8.14 and 8.15, respectively. The figures provide the percentage contribution of each visibility-affecting species, as well as Rayleigh scattering, to each 20% worst visibility day in baseline year 2004. The worst days are identified by month and day of the month at the bottom of the charts.

As seen in Figures 8.14 and 8.15, most of the 20% worst day light extinction at North Dakota Class I areas is dominated by sulfate and nitrate contributions. Rayleigh scattering is also a significant component, but otherwise the contribution of other visibility-affecting species (OMC,

EC, Soil, CC, and SS) is generally very small. The exception is worst days in late July and August, where organic carbon replaces sulfate and nitrate as the dominate contributor to extinction. This pattern was similar in other years of IMPROVE baseline data (2000-2003). A possible explanation is that fugitives associated with agricultural burning, prescribed burning within Class I areas, and wild fires may be the largest contributors to light extinction during late July and August, while emissions from conventional large point sources are the largest contributors during the remainder of the year.

WRAP CMAQ modeling results for the default EPA methodology were used to review the contribution of individual visibility-affecting species to projected light extinction for 20% worst/best days (NDDoH hybrid modeling did not include all species). Summaries of WRAP CMAQ modeling results including 2018 projections for individual species are provided in Tables 8.12 through 8.15. Tables 8.12 and 8.13 provide speciated summaries (averages) of 20% worst and best days, respectively, for TRNP. Tables 8.14 and 8.15 address speciated summaries of 20% worst and best days, respectively, for LWA. The tables include light extinction values for baseline conditions, natural conditions, 2018 uniform rate of progress target, and 2018 projected visibility conditions for each visibility-affecting species. Values for total light extinction and deciview are provided as well (note these values are consistent with results in Table 8.11). Note that 2018 projected values are not provided for CM and SS species, due to model performance issues. For these species, WRAP (and NDDoH) assumed an RRF of 1.0, and set the 2018 projection equal to the monitored baseline value.

In reviewing the 20% worst day summaries for TRNP and LWA in Tables 8.12 and 8.14, respectively, sulfate and nitrate are found to be the largest contributors to light extinction. This is true for both baseline monitored conditions and for future (2018) projected conditions. Because of its dominance in the late summer months, organic carbon is also a major overall contributor to 20% worst day light extinction for both baseline monitored and future projected conditions. As discussed previously, WRAP modeling results for 20% worst days (summarized in Tables 8.12 and 8.14) indicate the total light extinction URP target will not be achieved at either TRNP or LWA. Further, results for individual species indicate the URP species-specific target will be met only for elemental carbon and sea salt.

The 20% best day summaries for TRNP and LWA are reported in Tables 8.13 and 8.15, respectively. With exception of sea salt, all species appear to be significant contributors to light extinction on 20% best days. Sulfate is the largest contributor at both TRNP and LWA. As shown in the tables, the 2018 projected light extinction is lower than the baseline light extinction for both Class I areas. Thus, Regional Haze Rule requirements for 20% best days will be satisfied at TRNP and LWA for the first planning period.

Note that the WRAP projected emissions values for nitrate (NO_X) in Tables 8.12 through 8.15 are not consistent with the levels used by NDDoH in hybrid modeling. The NDDoH adjusted the WRAP NO_X emissions associated with oil and gas activity, as described in Section 8.5.3.1.

8.6.2.3 Apportionment by Source Group

As established in Section 8.6.2.2, sulfate and nitrate are the primary contributors to 20% worst day visibility in North Dakota Class I areas. In its hybrid modeling analysis, the NDDoH tracked the contribution of source groups to the total predicted sulfate and nitrate concentration for 20% worst days, in order to enhance the interpretation of modeling results. Contributions are available for the following source groups:

- North Dakota electrical generating units (EGU),
- all other point sources within the CALPUFF domain,
- all sources modeled as area sources within the CALPUFF domain,
- North Dakota oil and gas related sources (O&G), and
- boundary conditions representing the impact of all sources located outside of the CALPUFF domain.

Focus is on the ND EGU and boundary condition groups because of their relatively small and large contributions, respectively. O&G contributions are available for sulfate, only.

Contributions of the above source groups to 20% worst day average predictions, based on NDDoH hybrid modeling, are illustrated in Figures 8.16 through 8.19. Predictions for the base period (2000-2004) are compared with predictions for the future period (2018) in the figures. Contributions for sulfate at TRNP are compared in Figure 8.16. Figure 8.17 provides contributions for sulfate at LWA. Source group contributions for nitrate at TRNP are illustrated in Figure 8.18. Finally, Figure 8.19 addresses contributions for nitrate at LWA. Source group contributions in the figures reflect the percent of the total average predicted concentration for 20% worst days.

As consistently shown in Figures 8.16 through 8.19, the contribution of North Dakota EGUs to total sulfate and total nitrate is relatively small, while the contribution of boundary conditions is relatively large. This is true for both baseline and future projections. For sulfate, boundary conditions contributed no less than two-thirds of the total at North Dakota Class I areas. For nitrate, the boundary condition contribution was no less than 59 percent. The contribution of North Dakota EGUs to sulfate was no more than 21 percent, and to nitrate was no more than 6 percent, at North Dakota Class I areas.

As shown in Figures 8.16 and 8.17, the reduced impact from North Dakota EGUs due to BART controls is apparent. The projected future contribution of North Dakota EGUs to sulfate is less than one-half the baseline contribution for both TRNP and LWA. The difference for other source groups is less pronounced, although an exception would be area sources at LWA, where the baseline contribution of 4.0 percent is reduced to 2.4 percent in 2018. In comparing future with baseline contributions in Figures 8.16 and 8.17, it appears the contribution of boundary

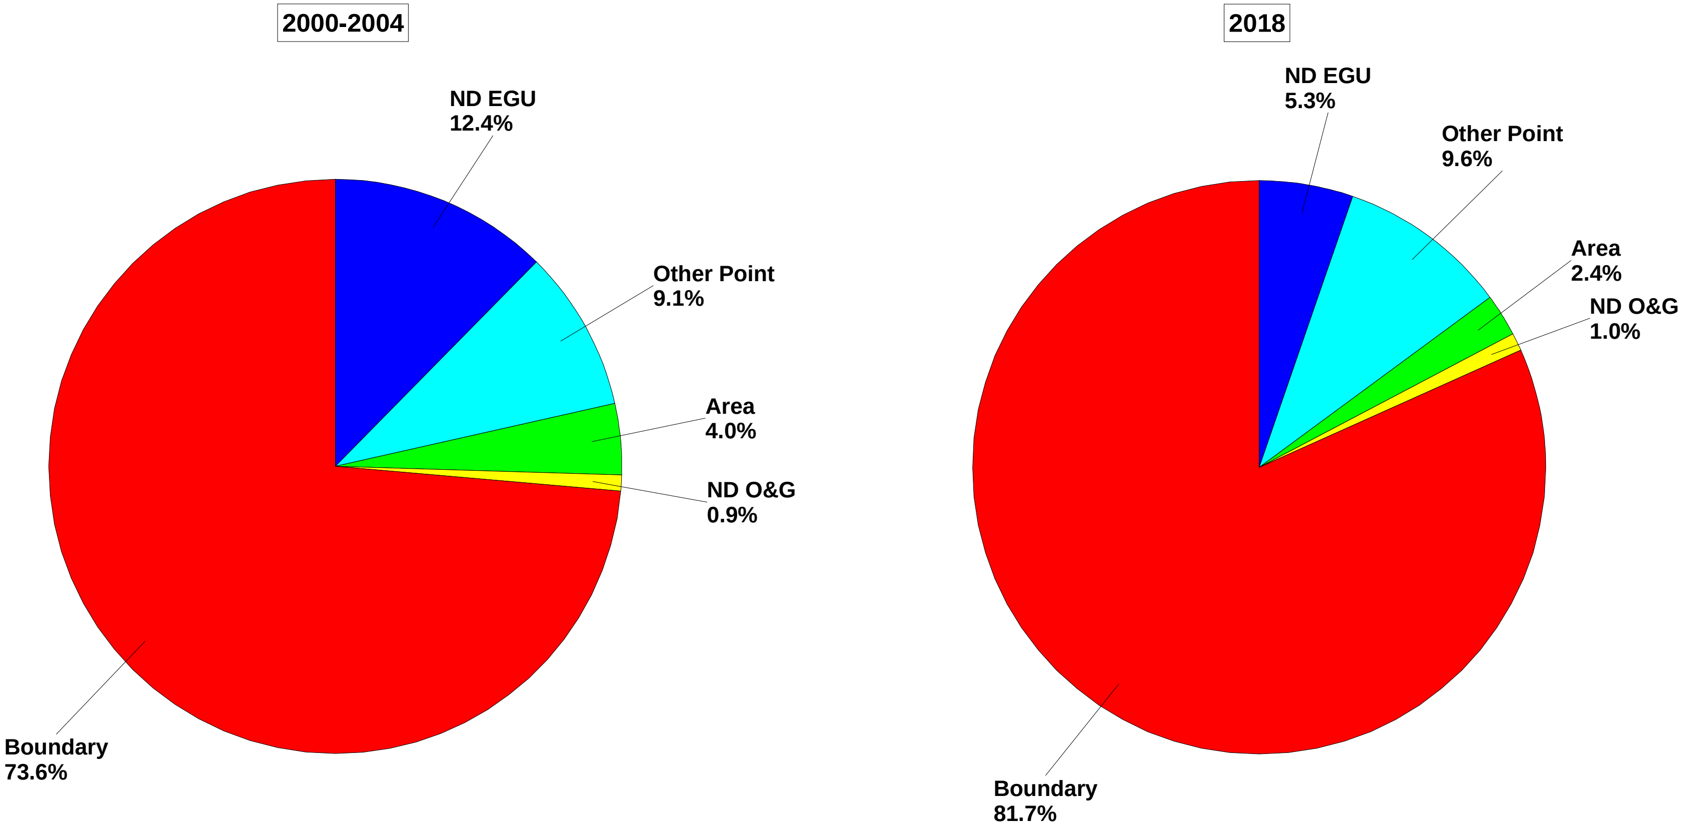

Figure 8.18
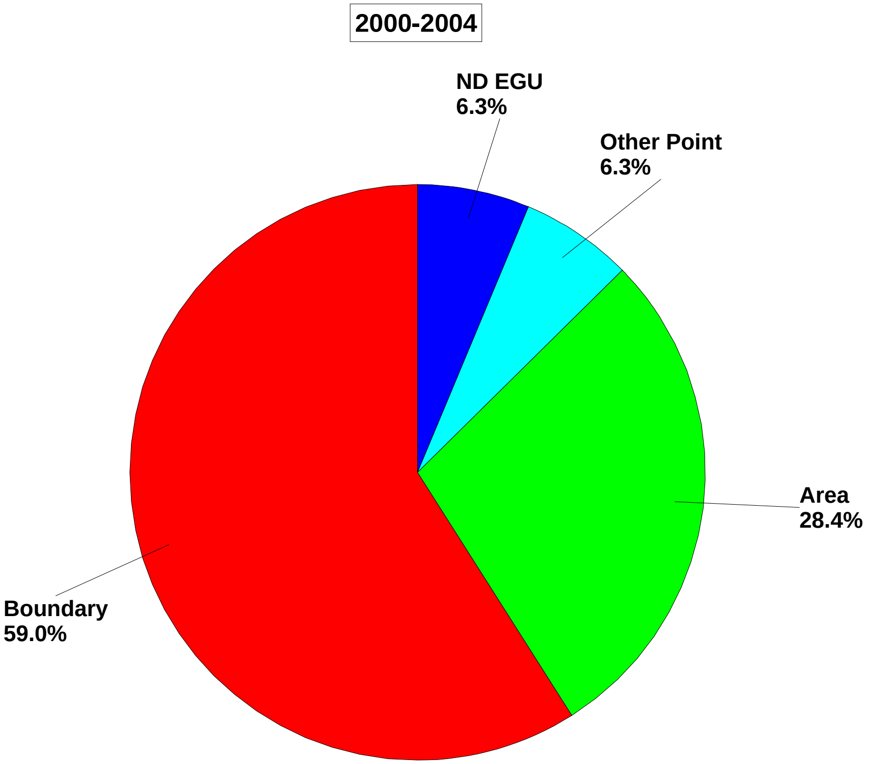
Hybrid Modeling Results
Source Group Contributions to 20% Worst Day NO_3 at TRNP (Base & Future)



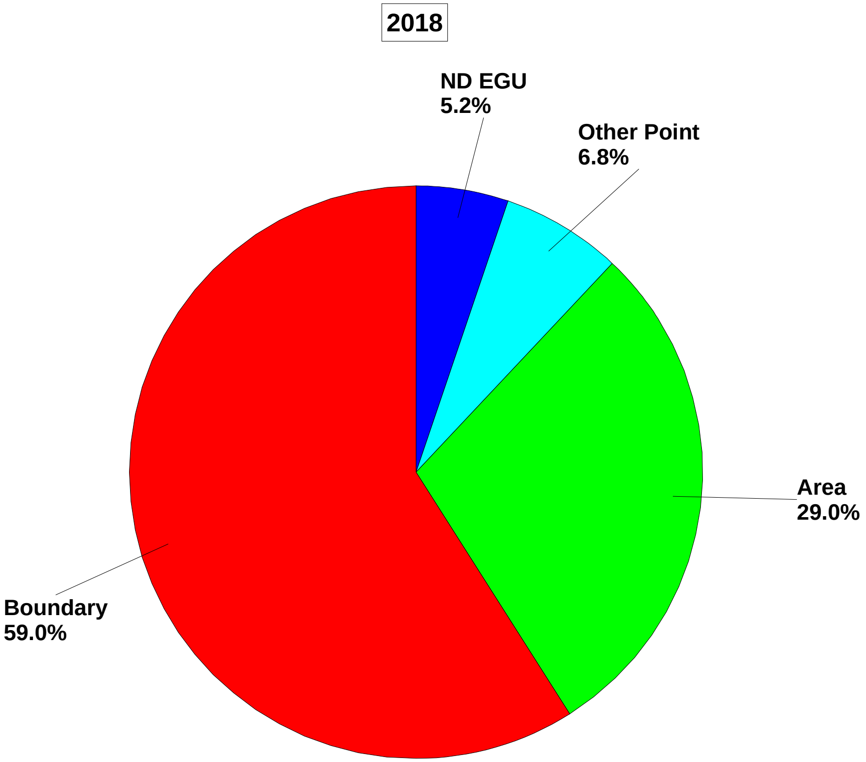


Figure 8.19
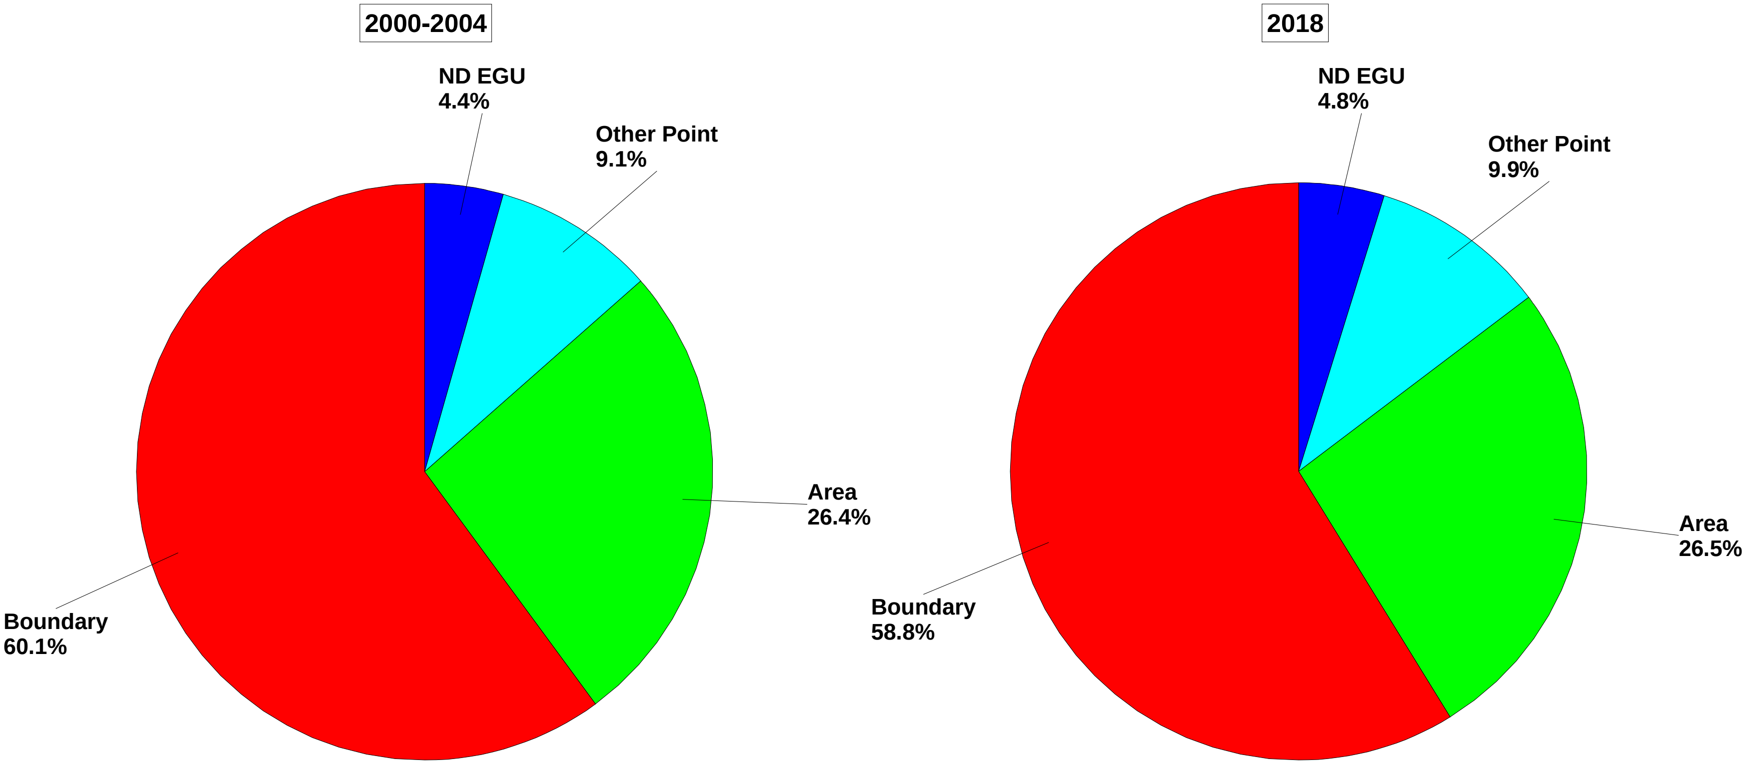
Hybrid Modeling Results
Source Group Contributions to 20% Worst Day NO_3 at LWA (Base & Future)



conditions is increasing as the contribution of North Dakota EGUs decreases in the future (other source groups remain relatively stable).

In Figures 8.18 and 8.19, the difference between future and baseline contributions for nitrate is less apparent than for sulfate. Percentage contributions for nitrate remained relatively stable from baseline to future for both Class I areas. Reduction in NO_X emissions due to BART controls was less than BART reductions for SO2, but the NO_X reduction was still significant. This lack of response to future BART reductions in NO_X may be linked to the CALPUFF chemistry, and the tendency observed in the performance evaluation (Section 8.6.1) for NO_3 production to overreact to newly freed ammonia from the lower production of SO_4.

NDDoH hybrid modeling results were further refined in order to extract the contribution of all North Dakota sources to total predicted sulfate and nitrate concentrations for 20% worst days. This additional source group includes all North Dakota EGUs, all North Dakota point sources other than EGUs, and all North Dakota emissions modeled as area sources. Because the NDDoH CALPUFF domain excludes the far eastern part of North Dakota, some adjustments in inventory and procedure were necessary to estimate the contribution of this source group.

Contributions of the North Dakota only source group to total sulfate and nitrate are summarized in Table 8.16. Percentage contributions are provided for baseline and future predicted concentrations at both North Dakota Class I areas. As shown in the table, contributions from North Dakota sources are relatively small and comprise no more than 29 percent of the total prediction for 20% worst days. Significant reduction in future sulfate concentrations due to BART controls on North Dakota EGUs is again apparent.

Table 8.16
Hybrid Modeling Results
Total North Dakota Contribution to 20% Worst Days Predictions

	Class I Area	**Baseline Percent**	**2018 Percent**
SO_4	TRNP	27.3	15.0
	LWA	17.6	9.7
NO_3	TRNP	29.0	28.6
	LWA	26.4	28.7

The relatively small contributions of North Dakota EGUs (and North Dakota sources in general) and the relatively large contributions of boundary conditions to 20% worst day visibility in North Dakota Class I areas, as observed in Figures 8.16 through 8.19, and Table 8.16, translates to restricted options for meeting visibility progress goals. These results indicate that most of the visibility impact on the 20% worst days in North Dakota Class I areas is due to impact from sources located outside of the State, and beyond the jurisdiction of the NDDoH. From additional hybrid modeling, the NDDoH found that even with *all future North Dakota* SO_2 *and* NO_X *emissions reduced to zero*, North Dakota Class I areas would not achieve the 2018 uniform rate of progress target (see Section 8.6.3).

Weight of evidence perspectives which address the contributions of sources located outside of North Dakota to worst day visibility at TRNP and LWA are discussed in Section 8.6.3.

8.6.2.4 Apportionment by Source Region

Visibility modeling conducted by WRAP RMC for North Dakota Class I areas included source-region attribution for all western states, central US, eastern US, Mexico, and Canada. In addition, WRAP also tracked the contribution of sources located outside of the CMAQ domain which includes the contiguous United States, southern Canada, and northern Mexico.

Results of the WRAP attribution analysis are summarized in the bar charts of Figures 8.20 through 8.23. These charts provide source-region contributions to baseline (PLAN02c) predicted concentrations of sulfate and nitrate for the 20% worst days. Figures 8.20 and 8.21 provide source region contributions for sulfate and nitrate, respectively, at TRNP. Figures 8.22 and 8.23 provide the corresponding contributions at LWA. Along with the bars labeled with familiar abbreviations for western states, the figures also include contributions with the following labels:

CAN – Canada,
CEN – Central US (CENWRAP),
EUS – Eastern US,
MEX – Mexico,
PO – Pacific Offshore, and
OD – Outside WRAP US-Canada-Mexico Modeling Domain.

The bar charts used in Figures 8.20 through 8.23 were obtained from the WRAP TSS web site. Note that the values in the charts actually reflect WRAP case PLAN02c, which is a predecessor to the updated PLAN02d. The differences between PLAN02c and PLAN02d, however, are not significant enough to affect conclusions regarding these charts.

In reviewing the bar charts of Figures 8.20 and 8.22, it is seen that emissions from North Dakota, Canada, and from outside the WRAP US-Canada-Mexico modeling domain (Figure 8.1) dominate total sulfate concentrations at North Dakota Class I areas on the 20% worst visibility days. The contribution of sources located outside the WRAP domain is larger than the

Figure 8.20

WRAP Modeling Results
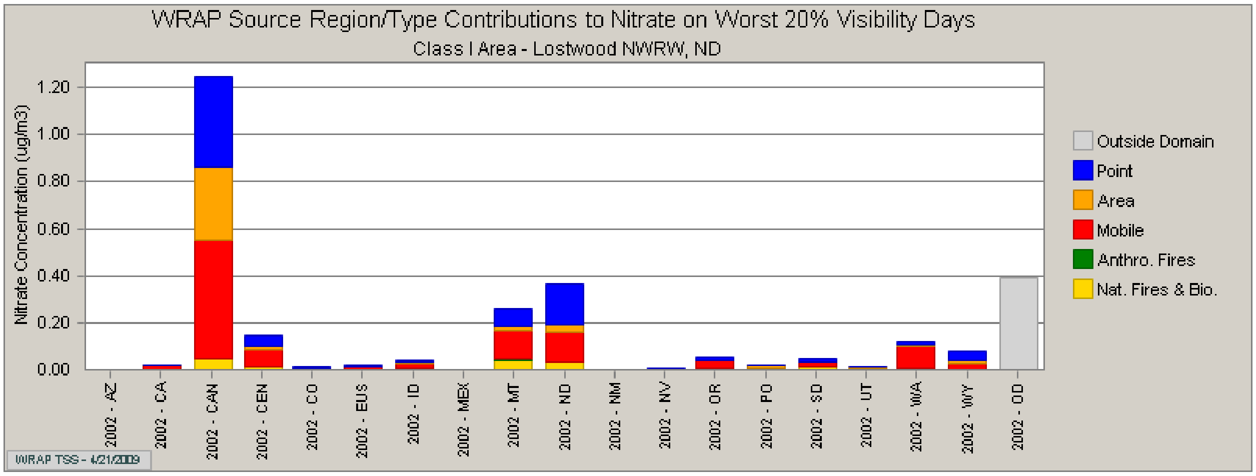
Source Region Contributions to 20% Worst Day NO_3 at LWA (baseline)



contribution from North Dakota sources at both Class I areas, and the contribution of Canadian emissions is significantly larger than the contribution from North Dakota sources at both Class I areas.

From Figures 8.21 and 8.23, one observes a similar pattern of dominant source-region contributors for 20% worst day nitrate concentrations, except that Montana becomes a dominate contributor in addition to North Dakota, Canada, and sources located outside of the WRAP domain. The overall dominance of Canadian emissions is even greater for nitrate than for sulfate, and at LWA the contribution to 20% worst day nitrate concentrations from Canadian sources is more than three times the contribution from North Dakota sources.

These source-region apportionment results illustrate that most of the contributions to 20% worst day nitrate and sulfate (species with the greatest effect on visibility impairment) at North Dakota Class I areas come from sources located outside of the state. Again, these sources are beyond the jurisdiction of the NDDoH, which poses a dilemma when seeking solutions for achieving visibility goals. This issue was addressed in the NDDoH weight of evidence interpretations which are discussed in Section 8.6.3.

8.6.2.5 Conclusions

Visibility progress modeling was conducted by WRAP and NDDoH using the default EPA methodology. This modeling was based on preliminary estimates of the effect of BART controls, and other growth and control factors. Results have been discussed in terms of general status with respect to the uniform rate of progress for North Dakota Class I areas, and in terms of apportionment by species, source group, and source region. Based on these modeling results, the following conclusions apply.

1) The uniform rate of progress goal for 2018 for 20% worst days will not be achieved at either TRNP or LWA. Therefore, weight of evidence arguments were addressed (see Section 8.6.3).

2) The Regional Haze Rule requirement for 2018 for 20% best days will be achieved at both TRNP and LWA.

3) NDDoH hybrid modeling (adjusted WRAP CMAQ) predicted better progress with respect to the 20% worst day uniform rate of progress goals than did WRAP modeling, at both TRNP and LWA.

4) Apportionment modeling results indicate the contribution of sources located outside of North Dakota is much greater than the contribution of in-state sources to 20% worst day visibility at TRNP and LWA (both baseline and 2018).

5) Though the addition of proposed BART controls substantially decreases the visibility impact of North Dakota EGUs, these EGUs comprise only a small component of total 20% worst day impact at TRNP and LWA. However, on certain worst days when meteorology favors

transport of North Dakota EGU emissions to TRNP or LWA, proposed BART reductions alone will significantly improve visibility.

6) Of the visibility affecting aerosols, sulfate and nitrate are primary contributors to 20% worst day visibility at North Dakota Class I areas.

7) The primary source-region contributors to 20% worst day visibility at TRNP and LWA are Canada, sources located outside of the WRAP modeling domain, North Dakota, and Montana (in that order).

8) When implemented as an adjustment to WRAP CMAQ modeling results, the NDDoH hybrid modeling approach is not critically tied to the parameterized CALPUFF chemistry.

8.6.3 Weight of Evidence Options

WRAP and NDDoH visibility modeling based on the default EPA methodology and glide path has been reviewed, with results as discussed in Section 8.6.2. Because projected 2018 visibility did not meet uniform rate of progress goals for 20% worst days in North Dakota Class I areas, the NDDoH pursued alternative or supplemental modeling approaches, which are discussed here. The Regional Haze Rule specifies that the State Implementation Plan may be based, in part, on evidence apart from modeling using the default EPA methodology. For example, the analysis could logically be modified to discount the impact of visibility-affecting emission sources over which the NDDoH has no jurisdiction.

These supplemental analyses are defined in the Rule as “weight of evidence” options. The following supplemental modeling analyses were conducted by NDDoH in the assessment of visibility progress goals.

1) Discounted the impact of international (in this case, Canadian) source visibility-affecting emissions on North Dakota Class I areas.

2) Discounted the impact of visibility-affecting emissions from all sources located outside of North Dakota, on North Dakota Class I areas.

3) Used the complete emissions inventory for the default EPA method, but zeroed out future SO_2 and NO_X emissions from all sources located in North Dakota (i.e., assumed 100 percent future control of all SO_2 and NO_X emissions in North Dakota), to determine progress with respect to the default glide path for North Dakota Class I Areas.

4) Based 20% worst visibility days for determining RRFs on baseline model results (CALPUFF) rather than IMPROVE monitoring data. This may be justified because neither CMAQ nor CALPUFF perform well on a “paired-in-time” basis. The resultant RRFs were still applied to 20% worst days based on IMPROVE monitoring to project future visibility.

Procedures and results for these supplemental, weight of evidence analyses are discussed in Sections 8.6.3.1 through 8.6.3.4.

8.6.3.1 Discounting the Impact of Canadian Source Emissions

The procedure used by the NDDoH to discount the impact of Canadian source emissions in the projection of future visibility at North Dakota Class I areas is consistent with the methodology described in Section 8.5.6.2. To discount the impact of Canadian source emissions on visibility projections, Canadian sources were removed from the baseline and future emissions inventories used with the hybrid modeling system to develop RRFs, and the URP glide path was adjusted by subtracting the impact of Canadian emissions from the baseline starting value. This weight of evidence analysis was applied for 20% worst days, only. The adjusted glide path is compared with the default glide path in Figure 8.24 for TRNP and LWA.

Because the NDDoH hybrid modeling addresses S and N species only, the discounting of Canadian source impact was limited to sulfate and nitrate, only. The RRFs and projected future contribution to light extinction of other visibility affecting species remained unchanged from the default EPA methodology (i.e., included Canadian emissions). As sulfate and nitrate are the primary contributors to light extinction at North Dakota Class I areas on the 20% worst days (see Section 8.6.2.2), this limitation should not significantly impact conclusions based on this weight of evidence analysis.

Note that once the glide path has been adjusted, the URP 2018 target value changes along with the baseline starting value (the adjusted glide path terminates at the same natural background value in 2064). Therefore, it is no longer meaningful to compare the 2018 projected progress with the absolute deciview target from the default EPA methodology (Table 8.11). Instead, for this weight of evidence scenario and others, 2018 progress is expressed as a percentage of the target rather than as a specific deciview value.

The NDDoH procedure used to discount the impact of Canadian source emissions is outlined as follows.

1) Canadian sources located within the NDDoH CALPUFF domain were eliminated from the *HybridPt* baseline and future emissions inventories to be used in Equation 8-3.

2) CALPUFF hourly boundary conditions (baseline and future *HybridPt*) were adjusted to eliminate the contribution of Canadian (anthropogenic) source emissions (leaving only the contribution of natural background) for 3-km boundary segments located in Canada (see Figure 8.5). The fixed adjustment factor utilized represents the ratio of species-specific natural background light extinction to species-specific baseline monitored light extinction for the 20% worst day average, at each Class I area. The adjustment was applied to all boundary species (SO_2, SO_4, NO_X, HNO_3, and NO_3). The SO_4 ratio was used for scaling SO_4 and SO_2 species. The NO_3 ratio was used for scaling NO_3, HNO_3, and NO_X species.

3) Hybrid modeling was applied to prepare a revised glide path and 2018 target using Equation 8-4 with the revised baseline emissions inventories (non-Canadian sources only) from Steps 1 and 2, for each Class I area. The 3-step ammonia limiting method was applied to refine NO_3 concentrations for non-Canadian sources.

4) Hybrid modeling was applied to project future visibility using Equation 8-3 with the revised baseline and future emissions inventories (non-Canadian sources only) from Steps 1 and 2, for each Class I area. The 3-step ammonia limiting method was applied to refine NO_3 concentrations for non-Canadian sources.

5) The projected future deciview value was compared with the revised glide path 2018 target deciview value to calculate the percent of the 2018 target achieved, at each Class I area.

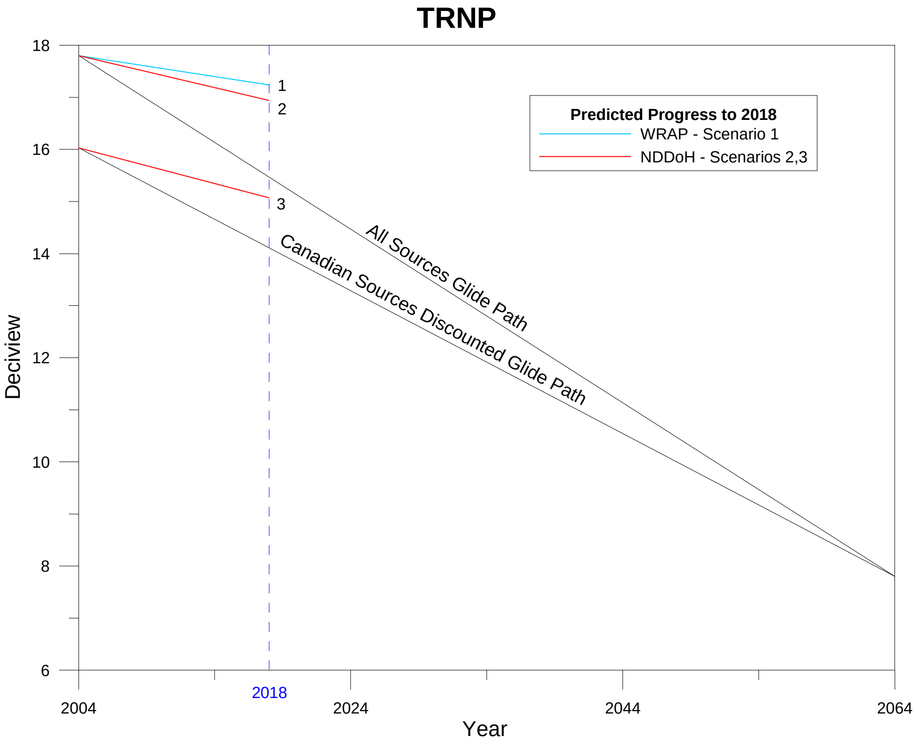
Results of the weight of evidence analysis for discounting the impact of Canadian source emissions are summarized in Table 8.17 and illustrated in Figure 8.24. Uniform rate of progress illustrations in Figure 8.24 are provided for both TRNP and LWA Class I areas. For comparison, the table and figure also include previous WRAP and NDDoH results for the complete emissions inventory and default EPA methodology from Table 8.11. WRAP results for the default EPA methodology are labeled Scenario 1 and NDDoH results for the default EPA methodology are labeled Scenario 2. They are compared with the weight of evidence entry which is identified as Scenario 3. For each scenario, the table provides percentage progress with respect to the 2018 target.

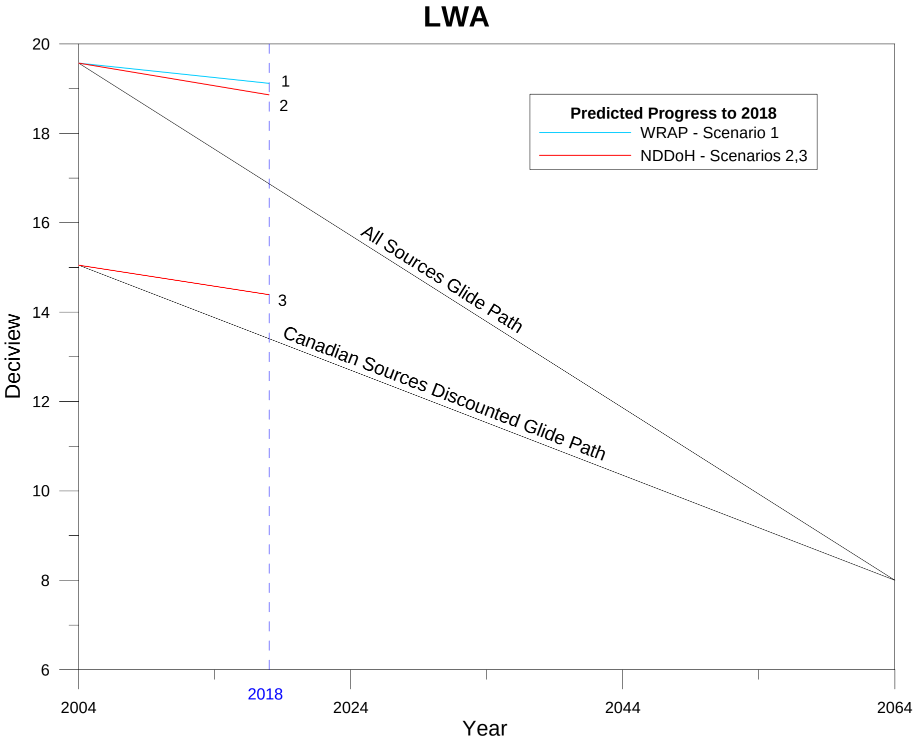
Table 8.17
NDDoH Visibility Modeling Results 20% Worst Days
Weight of Evidence – Discounting Canadian Emissions

Scenario	Description	Class I Area	Projected Percent of 2018 Target
1	WRAP CMAQ Default EPA Methodology	TRNP	24.0
		LWA	16.7
2	NDDoH Hybrid Default EPA Methodology	TRNP	38.1
		LWA	26.7
3	NDDoH Hybrid Canada Sources Discounted	TRNP	50.0
		LWA	40.2

As shown in Table 8.17 and Figure 8.24, progress with respect to the 2018 target is significantly improved when Canadian sources are discounted. The projected percent of the 2018 target with Canadian sources discounted is more than double the percentage obtained by WRAP for the default EPA methodology, and about 50 percent greater than the percentage obtained by NDDoH for the default EPA methodology, at both Class I areas. Though progress is significantly

Figure 8.24
Uniform Rate of Progress
EPA Default Methodology and Canadian Sources Discounted





improved under this scenario, the potential for greater improvement was limited because the contribution of US sources located outside of the hybrid model domain is very large (with little emissions reduction in the future), and the scenario could only address the discounted impact of SO_4 and NO_3.

8.6.3.2 Discounting the Impact of All Sources Located Outside of North Dakota

Because discounting the impact of Canadian emissions did not provide compliance with glide path targets, the NDDoH pursued other weight of evidence options. The next logical test after discounting Canadian emissions was to discount the visibility-affecting impact of all sources located outside of the jurisdiction of the NDDoH. Therefore, this new analysis discounted all contributions to North Dakota Class I areas, except for the impact of North Dakota sources and natural background. To discount the impact of *all sources located outside of North Dakota* on visibility projections, these sources were removed from the baseline and future emissions inventories used with the hybrid modeling system to develop RRFs, and the URP glide path was adjusted by subtracting the impact of these sources from the baseline starting value. This weight of evidence analysis was applied for 20% worst days, only. The adjusted glide path is compared with the default glide path in Figure 8.25 for TRNP and LWA.

Since the CALPUFF domain used by the NDDoH for hybrid visibility modeling excludes the extreme eastern part of North Dakota, area emissions for the easternmost column of the area source grid (see Figure 8.8) were adjusted upward to account for the impact of eastern North Dakota sources. Specifically, WRAP CMAQ (SMOKE) emissions for all grid cells located between the eastern edge of the CALPUFF domain and the eastern North Dakota border were added to the easternmost column of the CALPUFF area source grid. This addition was performed on a row by row basis. Because eastern North Dakota visibility affecting sources are relatively small and distant from TRNP and LWA Class I areas, this adjustment should have minimal impact on modeling results.

Because the NDDoH hybrid modeling addresses S and N species only, the discounting of out-of-state source impact was limited to sulfate and nitrate, only. The RRFs and projected future contribution to light extinction of other visibility affecting species remained unchanged from the default EPA methodology (i.e., included complete emissions inventory). As sulfate and nitrate are the primary contributors to light extinction at North Dakota Class I areas on most of the 20% worst days (see Section 8.6.2.2), this limitation should not significantly impact conclusions based on this weight of evidence analysis.

The procedure used by NDDoH to discount the impact of *all sources located outside of North Dakota* is similar to the 5-step procedure used to discount Canadian emissions, as outlined in Section 8.6.3.1., except that variables representing North Dakota sources replaced variables representing US sources in Equations 8.3 and 8.4. The procedure for discounting the impact of all out-of-state sources is outlined below.

1) All out-of-state sources located within the NDDoH CALPUFF domain were eliminated from the *HybridPt* baseline and future emissions inventories to be used in Equation 8-3.

2) As discussed above, emissions from all sources located outside of CALPUFF domain, but inside North Dakota, were added to easternmost column of CALPUFF area source grid.

3) CALPUFF hourly boundary conditions (baseline and future *HybridPt*) were scaled to eliminate the contribution of all out-of-state source emissions (leaving only the contribution of natural background) for all boundary segments. Scaling was based on the inverse distance squared weighted average of natural-to-baseline (2002) ratio from seven nearby IMPROVE monitoring locations. The ratio was obtained for the 20% worst day average SO_4 and NO_3 natural and baseline extinction for Theodore Roosevelt NP, Lostwood NWA, Medicine Lake NWA, UL Bend, Badlands NP, Wind Cave, and Voyageurs NP IMPROVE sites. The average SO_4 ratio was used for scaling SO_4 and SO_2 species. The average NO_3 ratio was used for scaling NO_3, HNO_3, and NO_X species.

4) Hybrid modeling was applied to prepare a revised glide path and 2018 target using Equation 8-4 with the revised baseline emissions inventories from Steps 1 and 2, for each Class I area (equation variables for North Dakota sources replaced variables for US sources). The 3-step ammonia limiting method was applied to determine NO_3 concentrations for North Dakota sources.

5) Hybrid modeling was applied to project future visibility using Equation 8-3 with the revised baseline and future emissions inventories from Steps 1 and 2, for each Class I area (equation variables for North Dakota sources replaced variables for US sources). The 3-step ammonia limiting method was applied to determine NO_3 concentrations for US sources.

6) The projected future deciview value was compared with the revised glide path 2018 target deciview value to calculate the percent of the 2018 target achieved, at each Class I area.

Results of the weight of evidence analysis for discounting the impact of *all sources located outside of North Dakota* are summarized in Table 8.18 and illustrated in Figure 8.25. Uniform rate of progress illustrations in Figure 8.25 are provided for both TRNP and LWA Class I areas. For comparison, the table and figure also include previous WRAP and NDDoH results for the complete emissions inventory with default EPA methodology from Table 8.11. WRAP results for the default EPA methodology are labeled Scenario 1 and NDDoH results for the default EPA methodology are labeled Scenario 2. They are compared with the new weight of evidence entry which is identified as Scenario 4. For each scenario, the table provides percentage progress with respect to the 2018 target.

As shown in Table 8.18 and Figure 8.25, progress with respect to the 2018 target is significantly improved after discounting the impact of *all sources located outside of North Dakota*, but projections do not meet the revised glide path targets. Also, the improvement is notably better at TRNP than at LWA. A likely explanation is that the location of BART sources in North Dakota, combined with prevailing meteorology, favors visibility improvement at TRNP compared with improvement at LWA (i.e., when there are no out of state influences).

Table 8.18
NDDoH Visibility Modeling Results 20% Worst Days
Weight of Evidence – Discounting All Out-of-State Sources

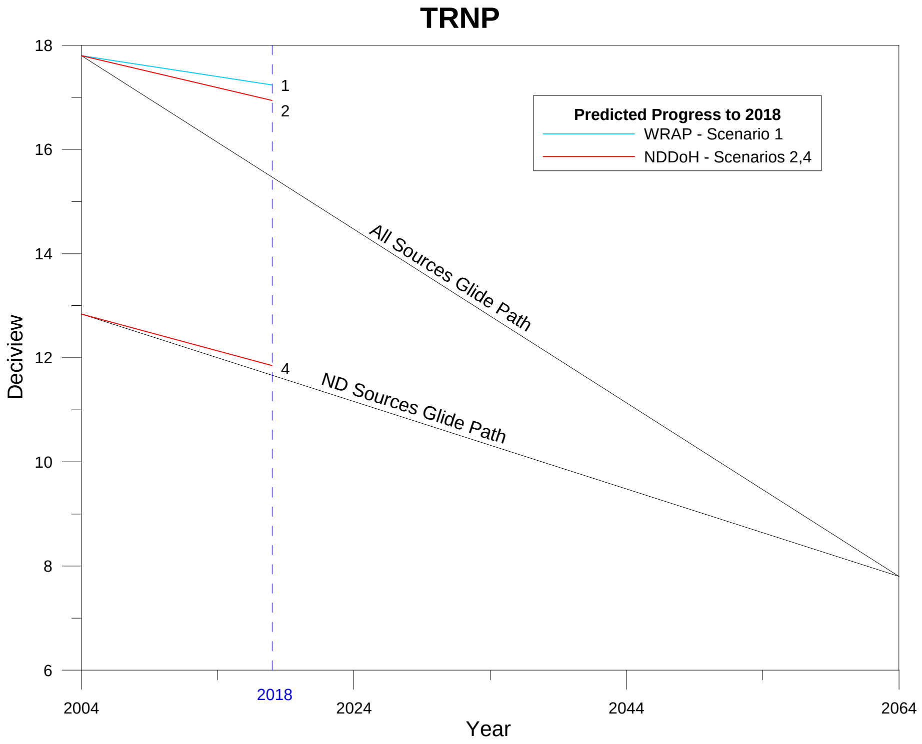
Scenario	Description	Class I Area	Projected Percent of 2018 Target
1	WRAP CMAQ Default EPA Methodology	TRNP	24.0
		LWA	16.7
2	NDDoH Hybrid Default EPA Methodology	TRNP	38.1
		LWA	26.7
4	NDDoH Hybrid All Sources Other Than ND Discounted	TRNP	83.9
		LWA	59.6

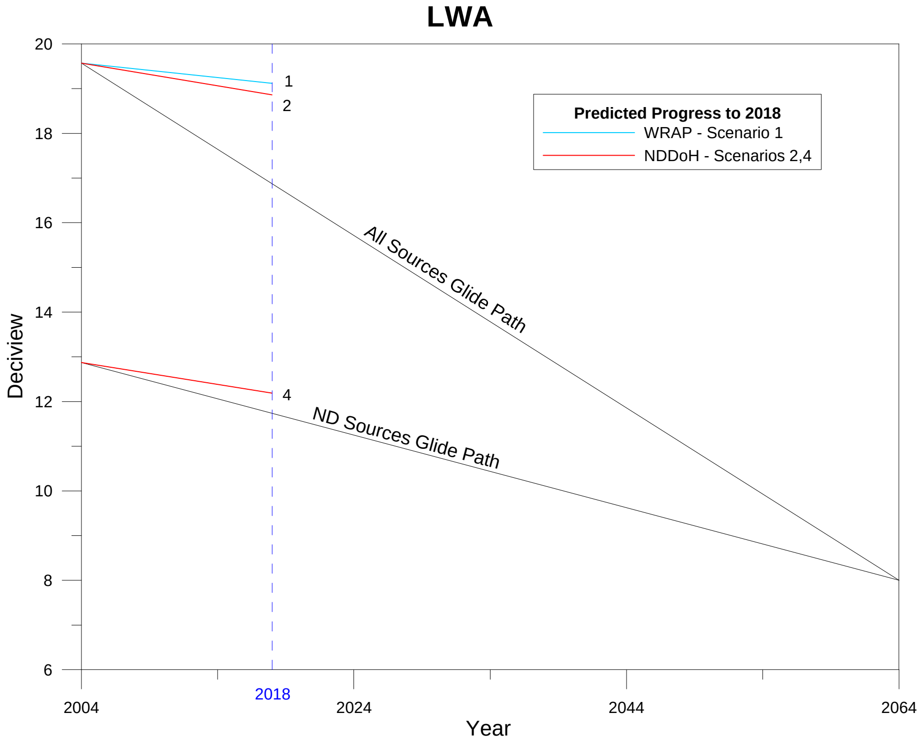
8.6.3.3 Use Default EPA Methodology with Zero North Dakota Future Emissions

The NDDoH next examined a “what if” scenario to see what would happen if all North Dakota sources were controlled to the hypothetical maximum degree and simply emitted no SO_2, SO_4, NO_X, or NO_3 in the future case. The concept here was to determine if the 2018 URP targets for the default EPA methodology for 20% worst days could be achieved even under maximum (albeit unrealistic) control conditions for North Dakota sources. Hybrid modeling for the baseline case (*HybridPt* in Equation 8-3) included the complete emissions inventory as used for the NDDoH EPA methodology analysis. Future case modeling (*HybridPt* in Equation 8-3) included the complete emissions inventory as applied by NDDoH for EPA methodology, except that all emissions for sources located in North Dakota were reset to zero. For this scenario, the glide path remains consistent with the default EPA methodology scenario.

Procedure for this new scenario followed the default EPA methodology, as discussed in Section 8.5. The only change was in the future case emissions inventory, where the emission rates for all North Dakota point and area sources were reset to zero. Note that because extreme eastern North Dakota is not included in the NDDoH CALPUFF domain, it was not possible to model the effect of zero future emissions from that part of the state. However, because visibility-affecting sources in extreme eastern North Dakota are relatively small and distant from the Class I areas

Figure 8.25
Uniform Rate of Progress
EPA Default Methodology and Non-ND Sources Discounted





which are both located in the western part of the state, this limitation should not detract from conclusions established regarding the analysis.

Results of the weight of evidence analysis involving zero future emissions for North Dakota visibility affecting sources are summarized in Table 8.19. For comparison, the table also includes previous WRAP and NDDoH results for the complete emissions inventory with default EPA methodology from Table 8.11. WRAP results for the default EPA methodology are labeled Scenario 1 and NDDoH results for the default EPA methodology are labeled Scenario 2. They are compared with the new weight of evidence entry which is identified as Scenario 5. For each scenario, the table provides percentage progress with respect to the 2018 target.

As illustrated in Table 8.19, even with all future North Dakota SO_2, SO_4, NO_X, and NO_3 emissions set to zero, the URP 20% worst day targets for 2018 are not achieved at North Dakota Class I areas. This result is consistent with earlier conclusions in this report that most of the visibility affecting impact on TRNP and LWA is coming from sources located outside of North Dakota. The implication of this weight of evidence test is that compliance with 20% worst day URP targets at North Dakota Class I areas cannot be achieved without significant additional emissions reductions from visibility affecting sources located outside of North Dakota.

Table 8.19
NDDoH Visibility Modeling Results 20% Worst Days
Weight of Evidence – Zero Future North Dakota Emissions

Scenario	Description	Class I Area	Projected Percent of 2018 Target
1	WRAP CMAQ Default EPA Methodology	TRNP	24.0
		LWA	16.7
2	NDDoH Hybrid Default EPA Methodology	TRNP	38.1
		LWA	26.7
5	NDDoH Hybrid Base Emissions Inv = Default Future Emissions Inv = All ND S and N Emissions set to zero	TRNP	83.8
		LWA	72.6

As indicated previously, the NDDoH CALPUFF visibility modeling was limited to the contribution of SO_2, SO_4, NO_X, and NO_3 species, only. Even if the effect of zeroing out all other visibility affecting species could have been accounted for, it is unlikely that 2018 URP targets for North Dakota Class I areas could have been achieved under this weight of evidence scenario.

8.6.3.4 Base 20% Worst Days on Modeling Results Rather than IMPROVE Monitoring Data

Though both models perform well when predicting maximum concentrations over a period of time, CMAQ and CALPUFF are less reliable when performance tests are based on predictions paired with concurrent observations. But the reliance of the Regional Haze Rule on the 20% worst/best monitored days to track visibility progress implies that the modeling system must demonstrate some skill on a temporal basis. To address possible temporal performance limitations in the NDDoH hybrid modeling system, visibility projection results based on the 20% worst monitored days were compared with results based on the 20% worst modeled days for the baseline case. The following procedure was used to develop results based on worst modeled days.

1) The hybrid modeling system was executed for the baseline case, using the emissions inventory for the default EPA methodology, and the entire year of 2002 meteorological data.

2) Daily modeling results for the baseline case were ranked in order to determine the 20% worst days (73 days) for visibility at both Class I areas (TRNP and LWA).

3) The hybrid modeling system was executed for the future (2018) case, using the emissions inventory for the default EPA methodology, and the 20% worst days determined for the baseline case in Step 2.

4) Relative response factors (RRFs) were developed from the modeling results for baseline and future cases in Steps 1 and 3, respectively.

5) RRFs were applied to IMPROVE baseline monitoring data for original 20% worst days to project future visibility.

This procedure provided deciview improvement predictions which were very similar to the original improvement predictions obtained through modeling the 20% worst IMPROVE days. Typical differences were less than five percent of the original predicted values at both Class I areas. Therefore, the NDDoH did not pursue this approach for any of the visibility modeling documented in this report (i.e., all modeling was based on the 20% worst/best IMPROVE days).

8.6.3.5 Weight of Evidence Summary and Conclusions

Results of the weight of evidence modeling analyses are summarized in Table 8.20, and in the illustrations of Figures 8.26 and 8.27. For comparison, the table and figures include results from all weight of evidence analyses, as well as previous WRAP and NDDoH results for the complete emissions inventory and default EPA methodology from Table 8.11. Scenarios are labeled as previously noted. For each scenario, the table provides percentage progress with respect to the 2018 target for 20% worst days at both North Dakota Class I areas. Figure 8.26 illustrates progress with respect to the URP glide path at TRNP for all scenarios, and Figure 8.27 illustrates progress with respect to the URP glide path at LWA for all scenarios.

Conclusions based on weight of evidence modeling analyses follow.

1) Compliance with 20% worst day URP 2018 targets at North Dakota Class I areas cannot be achieved through additional emissions reductions from North Dakota sources, alone. It will require significant additional visibility affecting emissions reductions from other western states, Canada, and from sources located outside of the WRAP CMAQ modeling domain.

2) A visibility progress analysis methodology which discounts the impact of International (Canadian) visibility affecting source emissions on 20% worst days is plausible, and was developed and implemented by the NDDoH. Using similar methodology, the NDDoH was able to also develop and implement a procedure to discount the impact of *all sources located outside of North Dakota* on 20% worst days.

3) After discounting the impact of Canadian sources, significantly greater progress (50 percent greater) was demonstrated, relative to URP 2018 targets for North Dakota Class I areas, than modeling with the entire emissions inventory. But 20% worst day targets were still not achieved.

4) After discounting the impact of *all sources located outside of North Dakota*, even greater progress was demonstrated, relative to URP 2018 targets for North Dakota Class I areas, than modeling with Canadian sources discounted. However, 20% worst day targets were still not achieved.

5) After zeroing out all future SO_2 and NO_X emissions in North Dakota under default EPA methodology (emulating a 100 percent, unrealistic control of all sources), compliance with 20% worst day targets was still not achieved at North Dakota Class I areas.

6) Basing 20% worst days on baseline model results rather than IMPROVE monitoring data made no meaningful difference in future visibility projections.

Table 8.20
NDDoH Visibility Modeling Results 20% Worst Days
Weight of Evidence Analysis Summary

Scenario	Description	Class I Area	Projected Percent of 2018 Target
1	WRAP CMAQ Default EPA Methodology	TRNP	24.0

9. Reasonable Progress Goals

9.1 Introduction

The Regional Haze Rule states that for each mandatory Class I Federal area located within the State and in each mandatory Class I Federal area located outside the State which may be affected by emissions from within the State, the State must establish reasonable progress goals for each area. For out-of-state Class I areas that are affected by in-state emissions, the State must consult with the affected state regarding the reasonable progress goals for those Class I areas. The reasonable progress goals (expressed in deciviews) must provide for reasonable progress towards achieving natural visibility conditions including improvement in visibility for the most impaired days (20% worst days) and ensuring no degradation in visibility for the least impaired days (20% cleanest days) over the planning period.

The EPA has published guidance[1] for setting reasonable progress goals. The basic steps include:

1. Establish Baseline and Natural Visibility Conditions

2. Determine the Glidepath, or Uniform Rate of Progress

3. Identify and Analyze the Measures Aimed at Achieving the Uniform Rate of Progress

    a. Identify the key pollutants and sources and/or source categories that are contributing to visibility impairment at each Class I area. The sources of impairment for the most impaired and least impaired days may differ.

    b. Identify the control measures and associated emission reductions that are expected to result from compliance with existing rules and other available measurements for the sources and source categories that contribute significantly to visibility impairment.

    c. Determine what additional control measures would be reasonable based on the statutory factors and other relevant factors for the sources and/or source categories you have identified.

    d. Estimate through the use of air quality models the improvement in visibility that would result from implementation of the control measures you have found to be reasonable and compare this to the uniform rate of progress.

4. Establish the Reasonable Progress Goal

---

[1] U.S. EPA 2007; Guidance for Setting Reasonable Progress Goals under the Regional Haze Rule: U.S. Environmental Protection Agency, Office of Air Quality Planning and Standards, Research Triangle Park, NC, June 1, 2007.

9.2 Establish Baseline and Natural Visibility Conditions

The baseline visibility conditions are established in Section 5.3 while the natural visibility conditions are addressed in Section 5.4. The following table summarizes the results for North Dakota's Class I Federal areas.

Table 9.1
Baseline and Natural Visibility Conditions

Area	Baseline (dv)		Natural Conditions (dv)	
	20% Best	20% Worst	20% Best	20% Worst
TRNP	7.8	17.8	3.0	7.8
LWA	8.2	19.6	2.9	8.0

9.3 Determine the Glide Path or Uniform Rate of Progress

The uniform rate of progress necessary to achieve natural conditions is addressed in Section 5.4. The results of that analysis are as follows:

Table 9.2
Visibility Improvement Required

Area	Total Improvement Required (dv) 20% Worst Days	2018 Target Improvement (dv) 20% Worst Days
TRNP	10.0	2.3
LWA	11.6	2.7

9.4 Identify and Analyze the Measures Aimed at Achieving the Uniform Rate of Progress

A. Identify key pollutants and sources contributing to visibility impairment in each Class I area.

The key pollutants contributing to visibility degradation in North Dakota's Class I areas are sulfur dioxide and nitrogen oxides which form sulfates and nitrates (see analysis in Section 8.7.2.2). For sulfates, the contributing sources are primarily point sources in Canada, sources outside WRAP's modeling domain and point sources in North Dakota.

For nitrates, point/area/mobile sources in Canada, North Dakota, Montana and sources outside of WRAP's modeling domain area are the primary contributors (see analysis in Section 6.3 and Section 8). North Dakota sources contributed 21% of the sulfate and 19% of the nitrate at TRNP during the 20% worst days of the baseline (WRAP Case Plan 02c). At LWA, North Dakota sources contributed 18% of the sulfate and 13% of the nitrate for the same period.

Organic carbon (primary organic aerosols) is the next largest contributor to extinction in the Class I areas of North Dakota. Organic carbon contributes 17.5% of the total extinction at TRNP and 14.9% at LWA during the baseline 20% worst days. As can be seen in Figures 9.1 and 9.2, much of the organic carbon emissions in North Dakota are from the "natural fire" source category or from the "fugitive dust" category. Natural fire cannot be controlled and will vary year to year in each state. Fugitive dust is addressed in Sections 9.5.2 and 10.6.2. Off-road mobile sources of organic carbon are expected to decrease 54% by 2018.

Figure 9.1

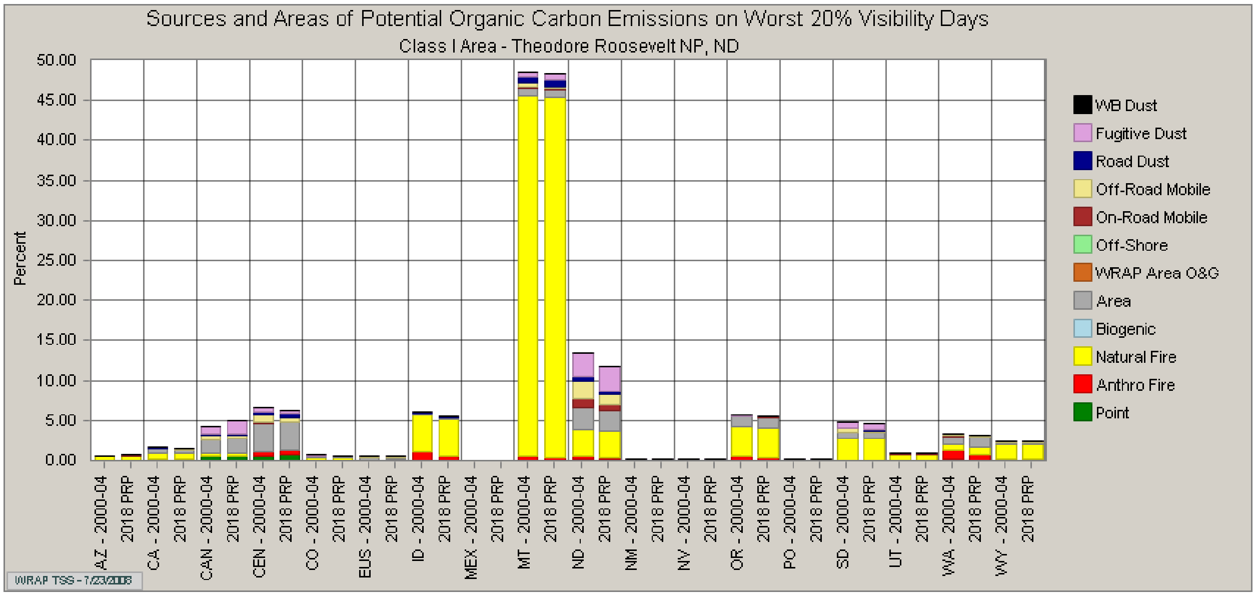

Figure 9.2

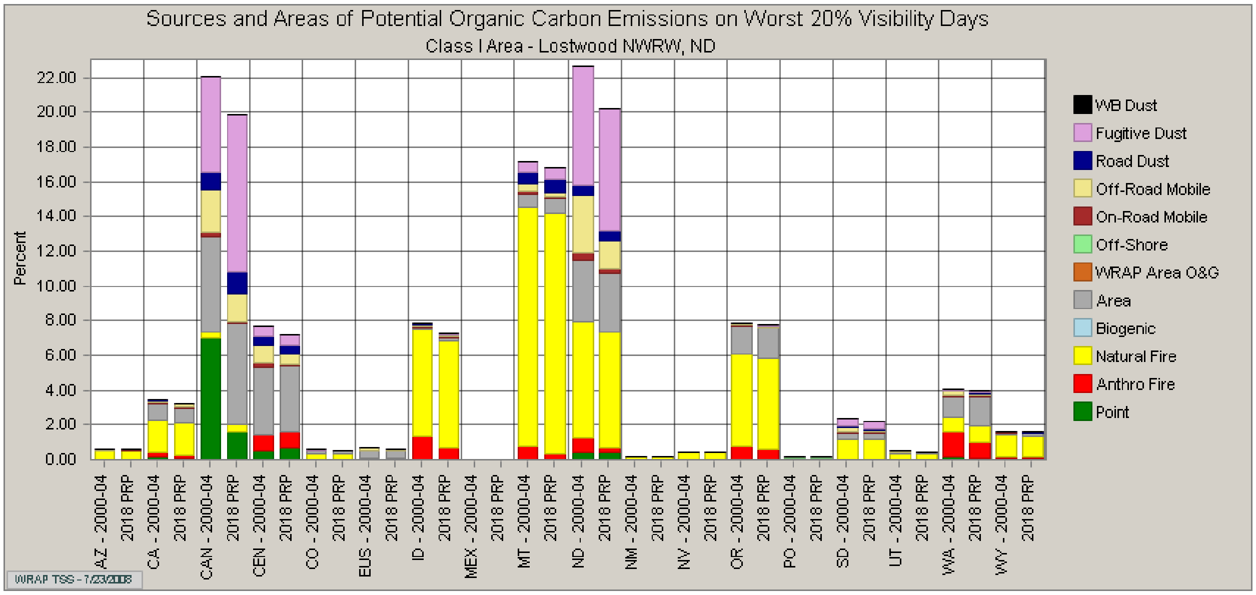

With regard to the contribution of North Dakota sources to the sulfate~~s~~ and nitrate~~s~~ concentration in the Class I areas, the sources in North Dakota are:

Table 9.3
North Dakota Sources
of
Sulfate and Nitrates
2000-2004

Area	**Source**	**In-State Sulfate Contribution (µg/m^3)**	**In-State Nitrate Contribution (µg/m^3)**	**Percent of Total In-State Contribution**	
				Sulfate	**Nitrate**
TRNP	Point	0.3148	0.1587	98	49
	Anthropogenic Fire	0.0002	0.0003	< 1	< 1
	Mobile	0.0151	0.1038	4	32
	Natural Fire & Biogenic	0.0002	0.0389	< 1	12
	Area	0.0071	0.0233	2	7
LWA	Point	0.3797	0.1760	92	48
	Anthropogenic Fire	< 0.0001	< 0.0001	< 1	< 1
	Mobile	0.0216	0.1197	5	33
	Natural Fire & Biogenic	0.0004	0.0362	< 1	10
	Area	0.0089	0.0334	2	9

North Dakota sources only contribute 21% of the total sulfate concentration in TRNP and 19% of the total nitrate concentration during the 20% worst days. At LWA, North

Dakota sources contribute 18% of the total sulfate and 13% of the total nitrate (see Table 2.1). Although mobile sources are a significant contributor to North Dakota's emissions that form nitrates, mobile sources in North Dakota only contribute 6% of the total nitrate concentration in TRNP and 4% in LWA during the 20% worst days (WRAP Case Plan 02c). Nitrogen oxides emissions from mobile sources are expected to decline by 51% by 2018 (see Table 6.1 and 6.3). Based on the above results, efforts to reduce sulfates and nitrates are primarily directed towards point sources of sulfur dioxide and nitrogen oxides emissions.

B. Identify the Control Measures and Associated Emission Reductions from Existing Rules

See Section 10. The WRAP has estimated that the "on-the-books" controls will reduce emissions of nitrogen oxides by approximately 28,000 tons per year, sulfur dioxide 1,700 tons per year, elemental carbon 2,700 tons per year, and fine particulate matter by 900 tons per year. Coarse particulate matter is expected to increase by 18,000 tons primarily due to fugitive dust. These "on the books" controls include:

- Tier 1 light-duty vehicle standards, beginning MY 1996;
- National Low Emission Vehicle (NLEV) standards, beginning MY 2001;
- Tier 2 light-duty vehicle standards beginning MY 2005, with low sulfur gasoline beginning summer 2004;
- Heavy-duty vehicle standards beginning MY 2004;
- Heavy-duty vehicle standards beginning MY 2007, with low sulfur diesel beginning summer 2006;
- Emission standards for new nonroad spark-ignition engines below 25 hp;
- Phase 2 emission standards for new spark-ignition hand-held engines below 25 hp;
- Phase 2 emission standards for new spark-ignition nonhand-held engines below 25 hp;
- Emission standards for new gasoline spark-ignition marine engines;
- Tier 1 emission standards for new nonroad compression-ignition engines above 50 hp;
- Tier 1 and Tier 2 emission standards for new nonroad compression-ignition engines below 50 hp including recreational marine engines;
- Tier 2 and Tier 3 standards for new nonroad compression-ignition engines of 50 hp and greater not including recreational marine engines greater than 50 hp; and
- Tier 4 emissions standards for new nonroad compression-ignition engines above 50 hp, and reduced nonroad diesel fuel sulfur levels.

Modeling by the WRAP indicates these "on-the-books" rules will improve visibility by 0.1 deciviews in the 20% worst day at TRNP and 0.2 deciviews at LWA.

C. Determine What Additional Control Measures Would be Reasonable Based on the Statutory Factors and Other Relevant Factors

See Section 9.5 and 9.6.

D. Estimate Through the Use of Air Quality Models the Improvement in Visibility that Would Result From the Implementation of the Control Measures Found to be Reasonable

See Section 9.5.

E. Establish the Reasonable Progress Goals

See Section 9.7.

9.5 Additional Controls

9.5.1 Point Sources Contributing to Visibility Impairment in the North Dakota Class I Areas

In determining reasonable progress goals for any Class I Federal area, 40 CFR 51.308(d)(1)(i)(A) requires a state to consider the costs of compliance, the time necessary for compliance, the energy and non-air quality environmental impacts of compliance, and the remaining useful life of any potentially affected sources, and include a demonstration showing how these factors were taken into consideration in selecting the goal.

In determining the cost of compliance for individual sources or source categories potentially subject to emission limitations, the following steps are suggested:

A. Identify the emission units to be controlled.

B. Identify the design parameters for emission controls, and

C. Develop cost estimates based upon those design parameters.

The Guidance for Setting Progress Goals under the Regional Haze Program states “it is not necessary for you to reassess the reasonable progress factors for sources subject to BART for which you have already completed a BART analysis.”

Cost of Compliance

Step 1: **Identify Emission Units to be Controlled**

The Department has identified sulfur dioxide and nitrogen oxides as the primary pollutants that are emitted by stationary point sources that contribute most of the visibility impairment. Particulate emissions from stationary sources have very little impact on visibility in North Dakota (see Figures 6.5 and 6.6) and represent only 1% of the total PM emissions in 2002 (see Table 6.1). Therefore, PM emissions from point sources were not evaluated under this section.

Under BART, it was determined that no additional controls were required for the largest sources of PM, the electric utility steam generating units. Primary sulfuric acid mist emissions are also a very small contributor to visibility impairment. The sources that were subject to BART, the largest emitters of sulfuric acid mist, were evaluated for emissions of this pollutant. Because of the small impact of sulfuric acid mist on visibility, sulfuric acid mist was not included in the reasonable progress analysis.

To identify point sources in North Dakota that potentially affect visibility in Class I Federal areas, the list of sources subject to Title V permitting requirements was established as the starting point. This represents more than 99% of the sulfur dioxide emissions from all point sources in North Dakota that have an operating permit (Title 5 or Minor Source Operating Permit) and greater than 98% of the nitrogen oxides emissions based on 2007 data. The sources subject to BART were also eliminated from the list as suggested by EPA guidance. The Department has included all controls on BART sources that have a reasonable cost. Any controls rejected under BART would also be rejected under the four factors for determining reasonable progress. Although sources were excluded from this analysis, all sources, including sources subject to BART, will be reviewed during future planning periods.

To further evaluate the list of sources, the actual emissions from the source were compared to the distance the source is located from the nearest Class I Federal area. The Department has determined from previous BART modeling that particulate matter emissions from point sources have a very small contribution to visibility impairment in the Class I areas. Therefore, only emissions of nitrogen oxides and sulfur dioxide were evaluated in this comparison. The Department initially used the average of the 2000-2004 emission rate for this analysis. The emission rate (Q) in tons per year was divided by the distance (D), in kilometers, to the nearest Class I area. A value of Q/D greater than 10 was chosen as a point for further evaluation of those sources. A Q/D of greater than 10 was chosen based on the FLM's proposed FLAG guidance amendments initial screening criteria for sources that may affect air quality related values. In addition, EPA in the preamble to the BART Guideline states, "Our analyses of visibility impacts from model plants provide a useful example of the type of analyses that might be used to exempt categories of sources from BART. Based on our model plant analysis, EPA believes that a State could reasonably choose to exempt sources that emit less than 500 tons per year of NO_x or SO_2 (or combined NO_x and SO_2), as long as they are located more than 50 kilometers from any Class I area; and sources that emit less than 1000 tons per year of NO_x or SO_2 (or combined NO_x and SO_2) that are located more than 100 kilometers from any Class I area." EPA's criteria is equivalent to a Q/D of 10. For all sources, except EGUs, the total SO_2 and NO_x emissions from the facility were used and no distinction was made for individual units. EGU's were separated by units because they can act as standalone facilities while other process units cannot.

Table 9.4
North Dakota Title V Sources Q/D Analysis

Permittee	Plant	$SO_2 + NO_x$ 2000-2004 Average (tons)	Nearest Class I Area	Distance to Nearest Class I Area (km)	Nearest Q/D (tons/km)

The Northern Border Pipeline Company Compressor Station No. 4 is powered by a natural gas turbine. In 2005, Northern Border replaced this turbine with a lower emitting turbine. From 2006-2008, the average nitrogen oxides plus sulfur dioxide emissions were 118 tons per year for a Q/D of 6.6. Because of the installation of the lower emitting turbine, this facility was eliminated from consideration of additional controls during this planning period.

The Tesoro Refining and Marketing Company's Mandan Refinery is subject to a Consent Decree which requires substantial emissions reductions. Since the baseline period, Tesoro has installed a wet scrubber and wet ESP to control sulfur dioxide emissions from the catalytic cracking unit, installed new lower emitting furnaces at the alkylation unit and are installing low NO_x burners in the boilers. From 2006-2008, the total sulfur dioxide and nitrogen oxides emissions from the facility averaged 1,438 tons per year for a Q/D of 7.9. This ratio is expected to decline significantly when the modifications to the boilers are brought on-line. Because of these changes, this facility was not considered for additional controls during this planning period.

Since the baseline period, Bear Paw Energy has been injecting the acid gas into deep wells at their Grasslands and Lignite Gas Plants. This injection eliminates all sulfur dioxide emissions except for those emissions due to a malfunction of the injection equipment. When a malfunction occurs, the acid gas goes to a flare which will emit sulfur dioxide. In 2007, total emissions of sulfur dioxide and nitrogen oxides (including malfunctions) from the Grasslands Gas Plant were 274 tons for a Q/D of 9.8. Without malfunction emissions, the total was 52 tons for a Q/D of 1.4. At the Lignite Gas Plant, the 2007 total sulfur dioxide and nitrogen oxides emissions (including malfunctions) were 121 tons for a Q/D of 8.1. Without malfunction emissions, the total was 48 tons for a Q/D of 3.2. These malfunctions are generally unplanned, short duration-episodes (a few hours) with very high SO_2 emission rates that vary from year-to-year. Controlling emissions during these malfunctions is not feasible and the acid gas is flared to prevent the release of high concentrations of hydrogen sulfide. These two sources were eliminated based on their change to acid gas injection which greatly reduces sulfur dioxide emissions. The requirement to inject their acid gas is included in the Title V Permit to Operate for each facility.

Petro Hunt’s Little Knife Gas Plant emissions include those emissions associated with malfunctions. If the malfunction emissions are eliminated, the average sulfur dioxide and nitrogen oxides emission rate for 2000-2004 is 337.7 tons for a Q/D of 8.7. The Little Knife Gas Plant has seen reduced operations recently due to a decline in gas volume. New oil wells that are being drilled are generally producing from the Bakken formation which contains sweet natural gas. In 2008, SO_2 plus NO_x emissions (including malfunctions) totaled 295 tons for a Q/D of 7.6. Because of the small amount of emissions and the expected decline in the future, the Little Knife Gas Plant was eliminated from consideration for additional control during this planning period.

All of the facilities that were eliminated from consideration for additional air pollution controls will be considered and reviewed again during future planning periods.

After review of the sources in Table 9.4, the following sources in Table 9.5 were considered for additional controls during this planning period:

Table 9.5
Sources Evaluated for Additional Control

Source	Owner	Unit	Type	Capacity
Antelope Valley Station	Basin Electric Power Coop.	1	EGU	435 MWe
Antelope Valley Station	Basin Electric Power Coop.	2	EGU	435 MWe
Coyote Station	OtterTail Power Co.	Main Boiler	EGU	450 MWe

Tioga Gas Plant	Hess Corp.	3	Sulfur Recovery Unit	225 LTPD
Tioga Gas Plant	Hess Corp.	C1-A to F	Compressor Engines	1920-2350 BHp each

Step 2: Identify the Design Parameters for Emission Controls

All of the source units identified for possible additional air pollutant control are equipped with varying degrees of air pollution control equipment, as shown in Table 9.6.

Table 9.6
Remaining Sources Existing Conditions

Source	Pollutant	Control Equipment	Current[a] Emission Rate	Current[a] Control Efficiency (%)
AVS 1	SO_2 NO_x	Spray Dryer OFA	0.36 lb/10^6 Btu 0.37 lb/10^6 Btu	77 --

[a] Based on 2005-2007 data

[b] Based on 2007 data

Work is currently underway to increase the efficiency of the spray dryers at AVS I and II. This work is being done because of an expected increase in the sulfur content of the coal used at the facilities. The increase in efficiency is expected to approach 90% which the Department considers the limit of spray dryer efficiency. Even though the efficiency will be increased, no reduction in emissions is expected because of the higher sulfur coal. Because upgrades of the spray dryers are already in progress, this option was not considered at AVS I or II during this planning period. At the Coyote Station, upgrades to the spray dryer would require a detailed engineering analysis to determine if improvements are possible. For this planning period, replacing the spray dryer is evaluated. Any upgrades to the spray dryer (if possible) will produce less emissions reductions and less visibility improvement when compared to a new wet scrubber. This source will also be reevaluated during future planning periods to determine if additional controls are reasonable.

The boilers at the Great Plains Synfuels Plant (GPSP) are equipped with an ammonia reagent wet scrubbing system followed by a wet electrostatic precipitator. This system is achieving 96-97% removal of sulfur dioxide from the flue gas. This removal efficiency is comparable to BACT or BART for industrial boilers of this size. Therefore, sulfur dioxide controls for these boilers were not evaluated further during this planning period.

The following control options were reviewed for possible implementation at the remaining sources:

Table 9.7
Control Options Evaluated

Source	Pollutant	Control Considered	Estimated Control Efficiency (%)
AVS 1 and 2	SO_2	New Wet Scrubber	95
	NO_x	LNB	30-75
		SNCR	30-75
		SCR w/Reheat	40-90[c]
Coyote	SO_2	New Wet Scrubber	95
	NO_x	ASOFA	40
		SNCR	30
		ASOFA + SNCR	50-60
		SCR w/Reheat	40-90[c]
Tioga Gas Plant SRU	SO_2	Tail Gas Cleanup	99.8-99.98[a]
1920 BHp Engines	NO_x	SCR	80-90[c]
		Engine Remanufacture	80-90
		Air-Fuel Ratio Controller	10-40
		Ignition Timing Retard	15-30
2350 BHp Engines	NO_x	SCR	33-67
GPSP – Boilers	NO_x	SNCR[b]	30-40
		SCR[b]	40-90[c]

[a] Overall efficiency of the sulfur recovery unit and tail gas cleanup unit. BACT determinations range from 99.8% for existing units to 99.98% for new units.
[b] The Department has concerns whether SCR and SNCR are technically feasible for the GPSP (see DGC's comments in Appendix I).
[c] The Department considers 90% efficiency reasonable for new installations and 80% reasonable for retrofits.

Step 3: Develop Cost Estimates Based on the Design Parameters

The available control options were evaluated by WRAP's contractor EC/R Incorporated. The report on this evaluation is found in Appendix I.1. The cost for the wet scrubber at the Coyote Station was adjusted to represent the gross capacity of the facility (450 MWe vs 427 MWe) which is larger than EC/R evaluated. Also, the removal efficiency for a new wet scrubber was adjusted from 90% to 95%. The costs associated with the various control technologies are shown in Table 9.8.

The cost effectiveness ($/ton) for new scrubbers at AVS I & II and Coyote Station is higher than at the BART sources that are not equipped with scrubbers. Because AVS and Coyote Station are already equipped with spray dryers, the cost effectiveness is higher because less sulfur dioxide will be removed than at the unit without a scrubber. The following control options were found to have an excessive cost effectiveness:

AVS 1 & 2 – Wet scrubber; SCR w/reheat; and LNB + SCR w/reheat
Coyote – SCR w/reheat and ASOFA + SCR w/reheat
Tioga Gas Plant – Tail Gas Cleanup
DGC – SNCR and SCR

The SRU at the Tioga Gas Plant is currently operating at less than 45% of its rated capacity. It is expected that the amount of sulfur recovered and emissions from the tail gas incinerator will continue to decline due to a decline in sour gas production in the area the Tioga Gas Plant serves. Most new gas produced comes from the Bakken formation which is sweet gas.

The Department has concerns whether SCR or SNCR can be successfully applied at the GPSP (see DGC comments in Appendix I). Pilot scale testing may be necessary to determine the technical feasibility of SCR or SNCR for the boilers which produce a flue gas with a high carbon dioxide and sulfur concentration.

Therefore, these control technologies were not evaluated further.

For the most efficient control options for which the cost effectiveness (as described in Table 9.8) was considered reasonable on a $/ton basis, the 2018 projected emissions were modeled by the NDDoH to determine the source-specific improvement in visibility. Cumulative modeling was conducted using the procedures (default EPA methodology), hybrid modeling system, and baseline and future (2018) emissions inventories as described in Section 8.5. The

Table 9.8
Control Options Cost

Source	Unit	Pollutant	Control Technology	Total Annualized Cost ($)	Control Efficiency (%)	Emissions Reduction (tpy)	Cost Effectiveness ($/ton)
AVS	1	SO_2	New Wet Scrubber	32,170,000	95	6,780	4,745
		NO_x	LNB	2,280,000	51	3,889	586

		NO_x	LNB	2,280,000	51	3,450	661
			SNCR	8,960,000	40	2,706	3,311
			LNB+SNCR	11,240,000	65	4,397	2,556
			SCR w/reheat[1]	44-63.2 million	80	5,411	8,132-11,680
			LNB + SCR w/reheat	46.3-65.5 million	90	6,087	7,606-10,761
Coyote	1	SO_2	New Wet Scrubber	33,280,000	95	12,835	2,593
		NO_x	ASOFA[1]	1,284,000	40	5,223	246
			SNCR	8,520,000	40	5,223	1,631
			ASOFA & SNCR[1]	11,245,000	55	7,182	1,566
			SCR w/reheat[1]	45.3-65.1 million	80	10,446	4,337-6,232
			ASOFA + SCR w/reheat	46.6-66.4 million	90	11,752	3,965-5,650
Tioga Gas Plant[3]	SRU	SO_2	Tail Gas Clean Up[2]	5,800,000	99.8	1,018	5,697
	1920 Hp Engines	NO_x	Air Fuel Ratio Controller	260,000	25	305	852
			Ignition Timing Retard	140,000	22	268	522
			LEC Retrofit	560,000	85	1,035	541
			SCR	1,600,000	80	974	1,643
	2350 Hp Engines		SCR	500,000	50	34	1,471
DGC	Boilers (each)		SNCR	1,690,000	30	259	6,525
			SCR	5,505,000	80	670	8,216

Notes: A) The Department does not consider high dust SCR to be technically feasible for North Dakota lignite (see BART analysis in Section 7). The uncertainties associated with designing an SCR system because of the high sodium and potassium submicron aerosols in the flue gas, even after the air pollution control equipment, dictates the use of the high end of the SCR cost range.

B) Replacement of the compressor engines with electric motors is not technically feasible since the compressor cylinder connecting rods are an integral part of the engines crankshaft.

[1] Based on BART cost estimate for Leland Olds Unit 2 and Minnkota 1 & 2 shared cost estimate.

[2] Based on an overall efficiency of the SRU and tail gas cleanup unit of 99.8%.

[3] Reductions are the total for all engines with the specified horsepower rating.

future emissions inventory was modified to reflect the control technology for each candidate source (AVS 1 EGU, AVS 2 EGU, Coyote EGU, and Tioga Gas Plant), and modeling was conducted using the revised future inventory for one source at a time. The reasonable progress goals in 40 CFR 51.308(d)(1) requires improvement in the most impaired days. The most impaired days are defined in 40 CFR 51.301 as the average visibility impairment for the twenty percent days with the highest amount of visibility impairment. Therefore, modeling addressed the 20% worst days for both TRNP and LWA Class I areas. The results for each candidate source were compared with the results using the unmodified future emissions inventory (Table 8.11) to determine the additional visibility improvement due to the tested control technology.

Modeled visibility improvement, for each candidate source/technology, is provided in Table 9.9. The single source controlled emissions (modeled tons per year) and annualized cost effectiveness (dollars per deciview) are also reported in the table. Reported visibility improvement (in deciviews) reflects the higher value for either TRNP or LWA. Note that visibility improvement reported for Coyote represents the total for both SO_2 and NO_x control technologies, and the improvement reported for the Tioga Gas Plant represents the total for all 1920 and 2350 horsepower engines. As shown in the table, predicted visibility improvement is very marginal for all candidate sources/technologies, and consequently cost per deciview is very high.

Table 9.9
Visibility Improvement and Cost Effectiveness

Source	**Pollutant**	**Control Technology**	**Emissions (TPY)**	**Visibility Improvement (dv)***		**Visibility Improvement (%)*****		**Cost Effectiveness ($/dv)****
				TRNP	**LWA**	**TRNP**	**LWA**	
AVS 1	NO_x	LNB+SNCR	2,358	0.005	0.01	0.03	0.05	1,124,000,000
AVS 2	NO_x	LNB+SNCR	2,144	0.005	0.01	0.03	0.05	1,124,000,000

*The less efficient technologies evaluated would provide less improvement.
**Based on the maximum visibility improvement (per source) at any Class I area in North Dakota.
***Improvement (%) from baseline conditions.

Time Necessary for Compliance

Up to 6.5 years after SIP approval is necessary to achieve compliance (see EC/R report in Appendix I.1). Additional time may be necessary if normal maintenance outages do not coincide with the projected schedule. It is anticipated that all required changes could be implemented by 2018 depending on the date of approval of this SIP. It is not anticipated that any of the remaining sources will be retired prior to 2018.

Energy and Non-Air Impacts

All of the control technologies for the various sources will consume energy (see EC/R report in Appendix I.1). In the case of the Antelope Valley Station and the Coyote Station, this would mean less electricity available for sale. The enhancement of the sulfur dioxide scrubbing system at the Coyote Station would increase the amount of solid waste generated (ash/$CaSO_4$) which must be handled and properly disposed. However, there are no non-air impacts identified that would preclude additional reductions of SO_2 or NO_x from the facilities.

Remaining Useful Life of the Source

The following table lists the expected remaining useful life of the remaining sources.

Table 9.10
Remaining Useful Life

Source	Unit	Startup Date	Estimated Remaining Useful Life (yrs)
AVS	Unit 1	1983	20-40
	Unit 2	1985	20-40
Coyote	Unit 1	1981	20-40
Tioga Gas Plant	Engines	1954	5-40

The engines at the Tioga Gas Plant are now 55 years old. Engines D and F have recently been refurbished. It is expected that the other engines could be refurbished which will extend their remaining useful life an indefinite period. Other than the engines at the Tioga Gas Plant, the remaining useful life of the affected sources would not preclude additional air pollution controls.

Reasonable Progress Goals - Required Controls for Point Sources

EPA has stated in their Guidance for Setting Reasonable Progress Goals Under the Regional Haze Program (June 1, 2007) “in assessing additional emissions reduction strategies for source categories or individual, large scale sources, simple cost effectiveness based on a dollar-per-ton calculation may not be as meaningful as a dollar per deciview calculation.” It has been determined that requiring additional controls, beyond BART, on existing point sources will not substantially improve visibility in the Class I Federal Areas. The maximum combined improvement based on the Department’s cumulative modeling for the average of the 20% worst days is 0.11 deciviews at LWA and 0.03 deciviews at TRNP for the most efficient control options for each source that is cost effective. This amounts to a 0.17% improvement at TRNP over the baseline condition for the most impaired days and 0.56% improvement at LWA. Other less efficient control technology options would provide substantially less visibility improvement in the Class I areas. The total capital cost to achieve this improvement is approximately 243 million dollars with an annualized cost of approximately 68 million dollars. Based on the data in Tables 9.8 and 9.9, the cost effectiveness is over 618 million dollars per deciview of improvement at LWA and 2.3 billion dollars per deciview at TRNP. For all sources evaluated individually and cumulatively, the cost ($/dv) is considered excessive. Therefore, no additional controls are proposed for these non-BART sources during this planning period. However, conditions at the plants and control technologies may change in the future. Therefore, all of these sources will be reevaluated during future planning periods.

9.5.2 Agricultural Tillage Operations

North Dakota has approximately 38 million acres of farm and ranch land or approximately 86% of the State’s area. Working the land can contribute significant amounts of fugitive and windblown dust. The WRAP has estimated that emission sources in North Dakota put more than 420,000 tons of particulate matter into the atmosphere in 2002. Fugitive dust from agricultural activities and windblown dust from farm fields were a major contributor to these emissions. Although there was a large amount of particulate matter emissions, the effect on visibility in the North Dakota Class I areas was small, but not insignificant, as shown in Figures 9.1 and 9.2 from the WRAP’s TSS. At TRNP, coarse mass and soil (fine mass) combined to contribute approximately 11% of the total extinction during the 20% worst days of the baseline period. At the Lostwood Wilderness Area, approximately 7% of the total extinction was due to coarse mass and soil. North Dakota sources contributed approximately 45 percent of the PMF and PMC at TRNP and approximately 30 percent at LWA during the 20 percent worst days in 2000-2004 (based on WRAP’s weighted emissions potential analysis).

Figure 9.2
TRNP Species Apportionment
20% Worst Days

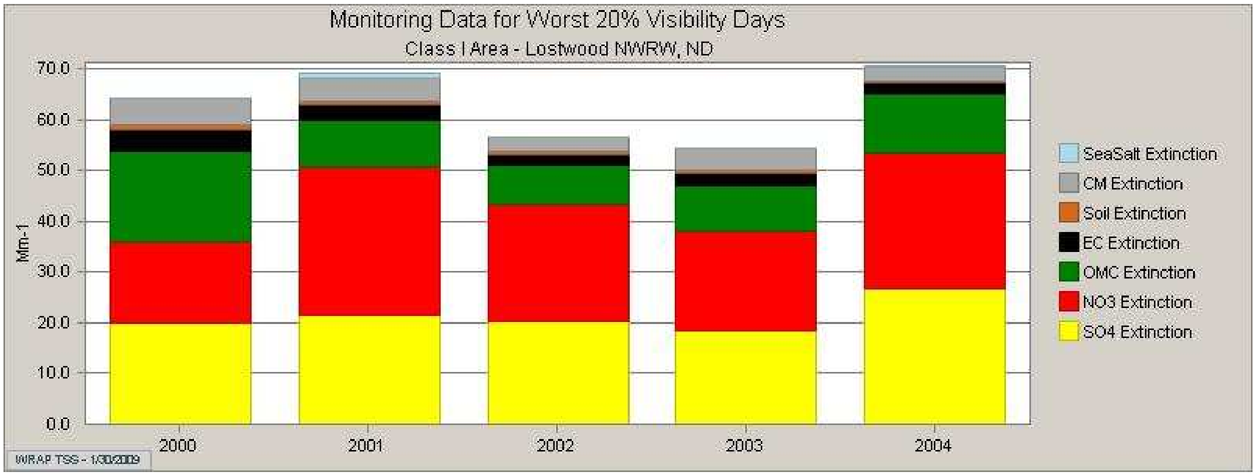

Figure 9.3
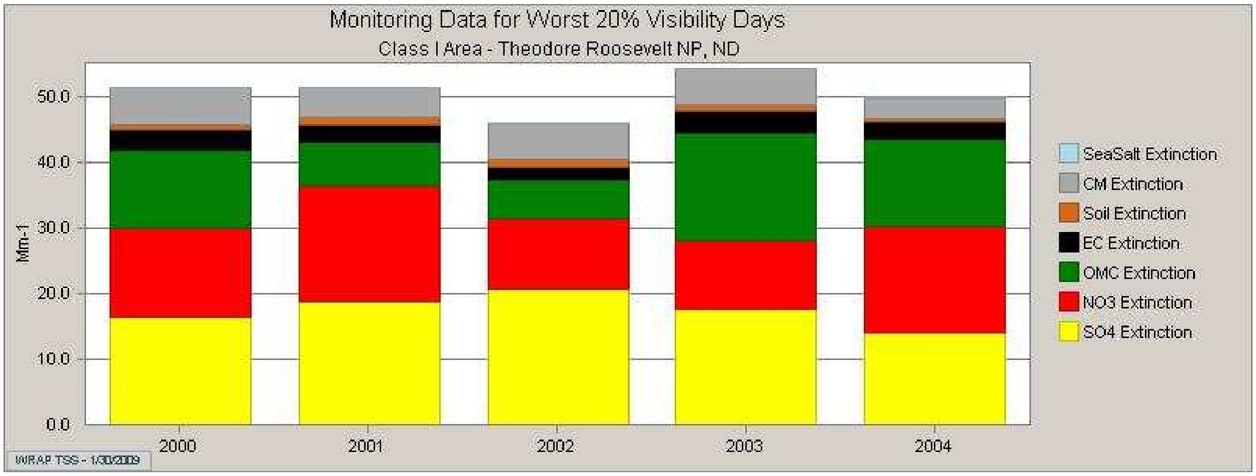
LWA Species Apportionment
20% Worst Days



The practice of conservation tillage is becoming more popular in North Dakota. The Conservation Technology Information Center (CTIC) in West Lafayette, Indiana specifies that 30 percent or more of crop residue must be left after planting to qualify as a conservation tillage system. Some specific types of conservation tillage include Minimum Tillage, Zone Tillage, No-till, Ridge-till, Mulch-till, Reduced-till, Strip-till, Rotational Tillage and Crop Residue Management. According to the Crop Residue Management survey conducted by the CTIC, total conservation tillage in North Dakota increased from 28% to 39% of total planted acres from 1998 to 2004. In general, conservation tillage practices are used more in the western part of the

State (near the Class I areas) than in the eastern part of the State due to the more arid conditions, thinner topsoil and the types of crops grown. In 2006, 77% of the crop acreage in Williams County in Western North Dakota was planted using conservation tillage practices versus 28% in Sargent County (southeastern North Dakota). It is expected that conservation tillage practices will increase over the planning period. Higher fuel, equipment and labor costs will entice farmers to reduce tillage. Other added benefits include better soil moisture storage and eventually less fertilizer usage. Additionally, conservation tillage practices, such as No-till farming, help sequester carbon which can be sold as carbon credits. As carbon dioxide controls are instituted, the money earned by farmers for carbon sequestration will also provide an incentive for conservation tillage practices.

Given the small contribution of coarse mass and soil to total extinction and that conservation tillage practices are increasing, the Department concludes there is no need to implement controls on farming practices. As outlined earlier, free market incentives should increase conservation tillage which will reduce emissions. The trend of increased conservation tillage practices from 1998-2004 is expected to continue during the planning period.

Sources in this category are subject to NDAC 33-15-17-02.6 which requires agricultural activities be managed in a manner as to minimize dust from becoming airborne. The Department will reevaluate the source category in future planning periods to determine if additional controls are required.

9.5.3 Smoke Management for Agricultural, Forest Management and Prescribed Burning

It has been determined that no additional rules or controls for smoke management are required (see Section 10.6.5). The worst short-term visibility degradation that occurs in the Class I areas is caused by prescribed burning conducted by the Federal Land Managers. In 2005, the entire LWA (5,577 acres) was burned by the FLM. In addition, 3,579 acres in the immediately adjacent Lostwood Wildlife Refuge were burned on 7 different days. Although the State of North Dakota recognizes the position of the FLMs that prescribed burning is necessary to maintain a healthy ecosystem, it must also be recognized that the actions of the FLMs that affect visibility in the Class I areas must be considered when evaluating controls for others that use prescribed burning (e.g., farming, road maintenance, etc). No additional smoke management requirements are proposed in this planning period. However, the Department will reevaluate this source category during future planning periods to determine if additional regulation is required.

9.5.4 Reserved

9.5.5 Oil and Gas Exploration and Production

Oil and natural gas production in North Dakota is generally limited to the western one-third of the State. In September 2009, there were 4,348 operating wells that produced approximately 238,000 barrels of oil per day. This is in contrast to states like Wyoming that has approximately

45,000 producing oil and gas wells and Colorado which has approximately 40,000 active wells. The primary difference is that North Dakota does not have any coal bed methane (CBM) wells. The lack of CBM wells means there are much fewer pumps, compressors and gas processing plants needed even though North Dakota produces more oil than either of these states. The baseline SO_2 and NO_x emissions from area oil and gas sources are estimated at less than 5000 tons per year of each pollutant (see Table 6.1).

North Dakota's oil production is highly dependent on the price of oil. Several peaks in production (i.e. 1996 and 1983) have been achieved only for production to drop severely (i.e. 42% from 1983 to 2003) and then increase as the price of oil increases. Several projections have been made regarding the amount of oil that will be produced in the future, the number of wells that will be producing and the number of drilling rigs that will operate in the State. All of these projections are highly speculative because of the volatility of oil prices. The price of North Dakota crude oil reached a high of approximately $127 per barrel in 2008 and dropped to as low as $25 per barrel in 2009. The number of drilling rigs also dropped dramatically from a high of 92 in November 2008 to 35 in May 2009. WRAP has projected a 4-5 fold increase in NO_x emissions from oil and gas activities by 2018. Although emissions may increase this amount during the planning period, the North Dakota Oil and Gas Division of the State Industrial Commission believes that emissions will decrease by 2018 to a level that is 2.0 to 2.5 times the baseline emission rate. The Oil and Gas Division believes that activity associated with the major oil producing formation (Bakken formation) will be decreasing by 2018 with a peak during this planning period. However, any estimate of future activity is suspect because the future of oil prices is unknown. Because current estimates of future oil and gas activity, and emissions from that activity, are very questionable, the Independent Petroleum Association of Mountain States (IPAMS) is sponsoring development of a third, or Phase III, inventory of emissions from the Williston Basin in North Dakota. This inventory is not complete and available for this planning period. Because of the serious flaws in the Phase I and Phase II inventories, the Department believes that the Phase III inventory is necessary for any planning activities for oil and gas emissions in North Dakota.

A Q/D type analysis does not work well for oil exploration or production facilities. These individual facilities generally have very low sulfur dioxide and nitrogen oxides emissions. However, when the facilities emissions are aggregated, there may be significant impact on visibility in a Class I area. The Q/D analysis in 9.5.1 included the larger compressor stations and natural gas processing plants (sources subject to Title V). North Dakota also permits minor oil and gas sources including small compressor stations (greater than 500 Hp), natural gas processing plants and tank batteries. The Q/D analysis indicates that only the larger facilities (i.e. larger Title V sources) have a significant impact on visibility in North Dakota Class I areas. Sulfur dioxide emissions from future oil and gas activities are not a concern because most new oil and gas production is from the Bakken formation which contains sweet (negligible sulfur content) oil and gas. In addition, engines will be required by Federal rule to use ultra low sulfur gasoline and diesel fuel. Nitrogen oxides emissions are the primary concern. These will emanate from vehicles, drilling rig engines, glycol dehydrators, flares, compressor engines, and other combustion sources. Stationary engines are subject to a number of New Source Performance Standards (NSPS) and Maximum Achievable Control Technology (MACT) standards which will help limit NO_x emissions. The EPA has also promulgated a 1-hour

NAAQS for NO_2. North Dakota had a 1-hour NO_2 AAQS set at 100 ppb until December of 1994. The new NAAQS is slightly more stringent than the former SAAQS for NO_2. The Department's experience indicates that oil and gas facilities will have to limit NO_x emissions through the use of control devices such as catalytic convertors on engines or low NO_x burners at heater/treaters or glycol dehydration unit boilers. Particulate emissions from oil and development and production are not expected to change appreciably from the baseline emission rate. Emissions from the production site are mostly from development of the well pad which is of short duration. Vehicle traffic would be the only other significant source of particulate matter emissions. Once the well is developed, these emissions should decrease substantially.

The WRAP, through its contractor EC/R Incorporated, has prepared an analysis of the four factors for reasonable progress for oil and gas exploration and production operations (see Appendix I.2, Section 4). Given the small amount of baseline emissions and the uncertainty of the projection of future emissions, the Department proposes no additional controls for oil and gas exploration and production facilities at this time. The Department will continue to track oil and gas emissions and will take into consideration the Phase III inventory when it is available. During the mid planning period review, the Department will review oil and gas emissions and take action if necessary. Oil and gas emissions will also be addressed during subsequent planning periods.

9.6 Visibility Modeling and Weight of Evidence

As detailed in Section 8, modeling has been conducted by both WRAP and the NDDoH to estimate visibility improvement resulting from implementation of BART and other reasonable control measures. Modeling addressed TRNP and LWA Class I areas in North Dakota. Visibility improvement modeling accounted for the cumulative effect of BART controls, and other growth and control factors. Modeling was initially conducted using the default EPA methodology, and results were compared with the default EPA uniform rate of progress (URP). Because results based on the default EPA methodology did not achieve compliance with default URP targets for 2018, additional modeling was conducted by the NDDoH for various weight of evidence options.

Supplemental weight of evidence modeling analyses conducted by the NDDoH, which have a bearing on the selection of reasonable progress goals, include the following.

1) Discounted the impact of international (in this case, Canadian) source visibility-affecting emissions on North Dakota Class I areas.

2) Discounted the impact of visibility-affecting emissions from all sources located outside of North Dakota, on North Dakota Class I areas.

3) Used the complete emissions inventory for the default EPA method, but zeroed out future SO_2 and NO_X emissions from all sources located in North Dakota (i.e., assumed 100 percent future control of all SO_2 and NO_X emissions in North Dakota), to determine progress with respect to the default glide path for North Dakota Class I areas.

4) Conducted modeling to determine the incremental visibility improvement, and cost effectiveness ($/dv), of enhanced control technology at AVS generating station, Coyote generating station, and Tioga Gas Plant (Section 9.5.1).

Modeling results for the default EPA methodology and weight of evidence analyses are summarized in Table 9.11. In the table, Scenarios 1 and 2 represent the implementation of default EPA methodology by WRAP and NDDoH, respectively. Scenarios 3, 4, and 5 reflect the first three NDDoH weight of evidence analyses outlined above. Results for the fourth weight of evidence analysis (above) were provided in Table 9.9. Results in Table 9.11 are presented as the projected percent of the 2018 target.

From results of visibility modeling based on standard EPA methodology, and results of the weight of evidence analyses, the following conclusions are applicable to the establishment of reasonable progress goals for North Dakota Class I areas.

1) The uniform rate of progress goal for 2018 for 20% worst days will not be achieved at either TRNP or LWA.

2) Apportionment modeling results indicate the contribution of sources located outside of North Dakota is much greater than the contribution of in-state sources to 20% worst day visibility at TRNP and LWA (both baseline and 2018).

3) Though the addition of proposed BART controls substantially decreases the visibility impact of North Dakota EGUs, these EGUs comprise only a small component of total 20% worst day impact at TRNP and LWA.

Table 9.11
NDDoH Visibility Modeling Results 20% Worst Days
EPA Methodology and Weight of Evidence Analysis Summary

Scenario	Description	Class I Area	Projected Percent of 2018 Target
1	WRAP CMAQ Default EPA Methodology	TRNP	24.0
		LWA	16.7
2	NDDoH Hybrid Default EPA Methodology	TRNP	38.1
		LWA	26.7
3	NDDoH Hybrid Canada Sources Discounted	TRNP	50.0
		LWA	40.2
4	NDDoH Hybrid All Sources Other Than ND Discounted	TRNP	83.9
		LWA	59.6

Scenario	Description	Class I Area	Projected Percent of 2018 Target
5	NDDoH Hybrid Base Emission Inv = Default Future Emissions Inv = All ND SO_2 and NO_x Emissions set to zero	TRNP LWA	83.8 72.6

4) Compliance with 20% worst day URP 2018 targets at North Dakota Class I areas cannot be achieved through additional emissions reductions from North Dakota sources, alone. It will require significant additional visibility affecting emissions reductions from Canada, other western states and from sources located outside of the WRAP CMAQ modeling domain.

5) After discounting the impact of Canadian sources, significantly greater progress (50 percent greater) was demonstrated, relative to URP 2018 targets for North Dakota Class I areas, than modeling with the entire emissions inventory but the 20% worst day targets were still not achieved.

6) After discounting the impact of *all sources located outside of North Dakota*, even greater progress was demonstrated, relative to URP 2018 targets for North Dakota Class I areas, than modeling with Canadian sources discounted. However, 20% worst day targets were still not achieved.

7) After zeroing out all future SO_2 and NO_X emissions in North Dakota under default EPA methodology (emulating a 100 percent, unrealistic control of all sources), compliance with 20% worst day targets was still not achieved at North Dakota Class I areas.

8) The use of enhanced control technology at AVS generating station, Coyote generating station, and Tioga Gas Plant provides minimal incremental improvement in 2018 visibility (Table 9.9), and does not meaningfully change status with respect to 2018 visibility goals.

Given these conclusions based on modeling, it appears most of the visibility impact at North Dakota Class I areas is due to emissions from sources located outside the jurisdiction of the NDDoH. But regardless of the extent to which visibility-affecting sources located outside of North Dakota are discounted, compliance with URP targets cannot be achieved. Further, the use of enhanced control technology on additional candidate sources (Item 8, above) within jurisdiction of the NDDoH does not provide a meaningful improvement in terms of 2018 URP visibility goals. It is not realistic to expect significant additional controls (beyond BART or other current controls) will be implemented in states or Canadian provinces apart from North Dakota before 2018. From a modeling perspective, therefore, setting reasonable progress goals for 20% worst days to be consistent with 2018 modeling results for the default EPA methodology (Table 9.11) would seem most realistic.

9.7 Establish Reasonable Progress Goals

As indicated in Section 8, control of emissions from North Dakota sources has only a small effect on visibility conditions in the North Dakota Class I areas. The source apportionment (based on WRAP modeling) for the 20% worst days in the Class I areas indicates that sources outside of North Dakota contribute from 79-87% of the sulfate or nitrate which cause the greatest visibility impairment in the North Dakota Class I areas. The source region apportionment provided by WRAP is presented in Table 9.12 for the North Dakota Class I areas. Note that the WRAP modeled contributions for North Dakota sources in Table 9.12 are somewhat smaller than the contributions based on NDDoH modeling in Table 8.16. This is because the NDDoH approach incorporated a more realistic representation of point source plumes, resulting in higher predictions for North Dakota sources (and greater visibility improvement).

Table 9.12
Source Region Apportionment 20% Worst Days

Contributing Area	Class I Area			
	TRNP		LWA	
	SO_4	NO_3	SO_4	NO_3
North Dakota	21.1%	19.1%	17.9%	13.0%
Canada	28.3%	31.8%	45.9%	44.6%
Outside Domain	32.6%	17.9%	20.2%	14.0%
Montana	3.1%	15.0%	2.4%	9.3%
CENRAP	4.9%	2.5%	5.3%	5.1%
Other	10.5%	13.7%	8.3%	14.0%

An analysis was conducted to determine if the uniform rate of progress could be achieved in the North Dakota Class I areas by controlling sulfur dioxide and nitrogen oxides emissions from in-state sources (see Section 8.7.3.3). The results indicate the uniform rate of progress cannot be achieved by reductions in North Dakota alone. If all sulfur dioxide and nitrogen oxides emissions in North Dakota were completely controlled (zero emissions), only 72.6% of the uniform rate of progress for the 20% worst days would be achieved at LWA and only 83.8% at TRNP. Significant reductions of emissions from sources outside of North Dakota will be required in order to meet the uniform rate of progress for this planning period.

North Dakota can only require emission controls for sources within its boundaries. Because of the large contribution to visibility impairment from sources outside of North Dakota, any estimate of reasonable progress on a deciview basis is tenuous at best. Any increase in emissions from sources external to North Dakota could offset any improvement from the reduction of emissions at in-state sources. By 2018, North Dakota BART controls plus other regulatory requirements are expected to reduce in-state SO_2 emissions by more than 60% and NO_x emissions by more than 25%. Table 9.13 shows the projected change in emissions for North Dakota as well as surrounding states and Canada.

Table 9.13
Projected Change in Emissions
2002-2018
(%)

	South Dakota	Montana	Minnesota	Canada	North Dakota
SO_2	-35.7	-11.8	-28.8	-6.8	-60.0
NO_x	-17.9	-26.0	-39.4	-0.8	-25.3
OC	-6.1	-3.3	-5.3	22.7	-19.4
EC	-51.1	-16.6	-28.9	75.2	-52.3
PMF	2.2	7.5	-1.3	34.8	2.0
PMC	4.2	8.8	-4.4	33.8	3.5
NH_3	0.3	1.2	33.9	-31.9	-0.3
VOC	-0.5	-0.6	2.9	-1.2	1.1
CO	-17.0	-15.9	-20.8	-11.7	-27.4

Note: Based on WRAP's Case Plans 02d and PRP18b.

The reasonable progress goals based on the Department's hybrid modeling approach in Table 9.14 are established. The analyses conducted indicate there will be no degradation in the 20% best days. The Department's modeling results show that visibility in the 20% best days will improve 0.14 deciviews at TRNP and 0.09 deciviews at LWA.

Table 9.14
Reasonable Progress Goals

Class I Area	Baseline Visibility 20% Worst Days (dv)	2018 RPG[a] 20% Worst Days (dv)	2018 RPG[b] 20% Worst Days (dv)
TRNP	17.8	16.9	17.2
LWA	19.6	18.9	19.1

[a] Based on Department's hybrid modeling approach.
[b] Based on WRAP's modeling approach.

40 CFR 51.308(d)(1)(ii) requires the State to provide for public review an assessment of the number of years it would take to attain natural conditions if visibility improvement continues at the rate of progress selected by the State as reasonable. Achieving natural conditions will require the elimination of all anthropogenic sources of emissions. Given current technology, achieving natural conditions is an impossibility. Any estimate of the number of years necessary to achieve

natural visibility conditions would require assumptions about future energy sources, technology improvements for sources of emissions, and every facet of human behavior that causes visibility impairing emissions. The elimination of all SO_2 and NO_x emissions in North Dakota will not achieve the uniform rate of progress for this, or any future planning period. Any estimate of the number of years to achieve natural conditions is questionable because of the influence of out-of-state sources. The number of years required to achieve natural conditions based on the proposed reasonable goals are as follows:

Table 9.15
Time Necessary to Achieve Natural Conditions

Class I Area	Baseline Visibility	Natural Visibility	Improvement Rate this Planning Period	Years to Natural Conditions[a]
	20% Worst Days (dv)	20% Worst Days (dv)	20% Worst Days (dv/yr)	20% Worst Days
TRNP	17.8	7.8	0.06429	156
LWA	19.6	8.0	0.05000	232

[a]Based on the Department's hybrid modeling approach.

If the most efficient cost effective control options evaluated for Coyote Station, Antelope Valley Station and the Tioga Gas Plant were implemented, the number of years to reach natural conditions would be 151 years at the three units of TRNP and 201 years at LWA. Implementing additional controls at these sources will not significantly affect current visibility conditions or the amount of time necessary to achieve natural conditions.

10. Long -Term Strategy

10.1 Long -Term Strategy Requirements

40 CFR 51.308(d)(3) contains the requirements for the long-term strategy for regional haze. Each State listed in §51.300(b)(3) must submit a long-term strategy that addresses regional haze visibility impairment for each mandatory Class I Federal area within the State and for each mandatory Class I Federal area located outside the State which may be affected by emissions from the State. The long-term strategy must include enforceable emissions limitations, compliance schedules, and other measures as necessary to achieve the reasonable progress goals established by States having mandatory Class I areas. In establishing its LTS for regional haze, the State must meet requirements of §51.308(d)(3)(i) through (3)(v).

10.2 Consultation With Other States

40 CFR 51.308(d)(3)(i) requires “Where the State has emissions that are reasonably anticipated to contribute to visibility impairment in any mandatory Class I Federal area located in another State or States, the State must consult with the other State(s) in order to develop coordinated emission management strategies. The State must consult with any other State having emissions that are reasonably anticipated to contribute to visibility impairment in any mandatory Class I Federal area within the State.”

North Dakota emissions are reasonably anticipated to contribute to visibility impairment in mandatory Class I Federal areas in Minnesota (Boundary Waters Canoe Area Wilderness Area and Voyageurs National Park), Montana (Medicine Lake National Wildlife Refuge Wilderness Area and U.L. Bend National Wildlife Refuge Wilderness Area), and South Dakota (Badlands National Park and Wind Cave National Park). Reasonably anticipated to contribute is considered to be a contribution of more than 5 percent to the total extinction (B_{ext}) in the Class I area. North Dakota emissions impacts on Michigan Class I areas (Isle Royal National Park and Seney National Wildlife Refuge Wilderness Area) are small or less than 5 percent of the extinction (B_{ext}). North Dakota emissions impacts on other more distant Class I areas are considered minimal. See the discussion in Section 2.4.

The NDDoH has consulted with Minnesota and Michigan as a part of the Northern Class I Areas consultation group and Minnesota individually. As a result of the consultations, Minnesota sent a memorandum dated September 19, 2007 to North Dakota and other states impacting Minnesota Class I areas. Minnesota requested a response documenting these consultations have taken place to the satisfaction of North Dakota or detailing areas where additional consultation should occur. In those states Minnesota has identified as additional contribution states, they asked such states to respond with their agreement or disagreement with Minnesota’s determination of contributing states and the additional control strategies that will be evaluated. Minnesota’s memorandum and the NDDoH letter of response dated August 22, 2008 are attached in Appendix J.2.

The NDDoH has consulted with Montana and South Dakota through the WRAP which we are members and as needed individually. Additionally the NDDoH has consulted with EPA Region 8 in Denver concerning the Montana Class I areas as they are preparing a FIP at the request of the State.

Minnesota, Montana and South Dakota are the only states that have emissions that are reasonably anticipated to contribute to visibility impairment in the North Dakota Class I Federal areas.

Consultation is further addressed in Section 3, Plan Development and Consultation.

10.3 Demonstration of Inclusion of Measures to Obtain RPGs in Class I Areas

40 CFR 51.308(d)(3)(ii) requires "Where other States cause or contribute to impairment in a mandatory Class I Federal area, the State must demonstrate that it has included in its implementation plan all measures necessary to obtain its share of the emission reductions needed to meet the progress goal for the area. If the State has participated in a regional planning process, the State must ensure it has included all measures needed to achieve its apportionment of emission reduction obligations agreed upon through that process."

The control measures and emission limits incorporated in this SIP for the seven electrical generating units subject to BART combined with Federal mobile source and other rules will reduce North Dakota sulfur dioxide emissions by 60 percent, nitrogen oxide emissions by 25 percent, organic carbon emissions by 19 percent and elemental carbon emissions by 52 percent. These percent reductions compare favorably with the uniform rate of progress first planning period required overall reduction by 2018 of approximately 23.3 percent (14 years ÷ 60 years x 100 = 23.3 percent). In addition, existing State smoke management and fugitive dust control rules will adequately control emissions from agricultural and forest burning and construction activities. North Dakota has met and included in this SIP all measures needed to achieve its apportionment of emission obligations agreed upon by the members of WRAP. These emission reductions will provide North Dakota's share of emission reductions needed for Class I Federal areas in Minnesota, Michigan, Montana and South Dakota.

10.4 Documentation of the Technical Basis for Modeling, Monitoring and Emissions Information

40 CFR 51.308(d)(3)(iii) requires "The State must document the technical basis, including modeling, monitoring and emissions information, on which the State is relying to determine its apportionment of emission reduction obligations necessary for achieving reasonable progress in each mandatory Class I Federal area it affects. The State may meet this requirement by relying on technical analyses developed by the regional planning organization and approved by all State participants. The State must identify the baseline emissions inventory on which its strategies are

based. The baseline emissions inventory year is presumed to be the most recent year of the consolidated periodic emissions inventory."

North Dakota is a member of the Western Regional Air Partnership (WRAP) regional planning organization and relied on the modeling, monitoring and emissions information and technical analyses developed by WRAP.

The NDDoH relied on the use of CALPUFF for single source BART screening modeling, WRAP CMAQ and PSAT modeling, and its own hybrid CALPUFF modeling in its cumulative impact analyses. The BART modeling conformed to the requirements of the BART guidelines and is described in Section 7. The WRAP CMAQ and PSAT modeling and the NDDoH hybrid CALPUFF modeling conformed with EPA modeling guidelines and are described in Section 8.

The NDDOH relied on IMPROVE monitoring data as available on the WRAP TSS website and discussed in Section 4.

The NDDoH used the WRAP Plan02d emissions inventory for the baseline emissions year 2002 which reflects a composite interpretation of emissions for the base 2000-2004 period; and the WRAP CMAQ PRP18a (Preliminary Reasonable Progress 2018 Scenario A) emissions inventory which reflects projected year 2018 emissions. Case PRP18a represents base period emissions projected to 2018, accounting for estimates of the effect of BART controls, and assuming other growth and control factors. The Plan02d and PRP18a emissions inventories were used in modeling and are discussed further in Section 8. A later Case PRP18b emissions inventory was prepared by WRAP and included in Section 6, Sources of Visibility Impairment in North Dakota Class I Areas.

10.5 Identification of Anthropogenic Sources of Visibility Impairment

40 CFR 51.308(d)(3)(iv) requires "The State must identify all anthropogenic sources of visibility impairment considered by the State in developing its long-term strategy. The State should consider major and minor stationary sources, mobile sources and area sources."

The anthropogenic sources of visibility impairment are identified in Section, 6 Sources of Visibility Impairment in North Dakota Class I Areas.

10.6 Seven Factors That Must be Considered in Developing the LTS

40 CFR 51.308(d)(3)(v) requires "The State must consider, at a minimum, the following factors in developing its long-term strategy:

(A) Emission reductions due to ongoing air pollution control programs, including measures to address reasonably attributable visibility impairment;

(B) Measures to mitigate the impacts of construction activities;

(C) Emissions limitations and schedules for compliance to achieve the reasonable progress goal;

(D) Source Retirement and Replacement schedules;

(E) Smoke management techniques for agriculture and forestry management purposes including plans as currently exist within the State for these purposes;

(F) Enforceability of emissions limitations and control measures; and

(G) The anticipated net effect on visibility due to projected changes in point, area, and mobile source emissions over the period addressed by the long-term strategy."

10.6.1 Emission Reductions Due to Ongoing Air Pollution Control Programs

10.6.1.1 In-Place Programs

40 CFR 51.308(d)(3)(v)(A) requires an assessment of emission reductions due to ongoing air pollution control programs. Programs that are in place which will assist in reducing emissions and help achieve reasonable progress toward the national visibility goal include:

- Minor Source Permit to Construct Program (NDAC 33-15-14-02)
- Prevention of Significant Deterioration Program (NDAC 33-15-15)
- New Source Performance Standards (NDAC 33-15-12)
- Emission Standards for Hazardous Air Pollutants (NDAC 33-15-13)
- Emission Standards for Hazardous Air Pollutants for Source Categories (NDAC 33-15-22)
- Oil and Gas Production Facilities Rules (NDAC 33-15-21)
- Open Burning Requirements (NDAC 33-15-04)
- Fugitive Dust Control Requirements (NDAC 33-15-17)
- Control of Sulfur Dioxide from Point Sources (NDAC 33-15-06)
- Control of Particulate Matter (NDAC 33-15-05)
- Control Requirements for Organic Compounds Sources (NDAC 33-15-07)
- Heavy Duty Diesel Engine Standard (2007)
- Tier 2 Tailpipe Standards
- Large Spark Ignitor and Recreational Vehicle Rule
- Nonroad Diesel Rule
- Industrial Boiler MACT
- Combustion Turbine and Reciprocating Internal Combustion Engines NSPS and MACT Standards

The Federal programs are described in more detail in Section 2.5.

Some MACT standards have been vacated; however, it is expected that revised versions of these standards will be promulgated by EPA during the planning period. The Department will continue to operate a PSD program and take delegation of NSPS standards and major source MACT standards for source categories located in North Dakota. As older sources are replaced, the new applicable rules should reduce emissions.

North Dakota has implemented a reasonably attributable visibility impact (RAVI) protection program since 1987. The rules implementing this program are found in NDAC 33-15-19, Visibility Protection. The control strategy and monitoring strategy are found in Chapters 3 and 6 of the State Implementation Plan. The existing RAVI program, with the existing permitting and emissions rules listed above is compatible with those needed for regional haze and no revisions are needed or planned at this time. The NDDoH will address the periodic review and revision requirements of the long-term RAVI strategy as required by 40 CFR 51.306(c) and coordinate them with the regional haze LTS periodic progress reports required by 40 CFR 51.308(g).

10.6.1.2 Coyote Station

Once reductions are achieved from the BART sources, the Coyote Station will be the largest point source of NO_x emissions in North Dakota. The analysis in Section 9.5.1 indicates that additional controls on the Coyote Station are not reasonable at this time; however, the State, through recent discussions with Otter Tail Power Company, has reached an agreement whereby Otter Tail has committed to reduce NO_x emissions at the station. Otter Tail Power Company has indicated they will install equipment by July 1, 2018 in order to reduce NO_x emissions to 0.50 lb/10^6 Btu. This represents a 35% decrease from the 2008 emission rate of 0.77 lb/10^6 Btu and 26% from the baseline emission rate evaluated in Section 9.5.1. The reductions are expected to be achieved by installing separated over fire air. This will reduce annual NO_x emissions by 4,213 tons from the 2000-2004 baseline, a 32% decrease. The mechanism/requirement for reducing NO_x emissions is included in a Permit to Construct found in Appendix A. Although there will be NO_x reductions at this facility, it will be reevaluated during future planning periods to determine if additional emissions reductions are required.

10.6.1.3 Heskett Station Unit 2 – Reserved

10.6.2 Measures to Mitigate the Impacts of Construction Activities

40 CFR 51.308(d)(3)(v)(B) requires the consideration of measures to mitigate the impacts of construction activities. North Dakota regulates fugitive emissions by rule (NDAC 33-15-17). This rule states:

> "No person shall cause or permit fugitive emissions from any source whatsoever, including a building, its appurtenances, or a road, to be used, constructed, altered, repaired, or demolished; or activities such as loading, unloading, storing, handling, or transporting of material without taking reasonable precautions to prevent such emissions from causing air pollution as defined in section 33-15-01-04."

NDAC 33-15-17-02 also states in part:

> "No person shall emit or cause to be emitted into the ambient air from any source of fugitive emissions as specified in section 33-15-17-01 any particulate matter which:
>
> 2. Exceed the ambient air quality standards of chapter 33-15-02 at or beyond the property line of the source.
>
> 3. Exceed the prevention of significant deterioration of air quality increments of chapter 33-15-15 at or beyond the property line of the source for sources subject to chapter 33-15-15.
>
> 4. Exceed the restrictions on the emission of visible air contaminants of chapter 33-15-03, at or beyond the property line of the source.
>
> 5. Would have an adverse impact on visibility, as defined in chapter 33-15-19, on any class 1 federal area."

The Department requires permits for asphalt concrete plants and rock, sand and gravel plants which are generally associated with major construction projects. The Department requires notification of the relocation of asphalt plants in order to track the emissions from these facilities.

The Federal Class I areas in North Dakota are located in the western part of the State, generally away from the major population centers. These population centers are 40 - 500 km away from the Class I areas. Any construction in these areas should have little effect on visibility in the Class I areas because of the transport distance and prevailing winds will generally move the fugitive emissions in the opposite direction. Any impacts on visibility in a Class I area due to construction activities would most likely be associated with energy development including oil and gas well pad construction, compressor station construction and gas processing plant construction. Owners of sources subject to permitting requirements, including the above energy facilities, are subjected to fugitive dust control requirements included in the permit issued for the construction of the facility. In addition, all sources are subject to the requirements of NDAC 33-15-17. NDAC 33-15-17-03 lists the measures which are considered reasonable precautions for abating and preventing fugitive dust. These include:

1. Unpaved roads and unpaved parking areas. Abatement and preventive measures include but shall not be limited to frequent watering, addition of dust palliatives, detouring, paving, closure, speed control, or other means such as surface treatment with penetration chemicals (ligninsulfonates, oil, water, cutbacks, etc.) or methods of equal or greater effectiveness in reducing the air contaminant produced.

2. Demolition, wrecking and explosive detonation activities; earth and construction material moving, mining, and excavation activities.

a. Abatement and preventive fugitive particulate control measures include, but are not limited to:

    (1) Wetting down, including prewatering.

    (2) Landscaping and replanting with native vegetation.

    (3) Covering, shielding or enclosing the area.

    (4) Paving, temporary or permanent.

    (5) Treating, the use of dust palliatives and chemical stabilization.

    (6) Detouring.

    (7) Restricting the speed of vehicles on sites.

    (8) Preventing the deposit of dirt and mud on improved streets and roads.

    (9) Minimizing topsoil disturbance and reclaiming as soon as possible.

b. Sequential blasting be employed whenever or wherever feasible to reduce the amounts of particulate matter.

c. Such dust control strategies as revegetation, delay of topsoil disturbance until necessary, or surface compaction and sealing, be applied.

d. Haulage equipment be washed or wetted down, treated, or covered when necessary to minimize the amount of dust becoming airborne in transit and in loading.

e. Stockpile of materials be treated to prevent blowing or the material be contained in silos or other suitable enclosures.

f. Waste disposal sites be so operated and constructed as to prevent particulate matter from becoming airborne.

g. All conveyors, transfer points, crushers, screens, and dryers be so constructed, protected, or treated as to prevent particulate matter from becoming airborne.

h. These measures also be used during period when actual construction work is not being conducted, such as on weekends and holidays.

The construction of oil well pads are normally a one or two-day undertaking. The emissions are generally ground level emissions and do not travel very far. In general, compressor stations and gas plant construction are subject to the Permit to Construct program. These permits and rules will assure that construction activities will not adversely affect visibility in any Federal Class I area.

Emissions from construction activities including construction of oil well pads, compressor stations and gas plants will be reevaluated in future Regional Haze SIP planning periods since this has the potential to be a growing source category.

10.6.3 Emissions Limitations and Schedules for Compliance

40 CFR 51.308(d)(3)(v)(C) requires the State to consider emissions limitations and schedules for compliance to achieve the reasonable progress goal in developing its LTS.

Emissions limitations and schedules for the seven BART sources are found in Section 7, Best Available Retrofit Technology (BART). They are included in the Air Pollution Control Permit to Construct for each source. The permits found in Appendix D are incorporated as part of this SIP.

10.6.4 Source Retirement and Replacement Schedules

40 CFR 51.308(d)(3)(v)(D) requires the State consider any source retirement and replacement schedules in developing its LTS. The Department is not aware of any anticipated major source retirements or replacements. Replacement of existing facilities will be managed in conformance with the existing State Implementation Plan including the Prevention of Significant Deterioration program.

The 2018 modeling conducted by WRAP included three new power plants to be located in the State. It is now unlikely that two of these plants will be built. Thus the modeling results for 2018 are probably conservative. Construction of new power plants or replacement of existing plants prior to 2018 is unlikely.

10.6.5 Smoke Management Techniques for Agriculture and Forest Management

40 CFR 51.308(d)(3)(v)(E) requires the State to consider smoke management techniques for agriculture and forestry management purposes including plans as currently exist within the State for these purposes in developing its LTS. North Dakota has an area of approximately 68,994 square miles (44.16 million acres). Of this total, 26.5 million acres is crop land, 10.98 million acres is pasture/rangeland and 236,000 acres is woodland/forest with the five State forests comprising 13,300 acres. The North Dakota State Implementation Plan contains rules which govern prescribed burning on crop land, pasture/rangeland or woodland. NDAC 33-15-04-02.2 lists the conditions that apply to any prescribed burning including:

c. Care must be used to minimize the amount of dirt on the material being burned and the material must be dry enough to burn cleanly.

d. Oils, rubber, and other materials that produce unreasonable amounts of air contaminants may not be burned.

e. The burning may be conducted only when meteorological conditions favor smoke dispersion and air mixing.

h. Except in an emergency, burning may not be conducted in such proximity of any class 1 area, as defined in chapter 33-15-15, that the ambient air of such area is adversely impacted.

i. Except in an emergency, the visibility of any class 1 area cannot be adversely impacted as defined in chapter 33-15-19.

j. Burning activities must be attended and supervised at all times burning is in progress.

Fires purposely set to woodland/forest or rangeland for the management of the land or game must be in accordance with practices recommended by State and Federal agencies and must be approved in advance by the Department (NDAC 33-15-04-02.1.e). Although agricultural crop burning does not require advanced approval by the Department, most of this burning takes place in the eastern two thirds of State away from the Class I areas in North Dakota. In general, prevailing winds carry the smoke from crop land burning away from the North Dakota Class I areas. For 2000-2004 (Case Plan 02d), the WRAP has estimated the annual emissions from fire in North Dakota as shown in Table 10.1.

Table 10.1
Annual Average Emissions from Fire (2000-2004)

Source	**PM_{fine} (tpy)**	**PM_{coarse} (tpy)**	**NO_x (tpy)**	**SO_2 (tpy)**	**Organic Carbon (tpy)**	**Elemental Carbon (tpy)**
Natural	225	441	773	250	2,214	424
Anthropogenic	596	62	1001	290	1,443	86
Total	821	503	1774	540	3,657	510

Based on the source apportionment analyses conducted by the WRAP, anthropogenic fire emissions in North Dakota contribute less than 1% of the total emissions of any of the pollutant species listed above during the 20% worst visibility days for either Lostwood Wilderness Area or Theodore Roosevelt National Park as shown in Table 10.2. The contribution of anthropogenic fire is expected to decrease by 2018. As indicated earlier, open burning is subject to regulation under NDAC 33-15-04 which specifically prohibits burning that will adversely affect visibility in any Class I area. The Department has determined that the current smoke management rules are sufficient to achieve reasonable progress toward the national visibility goal. However, the smoke management rules will be reevaluated during future planning periods.

Table 10.2
North Dakota Anthropogenic Fire Contribution to the 20% Worst Days

Class I Area	Pollutant	Contribution 2000-2004 (%)	Contribution 2018 (%)
TRNP	SO_x	0.013	0.004
	NO_x	0.019	0.006
	POA	0.364	0.112
	EC	0.067	0.024
	PMF	0.04	0.013
	PMC	0.001	0
LWA	SO_x	0.008	0.002
	NO_x	0.024	0.007
	POA	0.823	0.252
	EC	0.13	0.046
	PMF	0.049	0.015
	PMC	0.001	0

10.6.6 Enforceability of Emission Limitations and Control Measures

40 CFR 51.308(d)(3)(v)(F) requires the State must consider the enforceability of emission limitations and control measures in developing its LTS. The BART emission limits and control measures will be included in a BART Air Pollution Control Permit to Construct that is issued to each BART source and are incorporated into this SIP. The Permit to Construct program is established in the State Air Pollution Control Rules (NDAC 33-15-14-02). The program is also approved into the State Implementation Plan. The BART permits are included in Appendix D of this SIP. Other ongoing programs are already included in the State rules. Future NSPS and MACT rules for major sources will be adopted into the State Rules and delegation will be requested from EPA.

10.6.7 The Anticipated Net Effect on Visibility Due to Projected Changes in Point, Area and Mobile Source Emissions

40 CFR 51.308(d)(3)(v)(G) requires the State consider the anticipated net effect on visibility due to projected changes in point, area, and mobile source emissions over the period addressed by the long-term strategy in developing its LTS. The anticipated net effect on visibility due to projected changes in emissions from 2004 to 2018 is discussed in Section 8, Visibility Modeling.

10.7 Prevention of Significant Deterioration

In North Dakota, new and modified existing major stationary sources triggering significance thresholds are analyzed under the Prevention of Significant Deterioration (PSD) permitting program. The PSD program rules are found in NDAC Chapter 33-15-15 and have been approved as a part of the North Dakota SIP by EPA. The PSD permitting program is an integral part of North Dakota's long-term strategy for meeting its regional haze goals.

Among other things, the PSD permit program is designed to protect air quality and visibility in Class I areas by requiring best available control technology (BACT) and involving the public in permit decisions. The PSD permitting process requires a technical air quality analysis and additional analyses to assess the potential impacts of emissions on soils, vegetation and visibility. The cumulative impacts of emissions subject to the PSD program will be evaluated to ensure there is no degradation from baseline conditions on the 20 percent worst days and the 20 percent best days.

Therefore, North Dakota's current PSD program ensures that visibility at the Class I areas will not be impacted by growth in stationary sources.

11. Commitment to Consultation, Progress Reports, Periodic Evaluations of Plan Adequacy, and Future SIP Revisions

11.1 Future Consultation Commitments

11.1.1 FLM Consultation and Coordination

40 CFR 51.308(i) contains the requirements for State and Federal Land Manger consultation and coordination. §51.308(i) reads "What are the requirements for State and Federal Land Manager coordination?

(1) By November 29, 1999, the State must identify in writing to the Federal Land Managers the title of the official to which the Federal Land Manager of any mandatory Class I Federal area can submit any recommendations on the implementation of this subpart including, but not limited to:

  (i) Identification of impairment of visibility in any mandatory Class I Federal area(s); and

  (ii) Identification of elements for inclusion in the visibility monitoring strategy required by § 51.305 and this section.

(2) The State must provide the Federal Land Manager with an opportunity for consultation, in person and at least 60 days prior to holding any public hearing on an implementation plan (or plan revision) for regional haze required by this subpart. This consultation must include the opportunity for the affected Federal Land Managers to discuss their:

  (i) Assessment of impairment of visibility in any mandatory Class I Federal area; and

  (ii) Recommendations on the development of the reasonable progress goal and on the development and implementation of strategies to address visibility impairment.

(3) In developing any implementation plan (or plan revision), the State must include a description of how it addressed any comments provided by the Federal Land Managers.

(4) The plan (or plan revision) must provide procedures for continuing consultation between the State and Federal Land Manager on the implementation of the visibility protection program required by this subpart, including development and review of implementation plan revisions and 5-year progress reports, and on the implementation of other programs having the potential to contribute to impairment of visibility in mandatory Class I Federal areas."

North Dakota commits to coordinate and consult with the Federal Land Managers as required in §51.308(i)(1) through (4).

11.1.2 Tribal Consultation

North Dakota will continue to remain in contact with those Tribes which may reasonably be anticipated to cause or contribute to visibility impairment in North Dakota mandatory Class I Federal area(s). For those Tribes that adopted a RH TIP, North Dakota will consult with them directly. For those Tribes without a RH TIP, North Dakota will consult with both the Tribe and EPA. Documentation of the consultations will be maintained.

11.1.3 Interstate Consultation and Coordination

40 CFR 51.308(d)(1)(iv) and 40 CFR 51.308(d)(3)(i) contain the requirements for interstate consultation and coordination. §(d)(1)(iv) reads:

> "In developing each reasonable progress goal, the State must consult with those States which may reasonably be anticipated to cause or contribute to visibility impairment in the mandatory Class I Federal area. In any situation in which the State cannot agree with another such State or group of States that a goal provides for reasonable progress, the State must describe in its submittal the actions taken to resolve the disagreement. In reviewing the State's implementation plan submittal, the Administrator will take this information into account in determining whether the State's goal for visibility improvement provides for reasonable progress towards natural visibility conditions." §(d)(3)(i) reads:
>
> "Where the State has emissions that are reasonably anticipated to contribute to visibility impairment in any mandatory Class I Federal area located in another State or States, the State must consult with the other State(s) in order to develop coordinated emission management strategies. The State must consult with any other State having emissions that are reasonably anticipated to contribute to visibility impairment in any mandatory Class I Federal area within the State."

In accordance with 40 CFR 51.308(d)(1)(iv) and 51.308(d)(3)(i), North Dakota commits to continue consultation with Minnesota, Montana, and South Dakota, and any other state which may reasonably be anticipated to cause or contribute to visibility impairment in federal Class I areas located within North Dakota. North Dakota will also continue consultation with Michigan, Minnesota, Montana, and South Dakota and any other state for which North Dakota's emissions may reasonably be anticipated to cause or contribute to visibility impairment in those state's federal Class I areas.

With reference to the established or updated goals for reasonable progress, should disagreement arise between another state or group of states, North Dakota will describe the actions taken to resolve the disagreement in future RH SIP revisions for EPA's consideration. With reference to assessing or updating long-term strategies, North Dakota commits to coordinate its emission management strategies with affected states and will continue to include in its future RH SIP revisions all measures necessary to obtain its share of emissions reductions for meeting progress goals.

11.2 Commitment to Progress Reports

Requirements for the State to submit periodic progress reports are found in 40 CFR 51.308(g) which reads “Requirements for periodic reports describing progress towards the reasonable progress goals. Each State identified in §51.300(b)(3) must submit a report to the Administrator every five years evaluating progress towards the reasonable progress goal for each mandatory Class I Federal area located within the State and in each mandatory Class I Federal area located outside the State which may be affected by emissions from within the State. The first progress report is due 5 years from the submittal of the initial implementation plan addressing paragraphs (d) and (e) of this section. The progress reports must be in the form of implementation plan revisions that comply with the procedural requirements of §51.102 and §51.103. Periodic progress reports must contain at a minimum the following elements:

(1) A description of the status of implementation of all measures included in the implementation plan for achieving reasonable progress goals for mandatory Class I Federal areas both within and outside the State.

(2) A summary of the emissions reductions achieved throughout the State through implementation of the measures described in paragraph (g)(1) of this section.

(3) For each mandatory Class I Federal area within the State, the State must assess the following visibility conditions and changes, with values for most impaired and least impaired days expressed in terms of 5-year averages of these annual values.

    (i) The current visibility conditions for the most impaired and least impaired days;

    (ii) The difference between current visibility conditions for the most impaired and least impaired days and baseline visibility conditions;

    (iii) The change in visibility impairment for the most impaired and least impaired days over the past 5 years;

(4) An analysis tracking the change over the past 5 years in emissions of pollutants contributing to visibility impairment from all sources and activities within the State. Emissions changes should be identified by type of source or activity. The analysis must be based on the most recent updated emissions inventory, with estimates projected forward as necessary and appropriate, to account for emissions changes during the applicable 5-year period.

(5) An assessment of any significant changes in anthropogenic emissions within or outside the State that have occurred over the past 5 years that have limited or impeded progress in reducing pollutant emissions and improving visibility.

(6) An assessment of whether current implementation plan elements and strategies are sufficient to enable the State, or other States with mandatory Federal Class I areas affected by emissions from the State, to meet all established reasonable progress goals.

(7) A review of the State's visibility monitoring strategy and any modifications to the strategy as necessary."

In accordance with the requirements listed in 40 CFR 51.308(g) of the federal regional haze rule, North Dakota commits to submitting periodic progress reports to EPA every five years following the initial submittal of the SIP. The periodic progress reports will address at a minimum all the elements of §51.308(g). The periodic progress reports will be in the form of implementation plan revisions that comply with the procedural requirements of 40 CFR 51.102 and 51.103.

11.3 Determination of Current Plan Adequacy

Based on the findings of the 5-year periodic progress report, 40 CFR 51.308(h) requires a State to make a determination of adequacy of the existing implementation plan. §51.308(h) reads "Determination of the adequacy of existing implementation plan. At the same time the State is required to submit any 5-year progress report to EPA in accordance with paragraph (g) of this section, the State must also take one of the following actions based upon the information presented in the progress report:

(1) If the State determines that the existing implementation plan requires no further substantive revision at this time in order to achieve established visibility goals for visibility improvement and emissions reductions, the State must provide to the Administrator a negative declaration that further revision of the existing implementation plan is not needed at this time.

(2) If the State determines that the implementation plan is or may be inadequate to ensure reasonable progress due to emissions from sources in another State(s) which participated in a regional planning process, the State must provide notification to the Administrator and the other State(s) which participated in the regional planning process with the States. The State must also collaborate with the other State(s) through the regional planning process for the purpose of developing additional strategies to address the plan's deficiencies.

(3) Where the State determines that the implementation plan is or may be inadequate to ensure reasonable progress due to emissions from sources in another country, the State shall provide notification, along with available information, to the Administrator.

(4) Where the State determines that the implementation plan is or may be inadequate to ensure reasonable progress due to emissions from sources within the State, the State shall revise its implementation plan to address the plan's deficiencies within one year."

North Dakota commits, in accordance with 40 CFR 51.308(h), to make a determination of the adequacy of the existing implementation plan at the same time a five-year periodic progress report is due.

Should North Dakota determine that the implementation plan is or may be inadequate to ensure reasonable progress due to emissions from sources in another State or States, North Dakota will provide notification to the Administrator and the other State(s) and collaborate with the other States(s) through the regional planning process for the purpose of developing additional strategies to address the plan's deficiencies as required by §51.308(h)(2). In the event that no regional planning organizations or process exists, North Dakota will work directly with the other State(s).

Should North Dakota determine that the current implementation plan is or may be inadequate due to emissions from within the State itself, North Dakota will develop additional strategies to address the plan deficiencies and revise the implementation plan within one year, as required by §51.308(h)(4).

Should North Dakota determine that the implementation plan is or may be inadequate to ensure reasonable progress due to emissions from sources in another country, the State will provide notification, along with available information, to the Administrator as required by §51.308(h)(3).

Should North Dakota determine that the existing implementation plan requires no further substantive revision in order to achieve established goals for visibility improvement and emissions reductions, North Dakota will provide the Administrator a negative declaration that further revision of the existing implementation plan is not needed as required by §51.308(h)(1).

In addition, North Dakota commits to revise the implementation plan, including the reasonable progress goals, once RH SIPs from neighboring states become available and are approved by EPA, or if the unexpected or unforeseen occurs. This would include, but not be limited to, projected future emissions reductions that do not occur, are distributed differently over an alternate geographic area, or are found to be incorrect or flawed. These revisions will be made within one year as required by §51.308(h)(4). North Dakota also commits to accelerate this revision schedule if the present RH SIP is found to be significantly flawed and the 2018 reasonable progress goals cannot be reasonably attained.

11.4 Commitment to Future SIP Revisions

In addition to a SIP revision made for periodic progress reports as addressed in Section 11.2 and plan inadequacy as addressed in Section 11.3, 40 CFR 51.308(f) requires a State to revise and submit its regional haze implementation plan to EPA by July 31, 2018, and every ten years thereafter. 40 CFR 51.308(f) reads "Requirements for comprehensive periodic revisions of implementation plans for regional haze. Each State identified in §51.300(b)(3) must revise and submit its regional haze implementation plan revision to EPA by July 31, 2018 and every ten years thereafter. In each plan revision, the State must evaluate and reassess all of the elements required in paragraph (d) of this section, taking into account improvements in monitoring data collection and analysis techniques, control technologies, and other relevant factors. In evaluating and reassessing these elements, the State must address the following:

(1) Current visibility conditions for the most impaired and least impaired days, and actual progress made towards natural conditions during the previous implementation period. The period for calculating current visibility conditions is the most recent five year period preceding the required date of the implementation plan submittal for which data are available. Current visibility conditions must be calculated based on the annual average level of visibility impairment for the most and least impaired days for each of these five years. Current visibility conditions are the average of these annual values.

(2) The effectiveness of the long-term strategy for achieving reasonable progress goals over the prior implementation period(s); and

(3) Affirmation of, or revision to, the reasonable progress goal in accordance with the procedures set forth in paragraph (d)(1) of this section. If the State established a reasonable progress goal for the prior period which provided a slower rate of progress than that needed to attain natural conditions by the year 2064, the State must evaluate and determine the reasonableness, based on the factors in paragraph (d)(1)(i)(A) of this section, of additional measures that could be adopted to achieve the degree of visibility improvement projected by the analysis contained in the first implementation plan described in paragraph (d)(1)(i)(B) of this section."

In accordance with the requirements of section 51.308 (d) and (f) of the regional haze rule, North Dakota commits to revising and submitting its regional haze SIP by July 31, 2018 and every ten years thereafter addressing current visibility conditions, effectiveness of the long-term strategy and affirming or revising the reasonable progress goal for each mandatory Class I Federal area in North Dakota.

11.5 Monitoring Strategy

North Dakota commits to review and reevaluate the adequacy of and revise as necessary the existing RAVI monitoring strategy required by Section 51.305 and the existing regional haze monitoring strategy required by Section 51.308(d)(4) as a minimum, concurrently with the 5-year periodic progress reports and the 10-year plan revisions which start July 31, 2018 and every ten years thereafter. North Dakota will coordinate all reviews, reevaluations and revisions to both monitoring strategies with each other and will consult and coordinate any revisions with EPA and FLMs. The monitoring strategies are discussed further in Section 4 of this plan.

11.6 Rules for Non-BART Point and Area Sources

The Department adopted rules in 1987 to implement Phase 1 of the federal visibility program which is Section 40 CFR 51.300 – 307 (NDAC Chapter 33-15-19 Visibility Protection, effective date October 1, 1987) and in 2006 to implement the BART portion of Phase 2 which is Paragraph 40 CFR 51.308(e) (NDAC Chapter 33-15-23 Regional Haze Requirements, effective date January 1, 2007). For a more detailed description of Phase 1 and Phase 2 of the federal visibility program see Section 2.

As a result of addressing the core requirements of the federal visibility program which are found in 40 CFR 51.308(d), the Department has determined it will be necessary to clarify its legal authority to address emissions which adversely impact visibility in the Class I areas from non-BART and area sources which may in the future be found to be reasonably controllable and reduced (see Section 9).

The Department commits to develop and adopt any necessary rules to clarify its legal authority to control and reduce emissions from non-BART and area sources that adversely impact Class I areas as expeditiously as possible but no later than December 31, 2012.

12. Public Participation and Review Process

The Public Hearing Record is Appendix F. Included are the Hearing Notice (F.1), Press Release (F.2), Affidavit of Publication (F.3), Invoice of Publication (F.4), Registration List of Attendees (F.5), Hearing Transcript (F.6), Certification of Hearing (F.7), and Response to Public Comments (F.8).

12.1 Summary of Comments Received during Public Comment Period/Hearing

The written comments and oral comments received during the 30 day public comment period and public hearing are included in Appendix F.6 as a part of the Hearing Transcript and Response to Comments.

Written comments were received from the U.S. Environmental Protection Agency Region 8 in Denver CO; The U.S. Department of the Interior National Park Service in Denver CO; the National Parks Conservation Association in Chicago IL on behalf of the National Parks Conservation Association, the Dakota Resource Council, the Friends of the Boundary Waters Wilderness, the Plains Justice and the Dakotah Chapter of the Sierra Club; Basin Electric Power Cooperative in Bismarck ND; Great River Energy in Maple Grove MN; and Bob Paine of AECOM Environment on behalf of Basin Electric Power Cooperative, Great River Energy, and Minnkota Power Cooperative, Inc.

In addition, the Department received 31 nearly identical emails from various individuals. Mr. Jim Kambeitz presented oral testimony at the public hearing and submitted written comments that reiterated his oral comments.

12.2 Response to Public Comments

The Department’s responses to the comments received during the 30 day public comment period and public hearing are included in Appendix F.8.

12.3 Revisions to the State Implementation Plan

The Department made the following revisions to Regional Haze State Implementation Plan based on its review of the comments received during the 30 public comment period and public hearing:

- Page ii – An Approval Page was added.
- Section 4.2 – A discussion on the representativeness of the IMPROVE monitor at the South Unit of the Theodore Roosevelt National Park for the North Unit and Elkhorn Ranch Unit was added.

- Section 5.2 – A reference to the discussion in Section 4.2 on the representativeness of the IMPROVE monitor in the South Unit of TRNP was added.
- Section 5.2 – A reference was added for the WRAP methodology for determining baseline conditions under Table 5.1.
- Section 7.3.4 - Exclusion of Montana Dakota Utilities Heskett Unit No. 2 was updated.
- Section 8.6.1 – Performance evaluation expanded to include results for the 98th percentile metric.
- Section 8.6.2.5 – Per EPA suggestion, conclusions modified to acknowledge that BART emissions reductions from ND sources can significantly improve visibility under some meteorological conditions.
- Table 9.4 – MDU Heskett Unit No. 2 was added.
- Table 9.9 – Table was modified to add additional information.
- Section 9.5.1 – Reasonable Progress Goals – Required Controls for Point Sources – A sentence was added regarding the percent improvement in visibility for the control options evaluated.
- Section 9.5.4 – The section was relocated to Section 10.6.1.2 and updated.
- Section 9.5.5 – The section was updated to discuss PM emissions and Q/D for oil wells.
- Section 9.7 – The section was updated to indicate that the Reasonable Progress Goals are based on the Department's hybrid modeling.
- Section 10.6.1.2 – The section was added to address emissions reductions from the Coyote Station.
- Section 10.6.5 – The section was updated to indicate the North Dakota smoke management rules will be reevaluated during future planning periods.
- Section 11.6 – The section was updated.
- Section 12 – Each item is now addressed as the 30 day public comment period and hearing has been completed.
- Appendix A.5 – A new appendix was added to address the WRAP methodology for determining baseline visibility conditions.
- Appendix F.9 – The section was deleted as it was not required.
- Appendix I.2 – A new appendix was added to provide supplementary information for the four factor analysis by the WRAP states.
- Several spelling, grammatical and typographical corrections were made throughout the document.

12.4 Revisions to the BART Air Pollution Control Permits to Construct

The Department made the following revisions to BART Air Pollution Control Permits to Construct based on its review of the comments received during the 30 day public comment period and public hearing:

- The definition of 30 day rolling average was modified to match the NSPS Subpart Da language in all the BART permits.
- Condition II.A.2 was changed from "BART" to "Regional Haze" in the Stanton, Leland Olds and Minnkota permits.

- The location of the CEM was added to Condition II.A.3 in the Stanton permit. The condition was also changed to specify that emissions from Unit 1 and Unit 10 must be measured separately.
- Condition II.A.1.c was revised to include a procedure for demonstrating compliance if a startup is less than 24 hours in the Minnkota permit.
- Condition II.A.2 was changed from “Data” to “Date” in the Coyote permit.
- Condition II.A.4.a was changed from “94%” to “95%” in the Coal Creek permit.
- Condition II.A.1.a of the Coyote permit was amended to specify that EUI 1 is the main boiler.
- In Condition II.B.4 of the Coyote permit, Unit 1 was changed to EUI 1.
- In Condition II.A.5.e of the Coyote permit, “Condition II.5” was changed to “Condition II.A.5.”
- In Condition II.A.5.b of the Minnkota, Coal Creek, Leland Olds and Stanton permits, “Condition II.5.a” was changed to “Condition II.A.5.a.”

Appendix A NDDH PSD Class I Area Receptors

1 Overview

On June 15, 2005, EPA issued final amendments to its July 1999 regional haze rule[1]. These amendments apply to the provisions of the regional haze rule that require emission controls known as Best Available Retrofit Technology, or BART, for industrial facilities emitting air pollutants that reduce visibility in PSD Class I areas. These pollutants include fine particulate matter ($PM_{2.5}$), and compounds which contribute to $PM_{2.5}$ formation, such as nitrogen oxides, sulfur dioxide, certain volatile organic compounds, and ammonia. The amendments include final guidelines, known as BART guidelines, for states to use in determining which facilities must install controls and the types of controls the facilities must use.

The June 15 guidelines address how to identify BART-eligible sources, how to identify sources "subject to BART", and the BART determination including analysis of BART options. As part of this process, visibility computer modeling will assist in the identification of sources "subject to BART", and in the consideration of BART options to determine the degree of visibility improvement. The North Dakota Department of Health (NDDH) has established a protocol for BART-related modeling applicable to BART-eligible sources in North Dakota, which is the focus of this document. This protocol is intended to apply to visibility modeling for both identification of sources "subject to BART" (BART screening), and for determining the degree of visibility improvement related to the selection of BART control.

---

[1] Federal Register, 2005. EPA Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations; Final Rule. Federal Register, July 6, 2005, Vol. 70, No. 128, p. 39103-39172.

To ultimately determine compliance with Regional Haze visibility improvement goals, four phases of visibility modeling are anticipated. In chronological order, these are:

1) single-source modeling to determine which BART-eligible sources are subject to BART (or BART-applicable),
2) single-source modeling to determine the degree of visibility improvement attributable to proposed BART control for each BART-applicable source,
3) cumulative modeling to determine the combined effect of proposed BART controls for BART-applicable sources in North Dakota, and
4) regional-scale modeling to determine if the combined effect of proposed BART controls, and other emissions reductions, for all western states ultimately satisfies visibility improvement goals.

The protocol outlined in this document applies only to the first two phases involving single-source modeling, that is, screening to determine which BART-eligible sources are subject to BART, and single-source modeling to determine the degree of improvement related to the proposed BART control. With the exception of emission rates and stack parameters, the methodologies for these first two phases of modeling, including all model inputs, are identical. The NDDH recognizes that the "degree of improvement" modeling will be only one of several criteria used to establish optimum BART controls.

The NDDH will conduct visibility modeling to determine which North Dakota BART-eligible sources are subject to BART. It is expected that BART-applicable sources will want to conduct their own single-source modeling to determine the degree of visibility improvement, as they consider a variety of BART control options. Upon request, the NDDH will also perform the single-source degree of improvement modeling. Ultimately, the NDDH will review and verify all single-source degree of visibility improvement modeling analyses. Note that all BART-related single-source modeling for sources in North Dakota must follow the protocol outlined here. Because of this requirement, the NDDH will not expect companies which operate BART-eligible sources to provide individual protocols for their BART-related modeling.

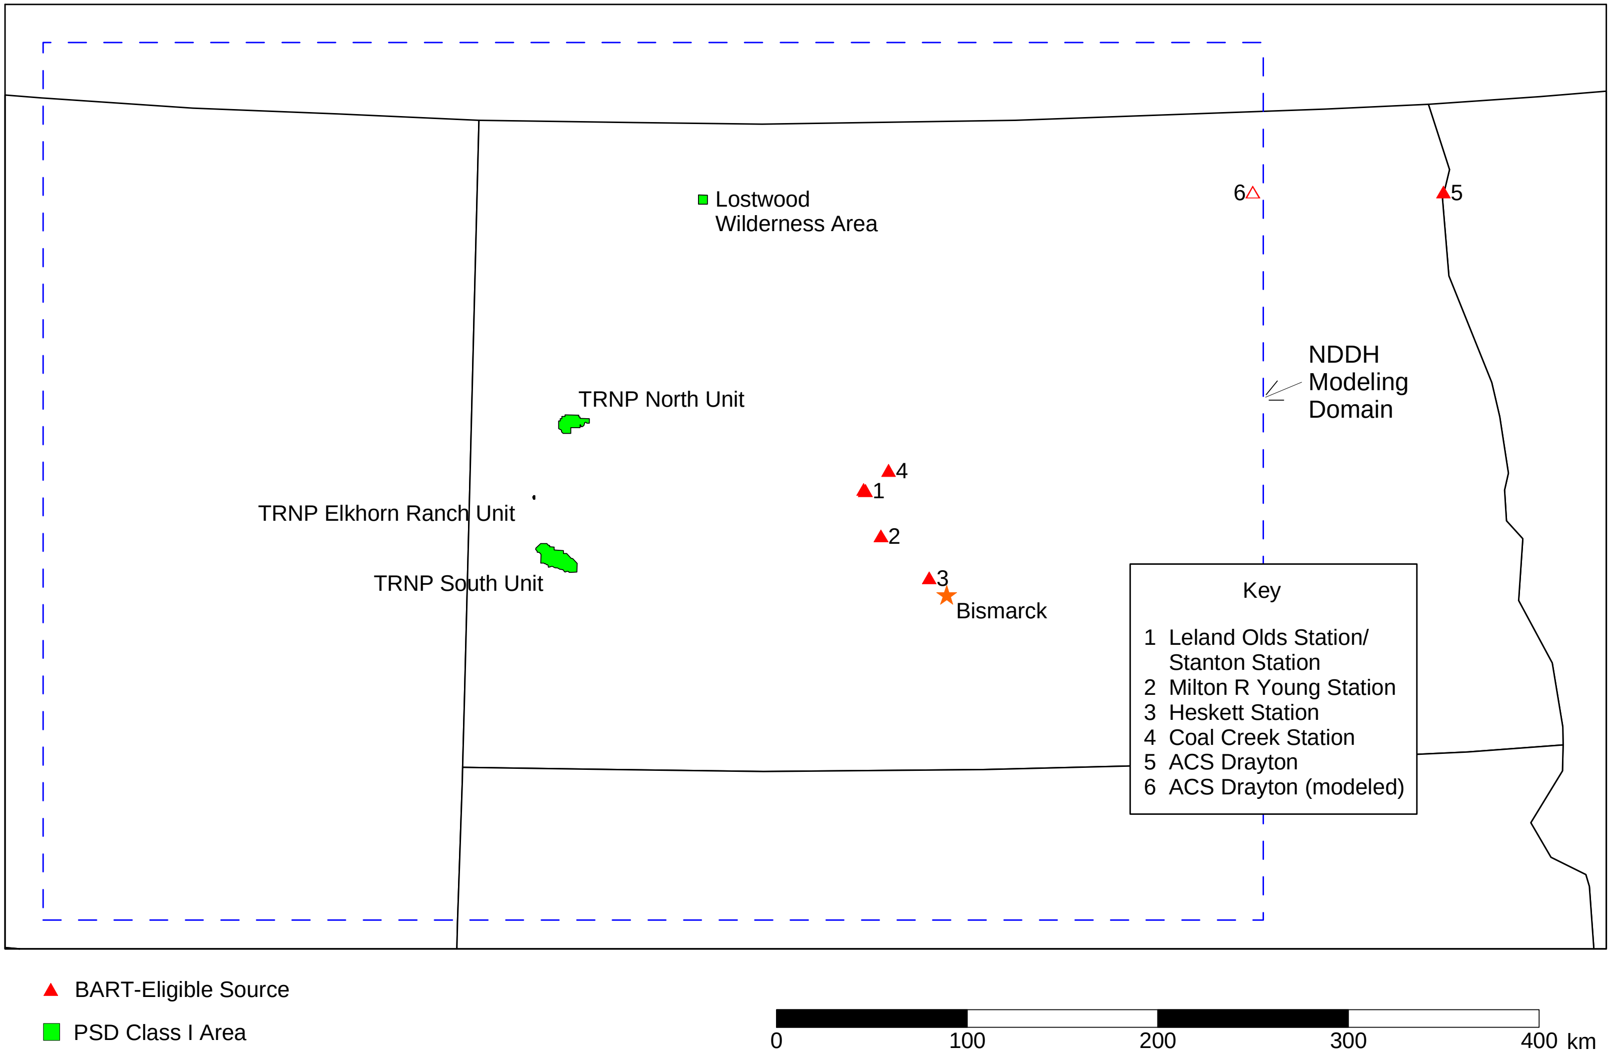
When all BART proposals have been submitted, the NDDH will conduct a cumulative modeling analysis to determine the combined effect of proposed North Dakota BART controls on visibility improvement in North Dakota Class I areas (Phase 3 modeling). A separate protocol for that analysis will be completed by the NDDH prior to modeling. The final regional-scale modeling analysis to ultimately determine compliance with visibility improvement goals (Phase 4 modeling) will be conducted by the Western Regional Air Partnership (WRAP) regional planning organization. WRAP is developing the protocol and establishing input data for that analysis. At this point, the timing of the WRAP regional-scale modeling analysis is unclear. Also unclear is the manner in which the NDDH cumulative analysis might interface with the WRAP regional-scale analysis.

BART-eligible sources in North Dakota have been previously determined by NDDH, and are listed in Table 1-1. BART-related visibility modeling for North Dakota BART-eligible sources will focus on PSD Class I areas in North Dakota, which include the Theodore Roosevelt National Park (three units) and the Lostwood Wilderness Area. Note that the three units of Theodore Roosevelt National Park will be treated as separate Class I areas for purposes of interpreting visibility modeling results (Section 4). Locations of BART-eligible sources with respect to PSD Class I areas in North Dakota are illustrated in Figure 1-1.

Table 1-1
BART-Eligible Sources in North Dakota

Facility	**Operator**
Leland Olds Station 1 Leland Olds Station 2	Basin Electric Power Coop.
Milton R. Young Station 1 Milton R. Young Station 2	Minnkota Power Coop.
Heskett Station 2	Montana-Dakota Utilities
Stanton Station 1	Great River Energy
Coal Creek Station 1 Coal Creek Station 2	Great River Energy
Drayton Sugar Beet Processing	American Crystal Sugar
Mandan Refinery	Tesoro

Figure 1-1: BART-Eligible Sources and PSD Class I Areas



Regarding the requirement to use the BART guideline for all BART-related visibility analyses, the guideline states,

> *"Section 169A(b) requires us to issue guidelines for states to follow in establishing BART emission limitations for fossil-fuel fired power plants having a capacity in excess of 750 megawatts .... For sources other than 750 megawatt power plants, however, states retain the discretion to adopt approaches that differ from the guidelines."*

In this matter, the NDDH has elected to use its discretion to require use of the BART guideline for all BART-eligible sources in North Dakota.

The single-source modeling protocol outlined here provides sufficient detail to ensure consistency among BART-related analyses for sources in North Dakota. In developing this protocol, the NDDH has implemented guidance outlined in the June 15, 2005 rule. Where clarification was needed, this guidance has been augmented through communications with EPA and FLM's.[2] To the extent applicable, the NDDH BART modeling protocol is consistent with the North Dakota alternative protocol for PSD Class I increment analyses.[3]

[3] NDDH, 2005. A Proposed Alternative Air Quality Modeling Protocol to Examine the Status of Attainment of PSD Class I Increment. North Dakota Department of Health, Bismarck, ND 58506.

The remainder of this document describes the NDDH single-source visibility modeling protocol. Modeling methodology for BART-related visibility analyses is discussed in general in Section 2. Section 3 provides detailed information regarding modeling system components and input data requirements. Model execution and interpretation of output are discussed in Section 4. NDDH Class I area receptor coordinates/elevations are provided in Appendix A.

NDDH contacts for questions on BART-related modeling and general Regional Haze issues are provided in Table 1-2.

Table 1-2
NDDH Contact Information

Name	Task	Phone	E-mail
Dana Mount	General Regional Haze Coordination	(701)328-5150	dmount@state.nd.us
Tom Bachman	Emissions/Rules/BART	(701)328-5188	tbachman@state.nd.us
Steve Weber	Modeling	(701)328-5188	sweber@state.nd.us
Rob White	Modeling	(701)328-5188	rwhite@state.nd.us

2 Modeling Methodology

For the determination of BART applicability for BART-eligible sources (BART screening), modeling methodology involves execution of an appropriate visibility model, then comparison of model predictions with the BART applicability threshold. To determine the degree of improvement from selected BART options, the visibility model is executed again for post-BART control conditions, and results are compared with those for pre-BART conditions. In both cases, modeling is applied on a single facility basis. With the exception of emission rates and stack parameters, model settings and input data for both pre-BART and post-BART model runs are identical.

For BART screening, all BART-eligible units contained within a subject facility must be modeled together before comparing results with the BART applicability threshold. This would include, for example, both BART-eligible units of a power plant. To determine the degree of visibility improvement from selected BART options, however, it may be desirable to model units individually, as required improvement and BART options may vary by unit.

2.1 BART Applicability Threshold

In general, to determine which BART-eligible sources must apply BART, single facility modeling results for PSD Class I areas are compared with a visibility threshold, expressed in deciviews. The NDDH will follow recommendations in the June 15 BART guideline which states,

> *"A single source that is responsible for a 1.0 deciview change or more should be considered to "cause" visibility impairment; a source that causes less than a 1.0 deciview change may still "contribute" to visibility impairment and thus be subject to BART .... As a general matter, any threshold that you use for determining whether a source "contributes" to visibility impairment should not be higher than 0.5 deciviews."*

As a practical matter, the NDDH sees no reason to distinguish among BART-eligible sources which "cause" visibility impairment versus those sources which "contribute" to visibility impairment in PSD Class I areas. Therefore, the NDDH will generally use a 0.5 deciview threshold to determine which BART-eligible sources must apply BART. The NDDH may reconsider the threshold value if subsequent multi-source modeling reveals difficulty in meeting visibility improvement goals.

2.2 **Pollutants to Consider**

For both BART applicability and degree of visibility improvement analyses, the BART guideline specifies that only primary emissions need to be considered. These primary emissions include SO_2, NO_x, and direct particulate matter (PM) emissions specified as either coarse (PM_{10} minus $PM_{2.5}$) or fine ($PM_{2.5}$). If this distinction in size of PM emissions cannot be made, it would be appropriate to consider all PM_{10} emissions as $PM_{2.5}$.

The BART guideline also discusses VOC or ammonia emissions as possibly impacting visibility. For BART eligible sources in North Dakota, the NDDH considers these emissions (and associated visibility impacts) to be negligible, and will not require inclusion of VOC or ammonia species in BART-related visibility analyses.

Emission rates and stack parameters for BART-related visibility modeling are discussed in detail in Section 3.

2.3 **Visibility Modeling System**

As shown in Figure 1-1, all BART-eligible sources will be located more than 50 kilometers from the nearest PSD Class I area in North Dakota. Source-receptor distances greater than 50 kilometers constitute long-range transport, and the EPA-approved model for long-range distances is CALPUFF[4]. As specified in the BART guideline,

> *"CALPUFF is the best regulatory modeling application currently available for predicting a single source's contribution to visibility impairment and is currently the only EPA-approved model for use in estimating single source pollutant concentrations resulting from the long-range transport of primary pollutants. It can also be used for some other purposes, such as the visibility assessments addressed in today's rule, to account for the chemical transformation of* SO_2 *and* NO_x *."*

---

[4] CFR, 2003. EPA Guideline on Air Quality Models. 40 CFR (Code of Federal Regulations) Part 51, Appendix W.

The NDDH therefore recommends and will use CALPUFF for BART-related modeling.

The CALPUFF computer modeling system includes the CALMET meteorological model[5], the CALPUFF dispersion model[6], and the CALPOST post processing program. The CALPOST program accommodates the visibility calculations. For visibility analyses, the CALPUFF system also provides the optional POSTUTIL program. POSTUTIL implements the ammonia limiting method to address double-counting of available ammonia for NO_x to NO_3 conversion chemistry in CALPUFF. In the sequence of execution, POSTUTIL would follow CALPUFF and precede CALPOST. CALPUFF system execution is depicted schematically in Figure 2-1. Earth Tech (Earth Tech, Inc., Concord, MA), the primary model developer, also provides several utility programs to accommodate pre-processing of meteorological and geophysical data for CALMET.

Appropriate versions of CALPUFF software for BART-related modeling are shown in Table 2-1. Note that these newer versions of CALPUFF software are not the same as versions utilized in the recent periodic review of PSD Class I increment in North Dakota. These newer versions, however, contain coding error corrections and other enhancements, and appear to be consistent with the versions being recommended by most Regional Planning Organizations for BART-related modeling. The CALPUFF system software can be downloaded free of charge from the Earth Tech web site

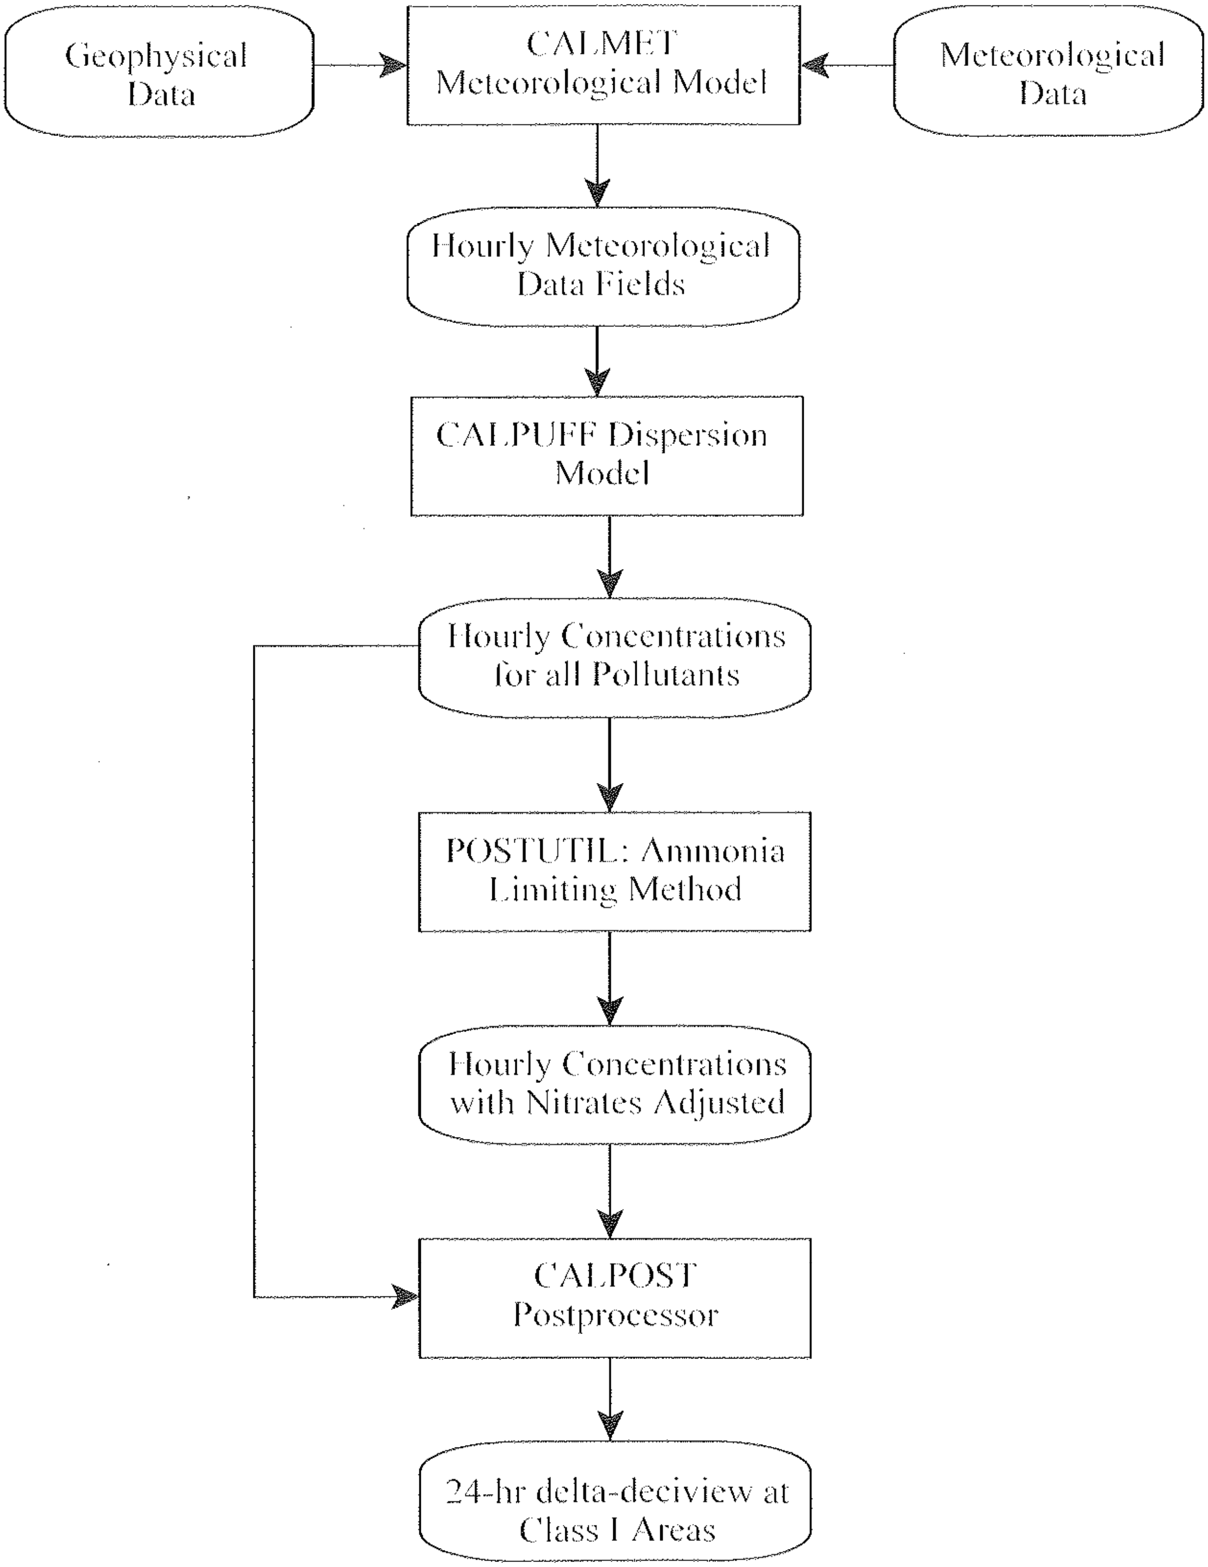
[6] Earth Tech, Inc., 2000. A User's Guide for the Calpuff Dispersion Model (Version 5). Earth Tech, Inc., Concord, MA 01742.

Figure 2-1. Calpuff Processing to Compute Visibility Impacts



(www.src.com/calpuff/calpuff1.htm). For consistency and to ensure executables can accommodate large file sizes, however, it is recommended that the software be obtained directly from NDDH.

Table 2-1
CALPUFF System Versions Applicable For BART Modeling

Program	**Version**	**Level**
CALMET	5.53a	040716
CALPUFF	5.711a	040716
POSTUTIL	1.4	040818
CALPOST	5.51	030709

Application of the ammonia limiting method, utilizing POSTUTIL, is recommended by NDDH. The NDDH will be applying the ammonia limiting method in BART-applicability analyses.

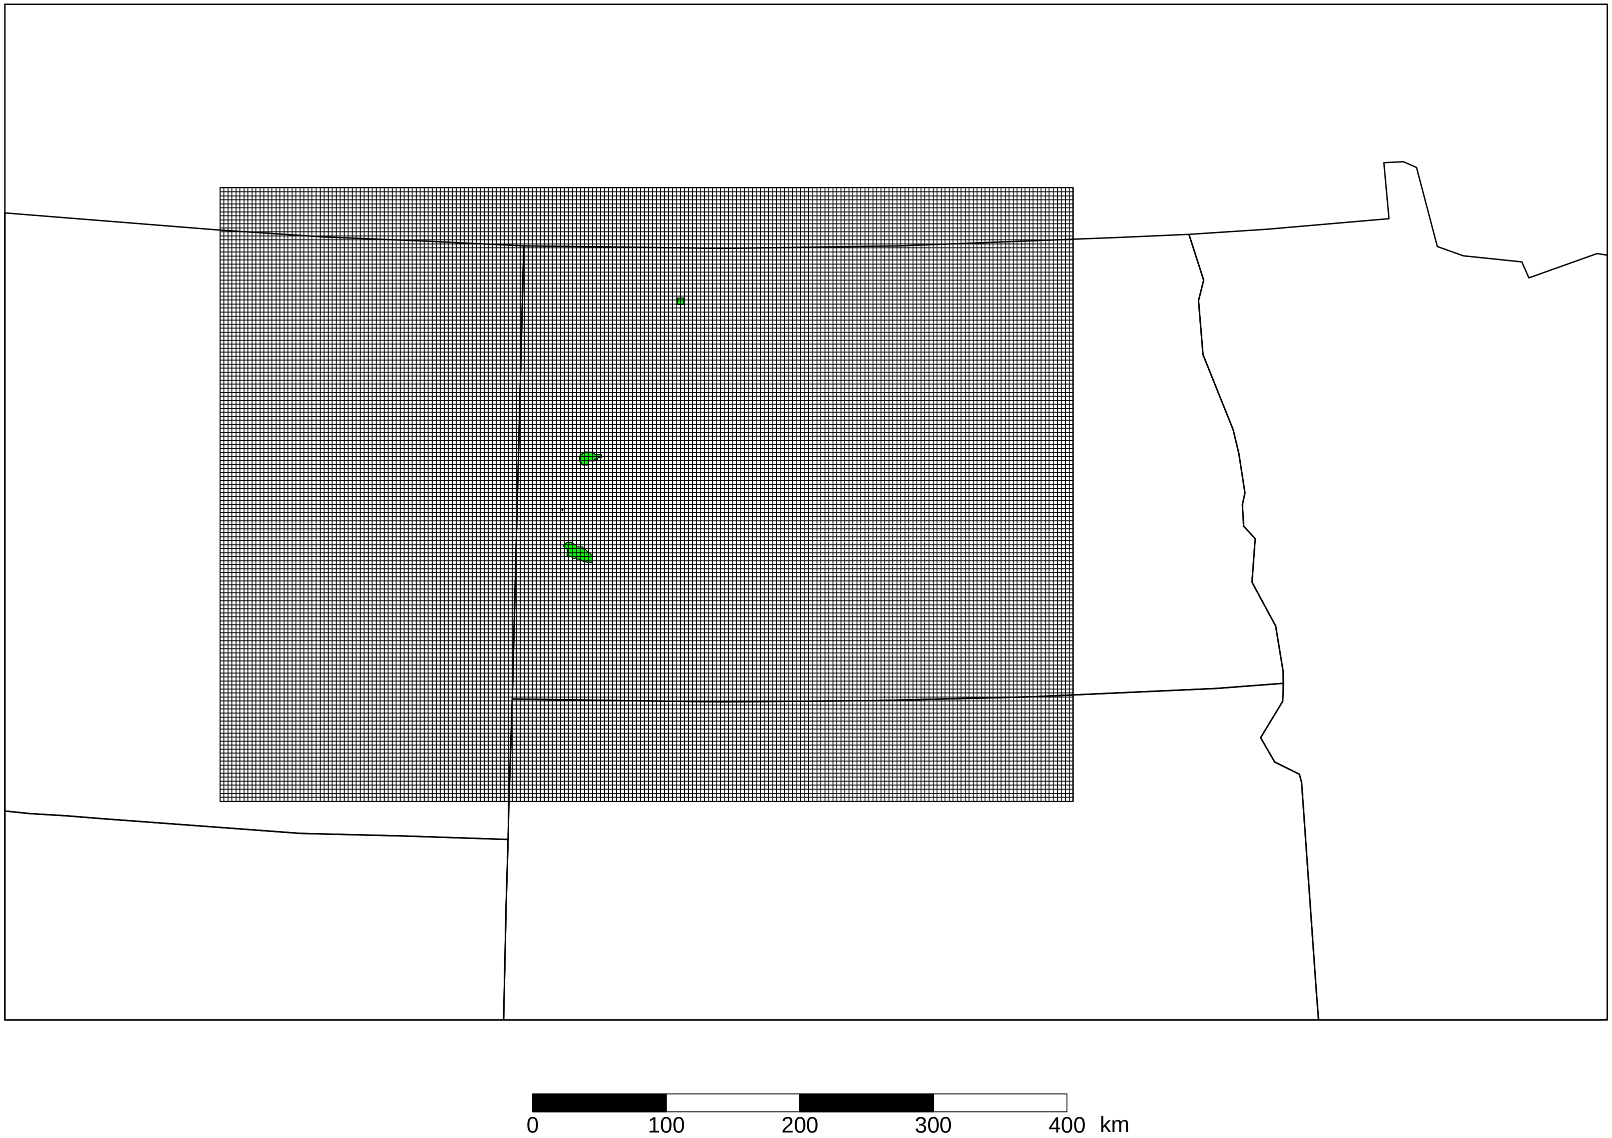
3 Model Input Data/Settings

The CALPUFF modeling system includes the CALMET meteorological model, the CALPUFF dispersion model, the CALPOST postprocessing program, and (optionally) the POSTUTIL program which can be used to implement the ammonia limiting method in visibility analyses. Each of these modules includes a control file which contains user-selected settings to control processing during model execution. CALMET and CALPUFF have additional input data requirements. Input data/settings which are consistent with the use of these programs for BART-related visibility analyses in North Dakota are discussed in Sections 3.1 through 3.4.

The CALMET/CALPUFF modeling domain preferred by the NDDH for BART-related modeling is illustrated in Figure 3-1. Dimensions of the domain are 639 kilometers east-west by 459 kilometers north-south, with a grid cell size of 3 kilometers. In the vertical, the domain is defined by twelve vertical layers. The domain is sized and positioned to encompass all North Dakota PSD Class I areas and BART-eligible sources (with exception noted below), with sufficient buffer area. Because the domain is relatively large, the Lambert Conformal map projection is used to better accommodate the earth's curvature.

As shown in Figure 1-1, the American Crystal Sugar Drayton plant is located outside of the NDDH modeling domain. Even if the domain was extended eastward to incorporate the Drayton plant, the plant is located about 400 kilometers from the nearest Class I area (Lostwood Wilderness Area), and

Figure 3-1: Gridded Modeling Domain



this distance is beyond the accepted range of CALPUFF (about 300 kilometers). For modeling purposes, therefore, the NDDH will reposition the Drayton plant about 100 kilometers to the west, to create a virtual source located just inside the east boundary of the current modeling domain (represented by the "ACS Drayton (modeled)" source in Figure 1-1). This adjustment will provide a source-receptor distance more consistent with the documented limits of CALPUFF, and should ensure conservative results.

3.1 CALMET Input

Input requirements for the CALMET model include various meteorological and geophysical data sets, and a control input file with appropriate settings. Required meteorological data include surface, upper-air, and precipitation observations, and mesoscale model output data fields. Geophysical input data include terrain elevation and land-use data. Though CALMET may be run with mesoscale model meteorological data, alone (i.e., no observations), the EPA modeling guideline[4] recommends "blending" observations with the mesoscale model fields. Therefore, the NDDH will include observations in a blended approach. As required in the EPA modeling guideline, meteorological observations and mesoscale model fields for three years (2000-2002) will be used with CALMET.

All meteorological and geophysical input data sets required for CALMET execution have been previously prepared for BART-related modeling analyses in North Dakota. Upon request, NDDH will provide these meteorological and geophysical data sets.

3.1.1 **Meteorological Data**

3.1.1.1 **Mesoscale Model Data**

Mesoscale model wind fields used with CALMET are based on the National Center for Environmental Predictions (NCEP) Rapid Update Cycle (RUC) forecast model. Mesoscale model fields in the MM5.DAT format required by CALMET were developed by a contractor[7]. The contractor obtained and archived RUC hourly initial analyses from NCEP for years 2000 through 2002. Resolution of these initial analyses was 40 km. The contractor used the ARPS Data Assimilation System (ADAS) to enhance resolution to 10 km, and converted the resultant hourly wind fields to the MM5.DAT format recognized by CALMET. The domain of these hourly wind fields is consistent with the CALMET/CALPUFF domain used by NDDH.

3.1.1.2 **Surface Observations**

Concurrent surface observations for the three-year period 2000-2002 were obtained in surface hourly abbreviated format from the National Climatic Data Center (NCDC). Data were obtained for approximately 35 ASOS/manual stations located within or near the NDDH CALMET/CALPUFF domain, although the specific number of stations varied among the three years. The ASOS/manual observations reflect data from stations operated by the National Weather Service, Federal Aviation

---

[7] WindLogics, 2004. RUC Analysis-Based CALMET Meteorological Data for the State of North Dakota. WindLogics, Inc., St. Paul, MN 55108.

Administration, U.S. Air Force, and Environment Canada. Location of these stations is shown in Figure 3-2.

To compensate for well-documented deficiencies in ASOS cloud data above 12,000 feet, NDDH also obtained concurrent GOES ASOS satellite cloud data for all selected surface stations. The satellite hourly observations included cloud amount (sky cover) and cloud height (ceiling height) data above 12,000 feet, and were therefore used to supplement the ASOS observations.

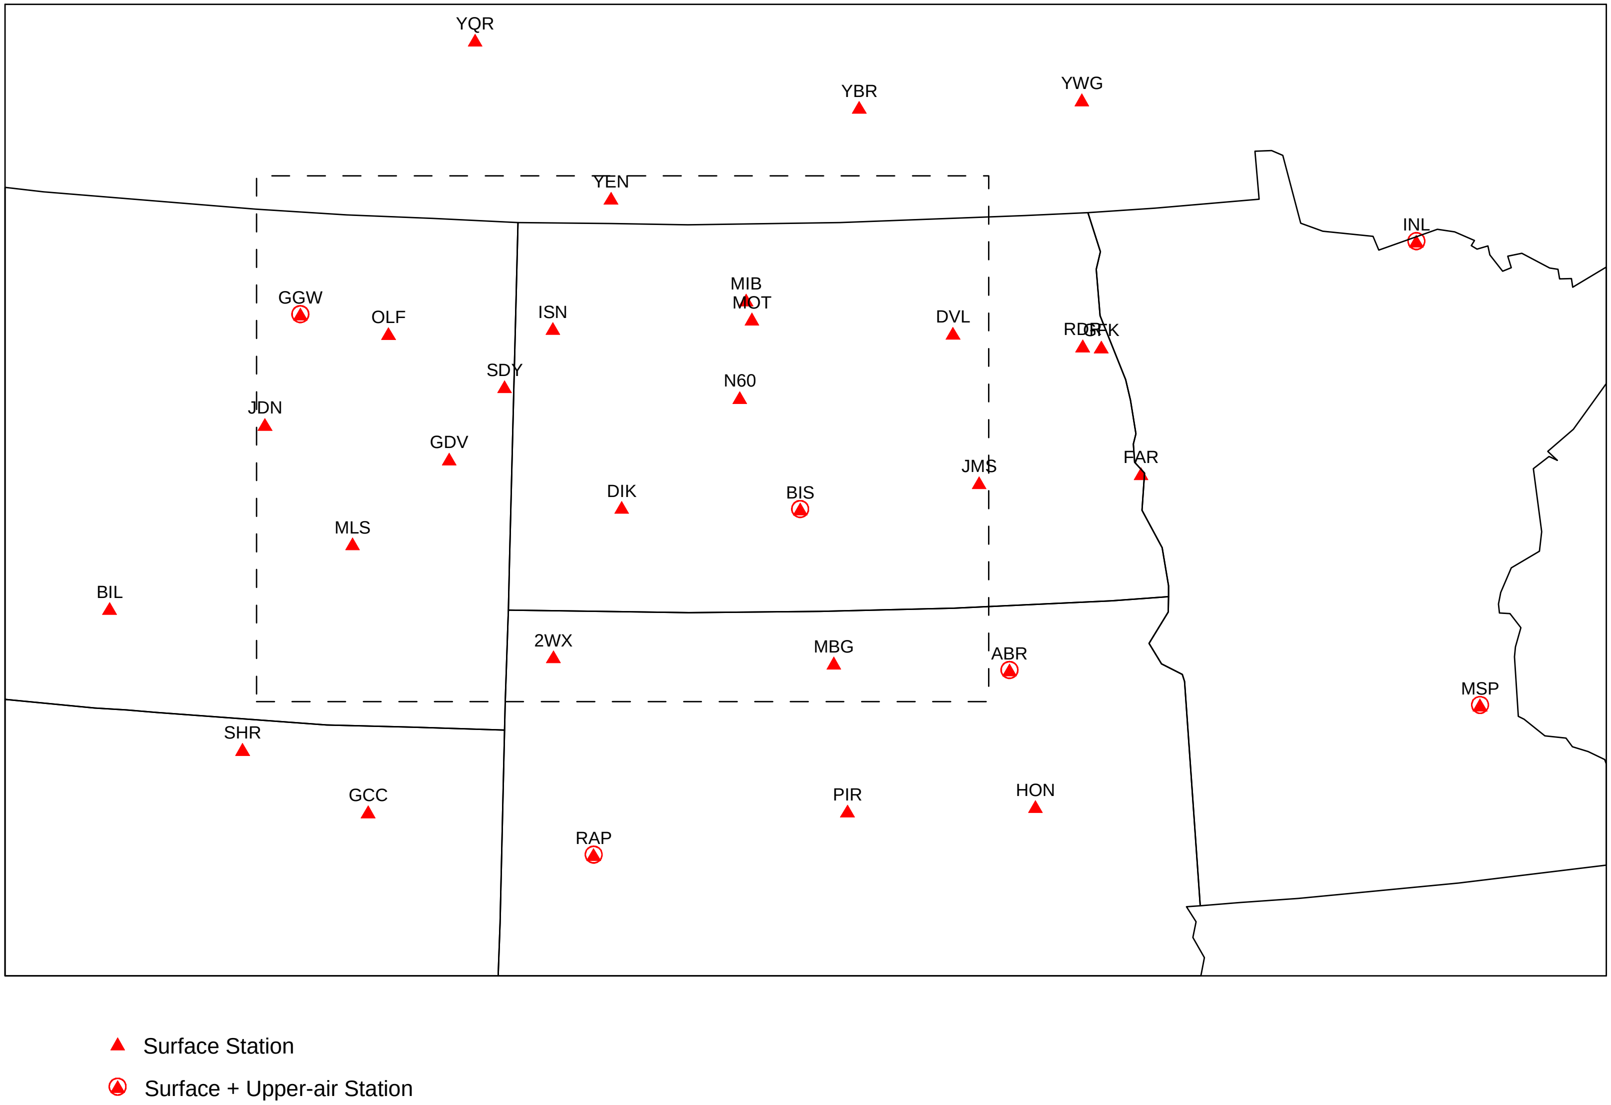
NDDH prepared custom software to merge the ASOS and satellite data. Earth Tech utility software was then used to quality assure merged data, and convert to the format required by CALMET (SURF.DAT). Standard methods were applied to provide substitutions for missing data.[8,9] The occurrence of missing data elements in the surface observations was generally very limited, and within the tolerances suggested by EPA.

---

[8] Atkinson, Dennis and Russell F. Lee, 1992. Procedures for Substituting Values for Missing NWS Meteorological Data for Use in Regulatory Air Quality Models.

[9] EPA, 1987. On-Site Meteorological Program Guidance for Regulatory Modeling Application. Office of Air Quality Planning and Standards, Research Triangle Park, NC 27711.

Figure 3-2: Surface / Upper-air Meteorological Stations



3.1.1.3 **Upper-Air Observations**

Upper-air observations for the three-year period 2000-2002 were obtained from NOAA's Forecast Systems Laboratory (FSL) in Boulder, Colorado. Upper-air sounding files were downloaded from the FSL website (www.fsl.noaa.gov) in the original FSL format, which is accepted for CALMET input as the option "NCDC CD-ROM". Data were obtained for six upper-air stations (NWS) located within or near the NDDH CALMET/CALPUFF domain. Location of these stations is shown in Figure 3-2.

Processing of the upper-air data for CALMET input involved using Earth Tech utility software, running custom software written by NDDH staff, and manual editing of data files. The main Earth Tech program quality checked the upper-air data files, output error messages to identify problems in the data to be corrected by the user, and converted the data to the format required by CALMET. The NDDH custom software performed additional quality checks, and, combined with manual editing of data files, corrected additional errors or problems in the data and filled in for missing data when necessary. Substitutions for missing data generally followed standard EPA guidance.[8,9] Upper-air soundings were processed up to the 500-mb level to accommodate mixing heights up to 4000 meters above ground level at Rapid City, South Dakota. In addition, the main Earth Tech processing program had to be modified slightly (corrected) to correctly read longitudes for Glasgow, Montana.

3.1.1.4 Precipitation Data

Hourly precipitation data for years 2000-2002 were obtained from NCDC in TD-3240 format. Data were included for approximately 90 NWS hourly recording stations located within or near the NDDH CALMET/CALPUFF modeling domain, although the specific number of stations varied among the three years. Location of these stations is shown in Figure 3-3.

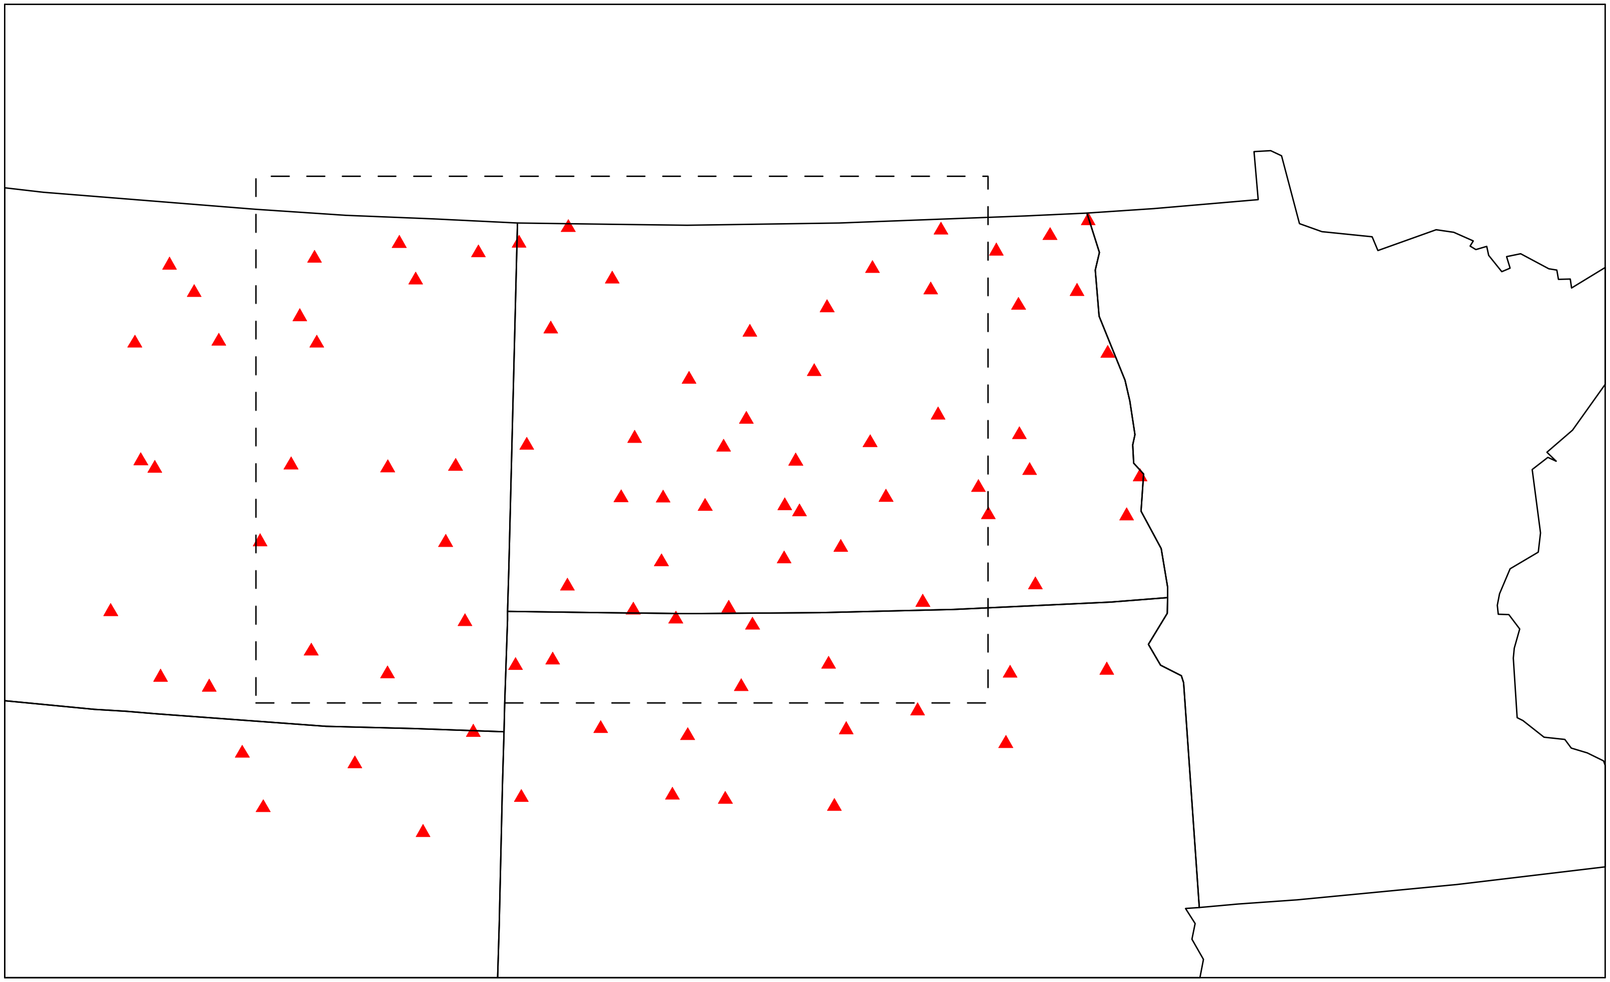
Earth Tech utility software was employed to quality assure the TD-3240 data, and process it into the format required by CALMET (PRECIP.DAT). No substitutions were made for missing data, because CALMET substitutes internally from the nearest available station, and the station resolution was relatively good (Figure 3-3).

3.1.2 Geophysical Data

CALMET requires specification of terrain elevation, and parameters related to the land-use profile, for each grid cell in the modeling domain. The NDDH derived terrain elevations from United States Geological Survey (USGS) GTOPO30 data sets for North America central and mountain zones. Land-use profiles were derived from the USGS Global Data Set for North America.

Using Earth Tech utility software, all gridded terrain and land-use data were processed into the single geophysical file (GEO.DAT) required by CALMET. NDDH assumed Earth Tech default values

Figure 3-3: Precipitation Stations



relating surface roughness length, albedo, Bowen ratio, soil heat flux, and leaf area index to land-use type.

3.1.3 **CALMET Control File Settings**

CALMET control file settings recommended for processing years 2000 through 2002 data for BART-related visibility analyses are generally consistent with guidance from the Interagency Workgroup on Air Quality Modeling (IWAQM)[10]. IWAQM recommendations for CALMET control file variable settings fall into two categories. IWAQM-defined variables are those for which IWAQM provides a default value as a general recommendation for all analyses. User-defined variables are those where IWAQM recognizes the input value will need to be tailored for a given application, and default values are therefore not provided.

For BART-related visibility analyses, the NDDH has established appropriate settings for user-defined variables, and has determined the need to adjust a limited number of IWAQM-defined variables from recommended values, as discussed below. The CALMET control file user-defined settings, as well as the IWAQM-defined settings which have been adjusted by NDDH, are summarized in Table 3-1. IWAQM-defined settings adjusted by NDDH have a highlighted background in the Table.

---

[10] EPA, 1998. IWAQM Phase 2 Summary Report and Recommendations for Modeling Long Range Transport Impacts. Publication No. EPA-454/R-98-019, Office of Air Quality Planning and Standards, Research Triangle Park, NC 27711.

Table 3-1
User-Defined and Non-IWAQM Settings for CALMET Control File

Variable	**Description**	**Value**
NSSTA	No. of surface stations	32,41,40*
NUSTA	No. of upper-air stations	5
NPSTA	No. of precipitation stations	89,93,93*
IBTZ	Base time zone	7
PMAP	Map projection (LCC=Lambert Conformal Conic)	LCC
FEAST	False easting at origin	0.0
FNORTH	False northing at origin	0.0
RLAT0	Origin latitude of projection	44.0N
RLON0	Central meridian of projection	102.0W
XLAT1	Latitude of 1st standard parallel for projection	46.0N
XLAT2	Latitude of 2nd standard parallel for projection	48.5N
DATUM	Datum-region for output coordinates	NWS-27
NX	No. of X grid cells	213
NY	No. of Y grid cells	153
DGRIDM	Grid spacing (km)	3.0
XORIGKM	Southwest grid cell X coordinate	-380
YORIGKM	Southwest grid cell Y coordinate	140
NZ	No. vertical layers	12
ZFACE	Cell face heights (m)	0.,20.,50.,90.,140.,200., 270.,370.,500.,1000., 1700.,2500.,4200.
NOOBS	No observation mode (0 = no)	0

Variable	Description	Value
IPROG	Use MM5.DAT file as initial guess wind field (14=yes)	14
RMAX1	Max. radius of influence of surface observation (km)	100
RMAX2	Max. radius of influence of upper-air observation (km)	200
RMAX3	Max. radius of influence over water (km)	200
TERRAD	Radius of influence of terrain features (km)	10
R1	Distance from a surface observation station at which the wind observation and the first guess field are equally weighted (km)	10
R2	Distance from an upper-air observation station at which the wind observation and the first guess field are equally weighted (km)	10
ISURFT	Surface station number used for the surface temperature for the diagnostic wind field module (Bismarck)	12,17,17*
IUPT	Upper-air station number used to compute the domain-scale temperature lapse rate for the diagnostic wind field module (Bismarck)	1
ZUPWND	Bottom and top of layer through which the domain-scale winds are computed (m)	1.,2500.
MNMDAV	Max. search distance (in grid cells) for spatial averaging of mixing ht. and temperature	7
ILEVZI	Layer of winds used in upwind averaging of mixing heights	3
ZIMAX	Maximum over land mixing height (m)	4000.
ZIMAXW	Maximum over water mixing height (m)	4000.

* Values for years 2000, 2001, 2002

Most of the user-defined settings are intuitive, related to parameterization of the meteorological grid used with CALMET, as previously discussed. The remaining user-defined variables, (RMAX1, RMAX2, RMAX3, TERRAD, R1, R2) control the influence of mesoscale model data, station observations, and terrain features in development of the final wind field. Settings for these variables are based on the NDDH alternative protocol for PSD Class I increment analyses.[3]

NDDH settings for IWAQM-defined variables are consistent with IWAQM recommendations, with limited exceptions as established in the alternative protocol for PSD Class I increment analyses. Because the use of mesoscale meteorological data is now being generally recommended for long-range modeling analyses, the IPROG variable has been changed from 0 to 14, which reflects use of MM5 format data (in this case RUC data) as the initial guess wind field. The ZUPWND setting has been changed for consistency with default values in recent versions of CALMET (the IWAQM setting reflected defaults for an older version of CALMET). Based on visual feedback testing, IWAQM settings for variables related to spatial averaging of mixing heights, MNMDAV and ILEVZI, are adjusted to provide averaging over a larger area. Because the NDDH CALMET/CALPUFF modeling domain extends into the western part of the upper Great Plains, maximum mixing height settings (ZIMAX/ZIMAXW) are increased from 3000 to 4000 meters to be consistent with maximum mixing heights reported for this region.[11] Note that the CALMET BIAS factors have no effect when mesoscale data are used as the initial guess wind field.

---

[11] Holzworth, 1972. Mixing Heights, Wind Speeds, and Potential for Urban Air Pollution Throughout the Contiguous United States. EPA Publication No. AP-101, Office of Air Programs

Settings as discussed above are incorporated in the CALMET control file prepared by NDDH for BART-related visibility analyses. A sample file with NDDH settings will be provided upon request.

3.2 CALPUFF Input

Along with the CALMET-processed meteorological data, CALPUFF requires the user to provide emissions and stack data, receptor locations, input control file settings, and (optionally) hourly ozone data before the model can be executed. A background ammonia value is also required.

3.2.1 Emissions and Stack Data

To determine which BART-eligible sources are subject to BART, the BART guideline stipulates modeling primary pollutants SO_2, NO_x, and PM_{10} (coarse and fine) using maximum emission rates. The guideline states,

> *"The emissions estimates used in the models are intended to reflect steady-state operating conditions during periods of high capacity utilization. We do not generally recommend that emissions reflecting periods of start-up, shutdown, and malfunction be used, as such emission rates could produce higher than normal effects than would be typical of most facilities. We recommend that States use the 24-hour average actual emission rate from the highest emitting day of the meteorological period modeled, unless this rate reflects periods of start-up, shutdown, or malfunction."*

Since the meteorological period modeled will be 2000 through 2002, the NDDH requested companies operating BART-eligible sources to provide maximum 24-hour emission rates (with exception of start-up, shutdown, and malfunction conditions) for this three-year period. Other stack data required by CALPUFF include stack height, stack diameter, exit velocity, exit temperature, location, and stack-base elevation. Entries for these stack parameters are taken from PSD increment modeling recently completed by NDDH.[3] Entries for the dynamic stack parameters, exit velocity and exit temperature, reflect an average for the 2000-2002 period.

Emission rates provided by BART-eligible source companies, and appropriate for BART-related visibility modeling, are shown in Table 3-2. When the BART-eligible source company only provided total particulate matter emission rates, PM_{10} emission rates were calculated based on data from recent Annual Emission Inventory Reports. Furthermore, the NDDH believes that assuming all PM_{10} emissions are $PM_{2.5}$ would be too conservative. Therefore, $PM_{2.5}$ emissions were calculated based on data in the 2004 Annual Emission Inventory Report. The NDDH recognizes that better data may become available on the particle size distribution of PM emissions at individual sources. BART-applicable source companies are free to use the better data in the BART-related modeling provided a justification is included as part of the BART analysis.

Associated stack parameters for modeling are found in Table 3-3. Tables 3-2 and 3-3 provide the appropriate emission rates and stack data to use in the CALPUFF analyses to determine which BART-eligible sources are subject to BART. Building downwash effects will not be considered in the CALPUFF visibility analyses.

To determine the degree of visibility improvement from BART controls, the BART guideline recommends comparing results of pre-control modeling with results of post-control modeling. Pre-control emission rates and stack data would be equivalent to those used for the BART screening analysis from Tables 3-2 and 3-3. Post-control emission rates and stack data must be provided by the BART applicable source company as part of the BART analysis. Post-control emission rates are calculated as a percentage of the pre-control emission rates, using the efficiency of the proposed control equipment and/or process changes.

If CALPUFF multi-source analyses are eventually conducted to address the combined effect of proposed BART controls, as alluded to in Section 1, it may be appropriate to reevaluate the use of peak 24-hour emission rates. Use of a non-peak emission characterization may be more realistic for determination of cumulative visibility impact.

3.2.2 **Ozone Background**

CALPUFF utilizes background ozone values in its chemistry module. The model accepts either a single constant background ozone value, or an input file of hourly ozone values commensurate with

Table 3-2

the period of meteorological data. The NDDH uses the hourly ozone file option with CALPUFF, and would regard this as the appropriate implementation for BART-related visibility modeling (this is also the IWAQM default option). The hourly ozone file option is implemented using year 2000-2002 hourly ozone data obtained from four NDDH monitoring sites located within the corridor of primary plume transport between major electric generating stations and Theodore Roosevelt National Park (TRNP). These monitoring sites include Hannover, Beulah, Dunn Center and TRNP South Unit. As indicated in Section 3.2.5, a constant ozone background value is also entered in the CALPUFF control file, so that it can be substituted when the hourly value is missing.

The NDDH prepared software to merge and format these ozone data into the input file required by CALPUFF (OZONE.DAT). The NDDH CALPUFF-compatible hourly ozone files for years 2000-2002 will be provided upon request.

3.2.3 **Ammonia Background**

The need for ammonia background concentrations in CALPUFF is also related to chemistry processing. CALPUFF accepts either a single annual value, or twelve monthly averages. To achieve a more realistic seasonal progression of nitrate predictions, the NDDH will be using monthly average ammonia background values for BART-related visibility analyses.

Monthly average ammonia concentrations suitable for visibility modeling in North Dakota are provided in Table 3-4. These values were derived from data collected at the State's only ammonia monitor located near Beulah. Hourly monitor data from years 2001-2002 (data not available for year 2000) were filtered to eliminate data from wind directions associated with sources causing a local bias, then remaining data were processed to produce the monthly averages. The Table 3-4 values should be generally representative of background ammonia concentrations in western North Dakota.

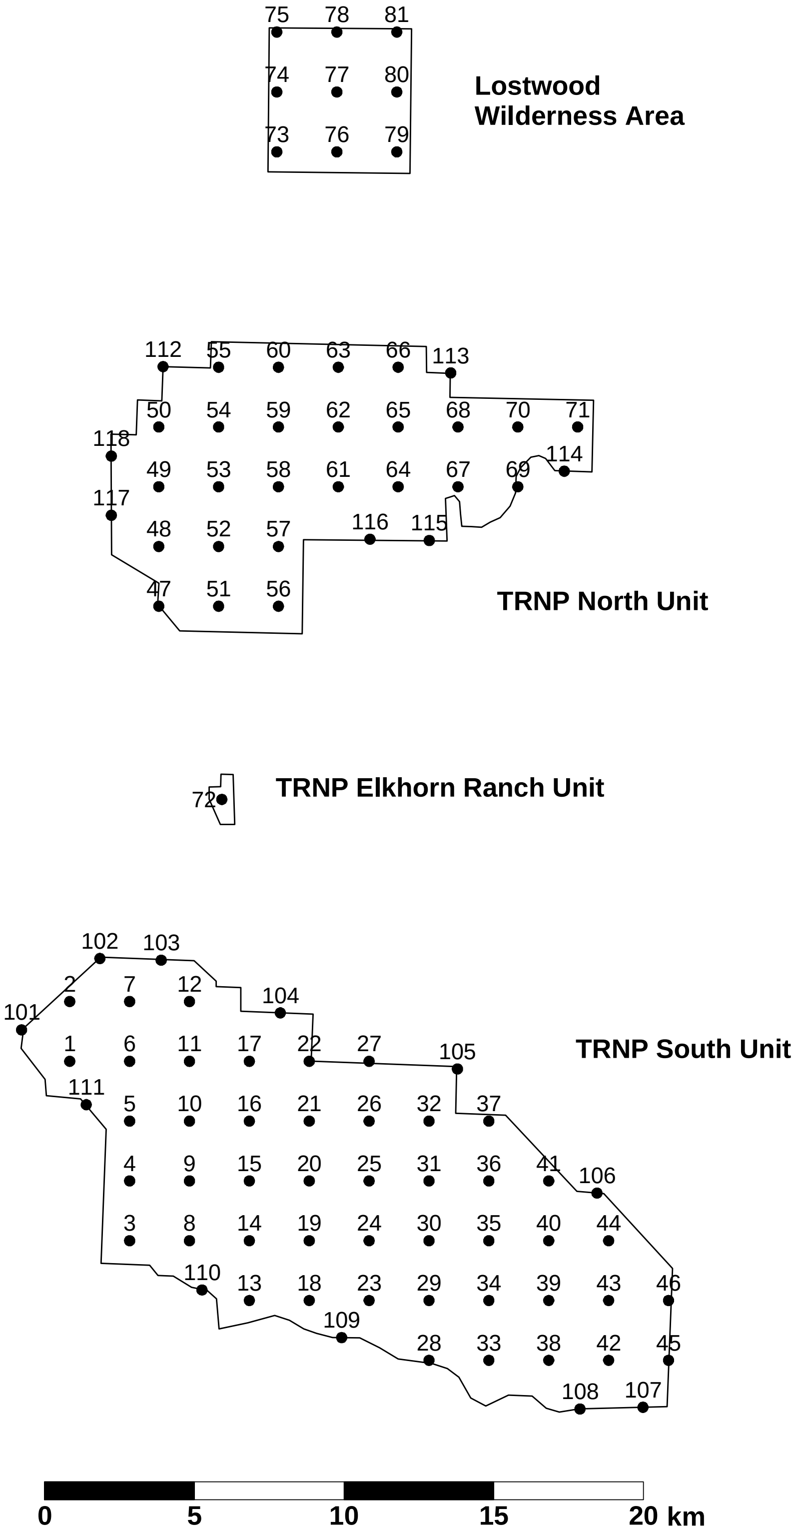
3.2.4 Receptor Locations

Receptor locations used by NDDH for PSD Class I area modeling analyses are shown in Figure 3-4. Receptor spacing for all Class I areas is generally 2 kilometers (km). Given the minimum distance of BART-eligible sources from Class I areas in North Dakota (about 100 km), single-source

Figure 3-4: Receptor Locations - North Dakota Class I Areas



concentration gradients (for visibility-related species) in the vicinity of Class I areas are not expected to be significant, and the 2 km receptor grids should be adequate for visibility analyses.

The BART guideline focuses on receptors at the nearest Class I area, only. Because all four Class I areas in North Dakota are located at relatively equal distances from BART-eligible sources, however, it is recommended that receptors for all Class I areas be accounted for in all BART-related visibility analyses. Class I area receptor coordinates and elevation, as implemented by NDDH, are provided in Appendix A. Receptor coordinates/elevation are also found in the example CALPUFF control file discussed in Section 3.2.5.

Note that receptor coordinates are provided in the same Lambert map projection as is used for source locations (Table 3-3). If needed, the NDDH can provide a utility (MAPCONI) to convert UTM or geographic coordinates to the North Dakota Lambert system.

3.2.5 **CALPUFF Control File Settings**

CALPUFF control file settings recommended for BART-related visibility analyses are generally consistent with IWAQM guidance.[10] IWAQM recommendations for CALPUFF control file settings fall into two categories. IWAQM-defined variables are those for which IWAQM provides a default value as a general recommendation for all analyses. User-defined variables are those where IWAQM recognizes the input value will need to be tailored for a given application, and default values are therefore not provided.

For BART-related visibility analyses, the NDDH has established appropriate settings for user-defined variables, and has determined the need to adjust a limited number of IWAQM-defined variables from recommended values, as discussed below. The CALPUFF control file user-defined settings, as well as the IWAQM-defined settings which have been adjusted by NDDH, are summarized in Table 3-5. IWAQM-defined settings adjusted by NDDH have a highlighted background in the table.

Most of the user-defined settings recommended by NDDH are intuitive, involving variables related to defining the meteorological/computational grid, variables related to the Lambert map projection, and the use of default values for dry and wet deposition parameterization. The variable IRESPLIT is set such that puffs are eligible for splitting on any hour of the day.

NDDH settings for IWAQM-defined variables are equivalent to IWAQM recommendations, with exception of settings for a limited number of variables related to puff splitting, dispersion, and mixing height. Variable MSPLIT is set to allow puff splitting, as this option is generally recommended when modeling source-receptor distances of 200 km or more. Based on performance testing of the CALPUFF model for PSD Class I increment modeling,[3] the NDDH uses adjusted settings for dispersion-related variables MDISP and MPDF, and for variables IVEG and ROLDMAX, as these adjustments provide better model performance. NDDH settings for MDISP and MPDF, reflecting the use of micro meteorological variables in calculating dispersion, are also more consistent with dispersion treatment in the local-scale model AERMOD. Values for background ozone and ammonia (variables BCKO3 and BCKNH3, respectively) are set to be

Table 3-5
User-Defined and Non-IWAQM Settings for CALPUFF Control File

Variable	Description	Value
IBTZ	Base time zone	7
NSPEC	Number of chemical species	7
NSE	Number of chemical species emitted	4
MSPLIT	Allow puff splitting (1=yes)	1
MDISP	Method used to compute dispersion coefficients	2

Wet Dep.	Wet deposition parameters	Model defaults
BCKO3	Monthly ozone background concentration (ppb)	30.0*
BCKNH3	Monthly ammonia background concentration (ppb)	Table 3-4
XMAXZI	Maximum mixing height	4000.
IRESPLIT	Hours when puff is eligible for vertical split	hours 1-24
ROLDMAX	Vertical puff split allowed only when the ratio of last hour's mixing height to max. mixing height experienced by the puff is smaller than this value	0.33
NSPLITH	Number of puffs that result when a puff is split horizontally	5
SYSPLITH	Minimum sigma-y (grid cell units) of puff before it may split horizontally	1.0
SHSPLITH	Minimum puff elongation rate (SYSPLITH/hr) due to wind shear, before it may split horizontally	2.0
CNSPLITH	Minimum concentration (g/m^3) in puff before it may split horizontally	1.0E-07
NREC	Number of discrete receptors	99

*Use same value for each month.

consistent with local monitoring data. Maximum mixing height (XMAXZI) is set to 4000 meters for consistency with CALMET settings.

Settings as discussed above are incorporated in the CALPUFF control file developed by NDDH for BART-related visibility analyses. A sample file with NDDH settings will be provided upon request.

3.3 **POSTUTIL Input**

The POSTUTIL processor provides repartitioning of total nitrate to adjust for possible double (or multiple) counting of ammonia in the CALPUFF chemistry. According to Escoffier-Czaja and Scire[12],

> *"In CALPUFF, a continuous plume is simulated as a series of puffs, or discrete plume elements. The total concentration at any point in the model is the sum of the contribution of all nearby puffs from each source. Because CALPUFF allows the full amount of the specified background concentration of ammonia to be available to each puff for forming nitrate, the same ammonia may be used multiple times in forming nitrate, resulting in an overestimate of nitrate formation .... In POSTUTIL, ammonia availability is computed based*

---

[12] Escoffier-Czaja, Christelle and J. Scire, 2002. The Effects of Ammonia Limitation on Nitrate Aerosol Formation and Visibility Impacts in Class I Areas. Earth Tech, Inc., Extended abstract. 12th Joint Conference on the Applications of Air Pollution Meteorology with the Air and Waste Management Association, American Meteorological Society, J5.13.

> *on receptor concentrations of total sulfate and total nitrate (HNO_3 + NO_3), not on a puff-by-puff basis."*

Input required by POSTUTIL includes an input control file and the hourly concentration output file from CALPUFF. Primary settings for the POSTUTIL control file include the ammonia background concentrations and a variable (MNITRATE) related to recomputing the nitrate partition. The monthly ammonia background concentrations are equivalent to the values used in CALPUFF (Table 3-4), and the appropriate setting for MNITRATE in BART-related visibility analyses is '1'. Species processing information (POSTUTIL Input Group 2) for BART-related visibility analyses is specified as shown in Figure 3-5, with PMC representing the name used in CALPUFF for coarse particulate, and PMF representing the name used for fine particulate. Note that entries are not necessary for Subgroups 2.c and 2.d. All other POSTUTIL settings are intuitive, with some simply repeated from the CALPUFF control file.

Settings as discussed above are incorporated in the POSTUTIL control file developed by NDDH for BART-related visibility analyses. A sample file with NDDH settings will be provided upon request.

3.4 **CALPOST Input**

CALPOST produces summary 24-hour average visibility results (in delta-deciviews) which are compared to the BART-related thresholds (Section 2.1). Required input for CALPOST includes an input control file and the hourly concentration output file from either CALPUFF or POSTUTIL.

```

CALPOST control file settings recommended by NDDH for BART-related visibility analyses are summarized in Table 3-6. The BART guideline specifies that daily (24-hour) visibility values should be calculated for each receptor as the change in deciviews (delta-deciview) compared against natural background visibility conditions. More specifically, the preamble to the final BART rule specifies use of natural background for the 20 percent best visibility days. The guideline also provides for the use of monthly average relative humidity (RH) values for BART-related visibility analyses. The preference for monthly average relative humidity implies the use of CALPOST visibility Method 6 (MVISBK = 6).

In order to develop background conditions for visibility Method 6, CALPOST requires monthly background concentrations of ammonium sulfate, ammonium nitrate, coarse particulate mass, organic carbon, soil, and elemental carbon. Annual averages reflective of natural background conditions for these species are found in EPA's "Guidance for Estimating Natural Visibility Conditions Under the Regional Haze Program" (2003)[13]. For each Class I area, this guidance document provides separate deciview values representative of annual average natural background, and natural background for the 20 percent best days.

The EPA natural visibility guidance document does not provide speciated background concentrations (above) representative of the 20 percent best days, as would be needed for implementation of

* Use same value for each month.

CALPOST Method 6 consistent with the BART rule. Upon consultation with EPA and National Park Service/Fish and Wildlife Service representatives[14], it was concluded that the annual concentrations (Table 2-1 in guidance document) should be scaled back, in equal proportion, until they converge to lower concentratons that produce the deciview value specified for the 20 percent best days (guidance document Appendix B) to provide the necessary CALPOST input. The scaling procedure would be conducted separately for each Class I area.

The scaling procedure as applied by NDDH is illustrated here for Theodore Roosevelt National Park (TRNP). From Appendix B in the natural visibility guidance document, the deciview value for annual average natural conditions at TRNP is 4.75, and the deciview value for the 20 percent best days is 2.19. Note that the TRNP annual average deciview value reflects natural background components for the US west region. To obtain the speciated background concentrations representative of the 20 percent best days at TRNP, the deciview value (2.19) must first be converted to light extinction. The relationship between deciviews and light extinction is expressed,

$$dv = 10 \ln (b_{ext}/10)$$

or

$$b_{ext} = 10 \exp (dv/10)$$

where

dv represents deciviews,
b_{ext} represents total light extinction expressed in inverse megameters (Mm^{-1}).

---

[14] NDDH, 2005. Electronic message summarizing BART modeling-related conference-call discussion with representatives of EPA, National Park Service, and Fish and Wildlife Service, August 31, 2005.

Using this relationship with a deciview value of 2.19, one obtains a light extinction value of 12.45 Mm^{-1}. Next, the natural visibility guidance document background concentrations for annual average (Table 2-1, west) are adjusted in order to provide the extinction value just determined (12.45 Mm^{-1}). The relationship between light extinction and background concentrations is:

$$\begin{aligned} b_{ext} = {} & (3)\ f\ (RH)\ [\text{ammonium sulfate}] + (3)\ f\ (RH)\ [\text{ammonium nitrate}] + \\ & (0.6)\ [\text{coarse mass}] + (4)\ [\text{organic carbon}] + (1)\ [\text{soil}] + \\ & (10)\ [\text{elemental carbon}] + b_{ray} \end{aligned}$$

where

bracketed quantities represent background concentrations in $\mu g/m^3$,
values in parenthesis represent scattering efficiencies,
f (RH) is the relative humidity adjustment factor (applied to hygroscopic species only),
b_{ray} is light extinction due to Rayleigh scattering (10 Mm^{-1} used for all Class I areas).

Substituting the annual average natural background values and TRNP f (RH) from the natural visibility guidance document, and including the coefficient for scaling, one obtains

$$\begin{aligned} 12.45 = {} & (3)\ (2.56)\ [0.12]\ X + (3)\ (2.56)\ [0.1]\ X + (0.6)\ [3.0]\ X + (4)\ [0.47]\ X + \\ & (1)\ [0.5]\ X + (10)\ [0.02]\ X + 10 \end{aligned}$$

where

X represents scaling factor to convert annual average natural background concentrations to values representative of 20 percent best days.

Solving for X provides a value of 0.403. This scaling factor was applied to the annual average natural background components in the natural visibility guidance document (Table 2-1, west region) to obtain background components for the 20 percent best days for TRNP. The scaling procedure was repeated for Lostwood Wilderness Area.

Results of the scaling procedure are shown in Table 3-7, which includes speciated natural background concentrations representative of annual average visibility, 20 percent best days for Theodore Roosevelt National Park, and 20 percent best days for Lostwood Wilderness Area. Note that west region natural conditions are assumed for North Dakota Class I areas. The Table 3-7

The remainder of CALPOST control file settings are intuitive, and mirror settings in the CALPUFF control file. Settings as discussed above are incorporated in the CALPOST control file developed by the NDDH for BART-related visibility analyses. A sample file with NDDH settings will be provided upon request.

4 Model Execution and Output Interpretation

For BART-related single-source visibility analyses in North Dakota, the CALPUFF modeling system should be executed with input data and settings as described in Section 3. Delta-deciview results necessary for comparison with visibility thresholds are obtained from the "24HR VISIBILITY (deciview)" table in the CALPOST output file.

The BART guideline states that the 98th percentile of 24-hour CALPUFF modeling results should be compared with the contribution threshold established by the State for purposes of determining BART applicability. Upon clarification from EPA and FLM's[14], the context of the 98th percentile 24-hour delta-deciview prediction is with respect to days of the year, and is not receptor specific. A 24-hour prediction greater than 0.5 delta-deciview at any receptor in a Class I area would constitute a day of exceedance, and up to 7 days of exceedance would be allowed per year per Class I area (i.e., the 98th percentile is approximated by the eighth-highest daily prediction).

4.1 BART Screening

To complete the BART screening analysis for North Dakota sources, CALPUFF (and optionally POSTUTIL) is executed for each year of meteorological data processed with CALMET (2000-2002). And for each year of CALPUFF (POSTUTIL) hourly output, CALPOST is executed separately for receptor groups representing each Class I area. Delta-deciview modeling results applicable to BART screening are found in the summary section at the bottom of the "24HR VISIBILITY (deciview)" table in the CALPOST output file. If the number of days with delta-deciview prediction greater than 0.5 is more than 7, for any year of meteorological data for any Class I area, the source is concluded to be BART-applicable. Note that the three units of Theodore Roosevelt National Park are treated as separate Class I areas for BART-related visibility analyses.

4.2 **Degree of Visibility Improvement**

For analyses to determine the degree of visibility improvement due to BART controls, the modeling system is executed as described above for BART screening. Model execution and results are needed for both pre-BART control and post-BART control scenarios, to allow comparison of CALPOST delta-deciview predictions for both scenarios. The context of this comparison is not specifically defined, leaving it to the State to determine the appropriate metric. The BART guideline states:

> *"Assess the visibility improvement based on the modeled change in visibility impacts for the pre-control and post-control emission scenarios. You have flexibility to assess visibility improvement due to BART controls by one or more methods. You may consider the frequency, magnitude, and duration components of impairment."*

Consistent with the goals stated in the BART guideline, the NDDH recommends the following specific approaches for evaluating the degree of visibility improvement from BART controls:

- Compare the 98th percentile delta-deciview prediction from pre-control and post-control modeling scenarios.
- Compare the number of days of exceedance of the 0.5 delta-deciview threshold for pre-control and post-control scenarios (to address "duration", the maximum number of consecutive days of exceedance should also be reported for both scenarios).
- For consistency with goals of the Regional Haze program (and WRAP regional-scale modeling), compare the 90th percentile delta-deciview prediction from pre-control and post-control modeling scenarios (i.e., average of the 20 percent worst days).

Again, these comparisons would be made for each Class I area and for each year of meteorological data.

While the above comparisons are proposed in the context of total deciview improvement attributable to BART controls for all species combined, it may be desirable to also test the relative effectiveness of controls for individual species. When evaluating visibility improvement for individual species, the following should be considered.

- To maintain reasonable balance in the CALPUFF chemistry, all four species (SO_2, NO_X, PM coarse, PM fine) should be included in the model input files for pre-control and post-control scenarios. The post-control input file should reflect the BART-control emission rate for the tested species, while the emission rate for other species remains at pre-control levels. Post-control input file stack parameters should reflect post-control values for the tested species.

- Alternatively, to refine the accuracy of single-species testing, the reactive species SO_2 and NO_X may be grouped separately from the non-reactive species PM coarse and PM fine (primary only) in the post-control input file. That is, the BART-applicable source unit would be configured as two virtual co-located sources in the post-control input file. One virtual source would include emission rates for reactive species SO_2 and NO_X, and the other virtual source would include emission rates for non-reactive species PM coarse and PM fine. If the species being tested is reactive, then post-control stack parameters (for the tested species) would be entered for the reactive virtual sources, and pre-control stack parameters would be entered for the non-reactive virtual source. If the species being tested is non-reactive, then post-control stack paramters would be entered for the non-reactive virtual source, and pre-control stack parameters would be assigned for the reactive virtual source.

- If information on particle size distribution is not available for the post-control scenario for primary particulate, the ratio of PM fine to PM coarse for the post-control scenario should be considered equivalent to the PM ratio for the pre-control scenario (Table 3-2).

Whether testing degree of visibility improvement for ensemble species or for one species at a time, testing should be conducted separately for each BART-applicable unit within a facility. When testing for individual species is complete, the overall degree of visibility improvement should be evaluated for each unit. When testing for individual units is complete, the degree of visibility improvement should be evaluated for the entire facility.

It is not the intent of the NDDH to develop specific thresholds for the comparisons of modeled visibility impact recommended above. Rather, the degree of visibility improvement represented by these modeled comparisons (and possibly others) will be evaluated in a qualitative manner, in concert with the review of other prescribed analyses of BART control options (i.e., technology available, cost of compliance, etc.), to establish an appropriate BART control.

4.3 **CALBART Utility**

To expedite recommended comparisons for determining the degree of visibility improvement, the NDDH has developed the CALBART utility software program. CALBART processes the hourly output file from either CALPUFF or POSTUTIL to provide the 24-hr delta-deciview metrics recommended for assessing the degree of visibility improvement due to BART controls. CALBART replaces CALPOST in the sequence of visibility model processing. CALBART produces delta-deciview results equivalent to CALPOST (i.e., when CALPOST input is set as prescribed in Section 3.4), but in a summarized format which includes results for all Class I areas in a single execution.

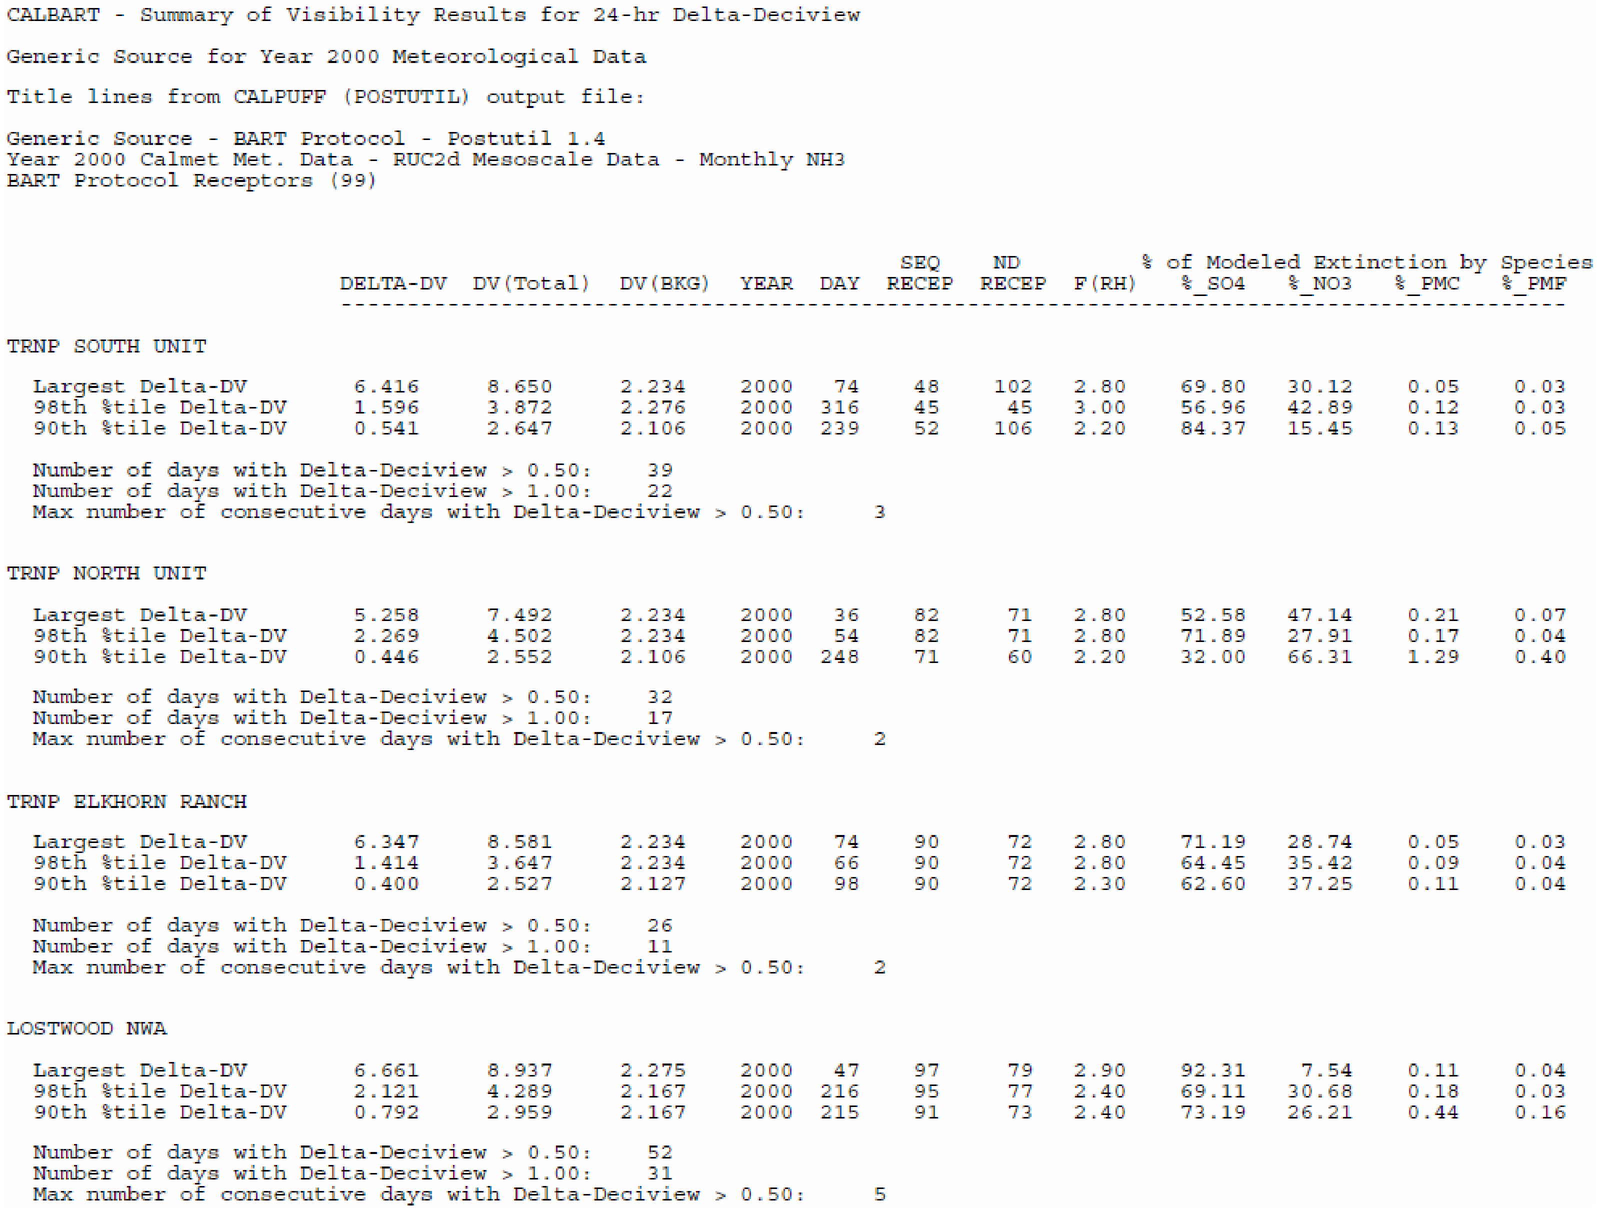
CALBART requires an input control file which must be named ‘CALBART.INP'. The file includes three lines:

Line 1 - Title (up to 80 characters)
Line 2 - File name and path for CALPUFF (POSTUTIL) output file (up to 40 characters)
Line 3 - Beginning year, julian day, and hour for the CALBART run (free format, time must be

equal to or later than that specified in the CALPUFF or POSTUTIL input file; also, the hour should always be specified as '0' to ensure that calendar days are simulated)

An example of CALBART output (file CALBART.LST) is provided in Figure 4-1. The CALBART software will be provided upon request.

Figure 4-1: CALBART Output Example



```
CALBART - Summary of Visibility Results for 24-hr Delta-Deciview

Generic Source for Year 2000 Meteorological Data

Title lines from CALPUFF (POSTUTIL) output file:

Generic Source - BART Protocol - Postutil 1.4
Year 2000 Calmet Met. Data - RUC2d Mesoscale Data - Monthly NH3

Re: Heskett Unit 2 BART Modeling Refinements

Dear Mr. O'Clair:

This letter is in reference to your letter dated November 30, 2005, in which the Department states our Heskett Unit 2 is subject to BART. Since the modeling results for Unit 2 were under the "causes" impairment level of 1.0 dv, but over the "contributes to" impairment level of 0.5 dv, Montana-Dakota Utilities Co. retained ENSR to evaluate the previous modeling.

In conducting their review, ENSR determined it is appropriate to refine the grid size in the model from 3 km to 1 km and to use the average background visibility to determine the change caused by Unit 2, in accordance with the recently announced EPA court settlement. These changes, even when offset by using speciated particulate matter inputs, consistent with National Park Service guidance, provide model results that are less than the "contributes to" impairment level, thus indicating that Unit 2 does not contribute to visibility impairment and that it is not subject to BART. These model results were based on the currently authorized and permitted allowable emissions from Unit 2.

Separately, and as we have previously discussed, Montana-Dakota will nonetheless voluntarily commit to control SO_2 emissions by installing and operating the necessary equipment to use limestone as the bed material in the boiler. Montana-Dakota will agree to include a condition in our Title V permit implementing this change, including a permit shield pertaining to BART applicability. We will be in contact at a later date to discuss the details of the permit modification.

We look forward to your concurrence with the attached refined modeling report and determination that Heskett Unit 2 is not subject to BART. If you have any questions regarding this submittal, please contact Jay Skabo at 222-7835.

Sincerely,

Andrea Stomberg

1.0 Introduction

1.1 Background

The North Dakota Department of Health (NDDH) has conducted CALPUFF modeling for emission sources for all BART-eligible facilities in North Dakota. This study focuses upon CALPUFF modeling for one of these facilities, the Heskett Station (specifically, Unit 2). Heskett Unit 1, operational in 1954, has a capacity of 40 MW and is not BART-eligible since if was put into service before 1962. Unit 2, operational in 1963, has a capacity of 75 MW. Unit 2 was retrofitted to a fluidized-bed combustor in 1987.

The NDDH has provided information regarding CALPUFF modeling they conducted to determine whether the Unit 2 at the Heskett Station is subject to BART. Some of these predicted visibility impacts exceed the 0.5 deciview (dv) threshold for "contributing to impairment" at the Theodore Roosevelt National Park and the Lostwood Wilderness Area, as noted in EPA's final BART rule published on July 6, 2005. The results are discussed in Section 3.0 of this report.

Recently, EPA has announced a court settlement agreement regarding BART that allows each state to use the annual average background visibility instead of the best 20% days' background visibility. This change occurred because the actual BART rule (published in the July 6, 2005 *Federal Register*) stipulated that the annual average background visibility value should be used, while the preamble was inconsistent and mentioned that the 20% best days' background visibility should be used.

For this analysis, ENSR conducted additional CALPUFF modeling with three appropriate refinements to the analysis conducted by the NDDH, as described below. This report documents the results of this modeling analysis.

1.2 Elements of the Refined Analysis

The three refinements that ENSR has considered in this alternative modeling analysis are summarized below.

- In the generation of the wind field, we have increased the grid resolution by a factor of 3 in the x and y directions by reducing the grid size from 3 km to 1 km. To make the runs manageable, we have set the modeling domain extent to 50 km beyond the modeled source and PSD Class I areas.
- To be consistent with other refined BART analyses, we have used guidance from the National Park Service on the speciation of particulate matter emissions into several components that have different light scattering potential: coarse matter, inorganic fine matter, elemental carbon, sulfuric acid mist, and organic aerosol fine particulate.
- In accordance with a recent EPA announced court settlement, we used the annual average background visibility to determine the change in visibility caused by the BART-eligible source under consideration.

The BART analysis modeling refinements are discussed in more detail in Section 2. The results of the new modeling runs and conclusions are presented in Section 3. References are provided in Section 4.

2.0 BART Analysis Refinements

Three refinements have been made by ENSR to the CALMET/CALPUFF modeling conducted by the NDDH for the BART determination for the Heskett Station Unit 2. Otherwise, the same CALMET and CALPUFF model versions used by the NDDH have been used in this modeling. The first step in the ENSR modeling was to replicate the results obtained by the NDDH with the modeling files and executable files that were supplied to ENSR. This step was completed satisfactorily.

2.1 Meteorological Processing with CALMET

One of the ENSR refinements involves the use of a 1-km grid size instead of the 3 km used by the NDDH. The digital terrain data used for this analysis consisted of 1-degree data (90-meter resolution). This change has the effect of better terrain and land use resolution for the CALPUFF modeling. No other changes to the CALMET processing from that which the NDDH did were made, except that the total grid domain was slightly reduced (to save on disk space) to provide a 50-km buffer around the source modeled as well as the PSD Class I areas. Figure 2-1 shows the modeling domain that ENSR used.

2.2 Particulate Matter Speciation

The National Park Service has issued guidance on how to divide, or speciate, particulate matter emissions into different constituents that have different light scattering EPA potential: coarse matter, inorganic fine matter, elemental carbon, sulfuric acid mist, and organic aerosol fine particulate. The guidance is located at http://www.vistas-sesarm.org/BART/calpuff.asp on the VISTAS regional planning organization web site. While NDDH did not include this guidance in its BART screening protocol, ENSR believes it is obligatory it be included in this analysis, even though it results in modeling higher visibility impacts.

Engineers from Montana-Dakota Utilities reviewed these speciation profiles and selected the data for a dry bottom PC with FGD and ESP controls spreadsheet as the most representative of the emissions from Heskett Unit 2. A series of Method 8 stack tests conducted August 24 – 26, 2000 found an average H_2SO_4 rate of 9.0 lb/hr (2.9 ppm) at full load. The resulting emissions used in the CALPUFF regional haze modeling are listed in Table 2-1. To simplify the modeling, the coarse and fine inorganic matter were combined as fine matter, which has a slightly higher visibility extinction efficiency than coarse matter.

Table 2-1 Heskett Unit 2 emissions data for refined BART modeling

Component	Emission Rate (lb/hr)
SO_2	1475.5
NO_2	227.5
Coarse matter	8.2
Inorganic fine matter	6.3
Elemental carbon	0.2
H_2SO_4	9.0
Organic aerosols	2.0

ENSR input file shows 302.8 for NO_x emission rate, which is correct

2.3 Natural Background Determination

The EPA final BART rule is ambiguous regarding the appropriate statistic to be used for the natural background level in deciviews. While the BART rule text indicates that the average annual value should be used, the preamble to the rule indicates that the best 20% days' value should be used. After the rule was published, EPA tried to clarify this issue and state that the best 20% days' value was actually intended. However, the Utility Air Regulatory Group challenged this interpretation in court. EPA has proposed a settlement to the litigation that indicates that each state can select either option. The NDDH has indicated that it is permissible for sources to use the annual average background visibility. The concentrations used in the CALPUFF input for the speciated particulate that contribute to visibility impairment are listed in Table 2-2, consistent with Table 3-7 in the NDDH final BART modeling protocol.

Table 2-2 Natural levels of aerosol components (μg/m³)

Component	Annual Average West Region(1)	20% Best Days Theodore Roosevelt NP	20% Best Days Lostwood NWA
Ammonium sulfate	0.12	0.048	0.049
Ammonium nitrate	0.10	0.040	0.041
Organic carbon mass	0.47	0.189	0.190
Elemental carbon	0.02	0.008	0.008
Soil	0.50	0.202	0.203
Coarse mass	3.00	1.209	1.215
Natural deciview(2)	-	2.19	2.21

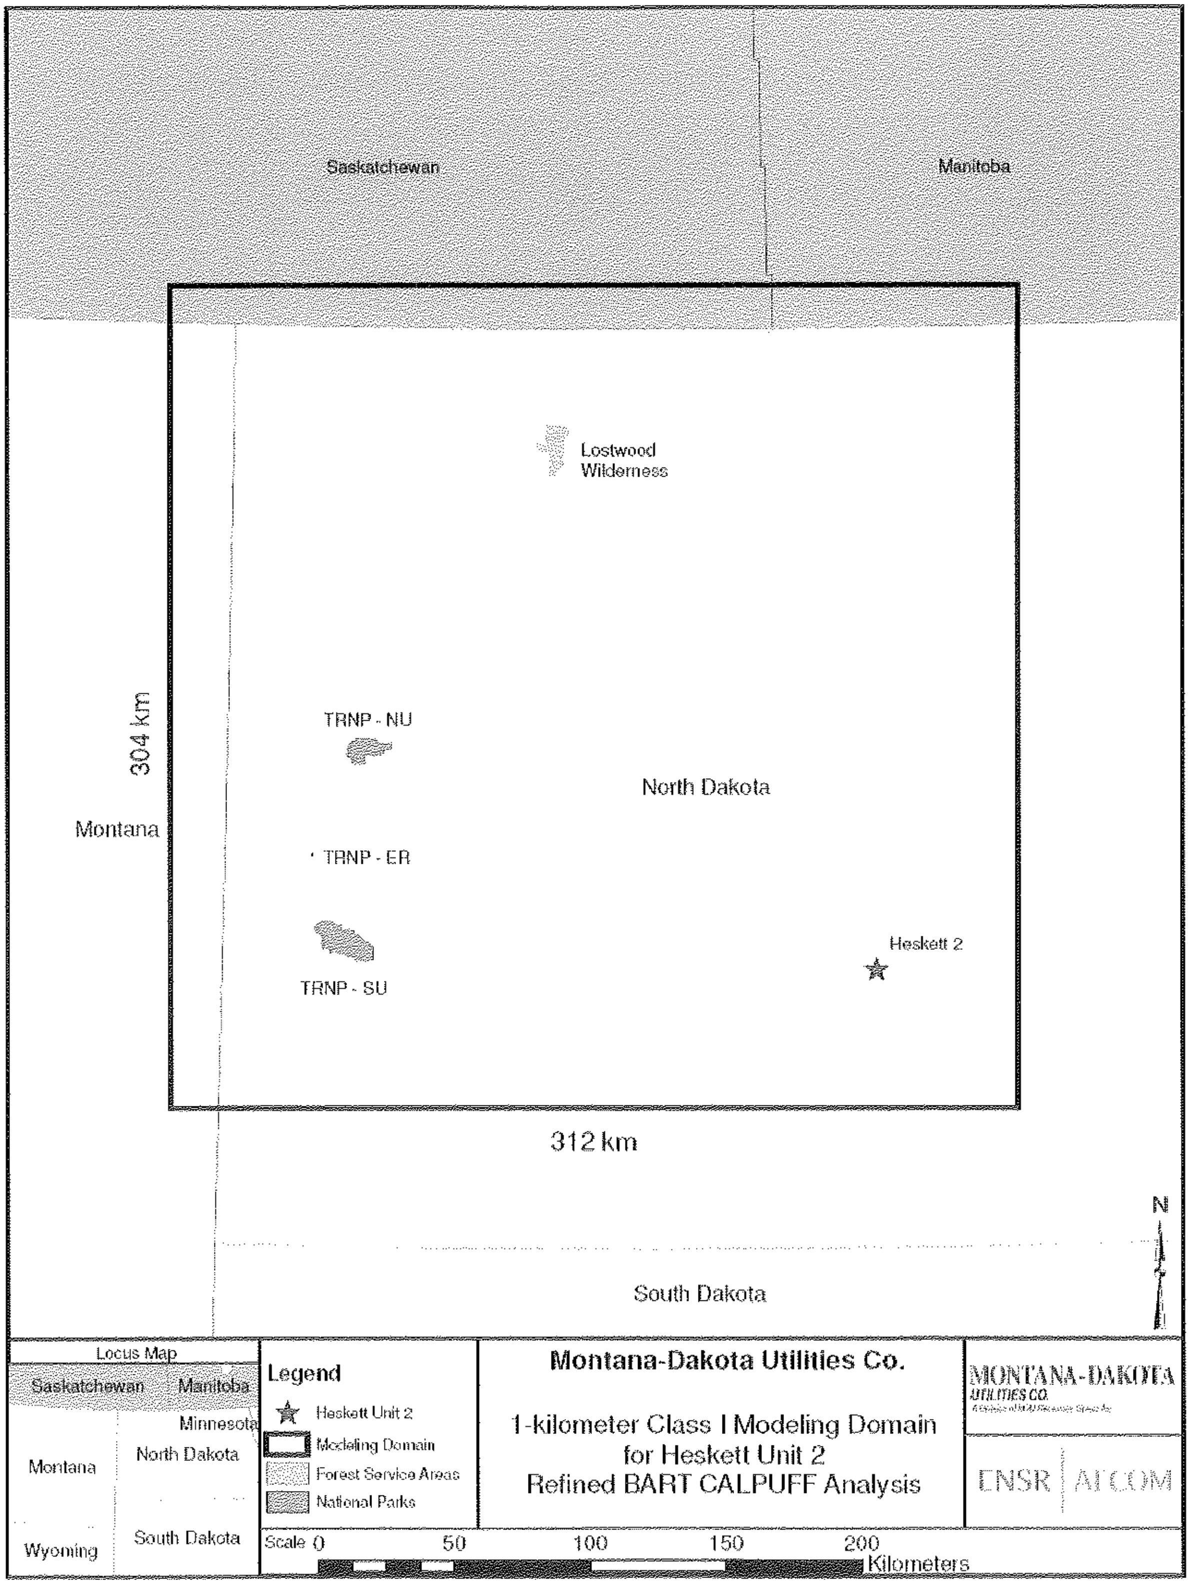
Figure 2-1 Modeling domain for 1 kilometer grid



3.0 Refined BART Analysis Results and Conclusions

A comparison of the NDDH and ENSR results are shown in Table 3-1. The results indicate that for all years tested, the ENSR refined BART modeling results indicate that all 98th percentile predictions of the change in visibility are below 0.5 deciviews.

Table 3-1 Comparison of NDDH BART results and ENSR BART results

NDDH BART Results (3-km grid, best 20% days' background, no PM speciation)	98th Percentile Change in Visibility			
	TRNP South	TRNP North	TRNP Elkhorn Ranch	Lostwood NWA
2000	0.350	0.355	0.381	0.346
2001	0.351	0.536	0.400	0.583
2002	0.822	0.496	0.606	0.457
ENSR BART Results (1-km Grid, annual average background, with PM speciation)	98th Percentile Change in Visibility			
	TRNP South	TRNP North	TRNP Elkhorn Ranch	Lostwood NWA
2000	0.201	0.267	0.217	0.278
2001	0.209	0.347	0.223	0.436
2002	0.428	0.397	0.388	0.224

Based upon these results, we conclude that upon verification of the modeling results by the NDDH, the Heskett Station Unit 2 does not cause or contribute to visibility impairment, and thus is not subject to BART.

Bismarck, ND 58501

Re: Heskett Unit 2 BART Applicability

Dear Ms. Krebsbach:

The Department has reviewed the modeling analysis for the Heskett Station Unit 2 that was submitted June 9, 2006. The modeling analysis was conducted to determined the effect Unit 2 has on visibility in the Class I areas of North Dakota. This modeling analysis indicates that Unit 2 has an impact on visibility impairment of less than 0.5 deciviews.

On December 12, 2006, the Department and Montana Dakota Utilities (MDU) met to discuss the modeling analysis and proposed sulfur dioxide reductions at Heskett Unit 2. On December 27, 2006 we received a letter from MDU which outlined commitments stated at the December 12, 2006 meeting. From that meeting and the letter, it is the Department's understanding that MDU has committed to reduce sulfur dioxide emissions from Heskett Unit 2 by at least 70% on a 30-day rolling average basis (coal-to-stack) by the end of 2013. In addition, it is our understanding that Montana-Dakota Utilities has committed to conduct an optimization study to determine the removal efficiency due to limestone injection into the bed. The optimization study will be utilized to determine an enforceable reduction efficiency for Heskett Station Unit 2; however, removal efficiency shall not be less than 70%.

Based on the results of the modeling analysis and our understanding of Montana Dakota Utilities commitments regarding sulfur dioxide control from Heskett Unit 2, the Department has determined that Best Available Retrofit Technology (BART) requirements are not applicable to Heskett Unit 2.

If you have any questions, please feel free to contact me.

Sincerely,

Terry O'Clair

Comments on EPA Region 8 and FLM Concerns Regarding BART Exemption Modeling for Montana-Dakota Utilities Company's R.M. Heskett Station Unit 2: August 2009 Update

Robert Paine
AECOM Environment (formerly ENSR)
Westford, MA
August 12, 2009

Introduction

In 2006, Montana Dakota Utilities Co. (Montana-Dakota) asked ENSR (now AECOM) to review the results of the North Dakota Department of Health (NDDH's) 2005 Best Available Retrofit Technology (BART) CALPUFF modeling analysis of Unit 2 at the R.M. Heskett Station to determine whether there were any aspects of the modeling procedures that should be refined to make the modeling results more accurate. In addition to utilizing annual average background visibility instead of the best 20% days' background visibility in the model, ENSR found two additional areas of refinement.

First, and in accordance with EPA's CALPUFF modeling "Frequently Asked Questions" and EPA guidance on resolving terrain features, ENSR decreased the horizontal grid spacing in the model from 3 km to 1 km. Use of the 1-km grid spacing for modeling the projected visibility impacts of Unit 2 is supported by both the intervening complex terrain and the proximity of R.M. Heskett Station to the Class I areas of concern. The effect of using the finer grid spacing over the three years modeled at the Class I areas ranged from a slight increase in visibility impacts to about a 40% decrease. Since the smaller grid size forces a smaller step change in the CALPUFF model and a better representation of causality effects, the 1-km grid size improved upon independent NDDH CALPUFF evaluations that show an overprediction tendency in the range of 50-70% relative to observed 24-hour concentrations in the Theodore Roosevelt National Park with the use of a 3-km grid spacing.

Second, since the NDDH modeling did not consider speciation of PM_{10} emissions, ENSR introduced a PM_{10} speciation input into the CALPUFF modeling in accordance with technical advice provided by other BART protocols, which had the effect of increasing the predicted impacts because the added species have a larger extinction efficiency than the model default for "soils" used by NDDH.

Application of the available refinements to the CALPUFF BART modeling for Heskett Unit 2 showed a worst-year 98th percentile deciview change from background of 0.421 at Theodore Roosevelt National Park and 0.399 at the Lostwood Wilderness Area. These values are below the 0.5 dv threshold which is used to determine if a BART-eligible source is contributing to regional haze at a Class I area. NDDH therefore concluded that Heskett Unit 2 is not a BART-subject source.

One additional area of refinement that was not available in the CALPUFF modeling system until 2008 was the ability to use the new IMPROVE equation, which is a more accurate method to convert the predicted particulate concentrations into visibility impairment. ENSR's experience with this new method is that it typically reduces the visibility impairment for emissions sources such as power plants in the range of 20-30%. The availability of this method would have further reduced the modeled visibility impact of Heskett Unit 2 over that which was reported to the NDDH in 2006. Therefore, the ENSR-reported visibility impact is overly conservative.

By letter to NDDH dated August 4, 2008, EPA Region 8 expressed concerns regarding the use of 1-km grid spacing in the Heskett Unit 2 BART exemption modeling analysis, although the ENSR modeling report did provide a discussion justifying the grid spacing selection. These comments provide an updated technical justification for the use of finer grid spacing.

Summary Background

In 2005, NDDH conducted CALPUFF modeling for emission sources at several BART-eligible facilities in North Dakota. One of these sources was Unit 2 at the R.M. Heskett Station (Heskett). This unit became operational in 1963 with a capacity of 75 MW, and was retrofitted to a fluidized-bed combustor in 1987.

The NDDH conducted initial CALPUFF modeling to determine whether Unit 2 at Heskett is subject to BART. The NDDH's CALPUFF modeling, which was provided to Montana-Dakota, indicated that baseline emissions impacts would result in a visibility impact of 0.82 deciviews (dv) at the Theodore Roosevelt National Park (TRNP) and 0.58 at the Lostwood Wilderness Area (LWA). These predicted visibility impacts exceed the 0.5 dv threshold for “contributing to impairment” as noted in the United States Environmental Protection Agency's (EPA's) final BART rule published on July 6, 2005 (70 Fed. Reg. 39104). This determination was based upon the use of the 20% best days' background visibility and the use of a 3-km grid spacing in CALMET and CALPUFF.

Subsequent to that modeling exercise, EPA announced a court settlement regarding BART that allows each state to use the annual average background visibility instead of the best 20% days' background visibility. This change occurred because the final July 6, 2005 BART rule stipulated that the annual average background visibility value should be used, while the preamble was inconsistent and mentioned that the 20% best days' background visibility should be used. NDDH elected to adopt a policy to use the annual average option for determining the results of BART exemption modeling analyses. This change alone resulted in a nearly 25% reduction of visibility impacts, adjusting the results at LWA to be below the 0.5 delta-dv threshold. The adjusted results at TRNP were also lower, but still above the 0.5 delta-dv threshold.

In 2006, Montana-Dakota asked ENSR to review the results of NDDH's CALPUFF modeling analysis and to determine whether there were any aspects of the modeling procedures that should be changed or refined to make the modeling results more accurate. ENSR found two areas for such refinement (in addition to the selection of the background metric mentioned above). These included the following:

1) In accordance with EPA's CALPUFF modeling “Frequently Asked Questions” and EPA guidance on resolving terrain features, ENSR decreased the horizontal grid spacing in the model from 3 km to 1 km. The effect of the finer grid spacing over the three years modeled at the various Class I areas (LWA and three units of TRNP) ranged from a slight increase in visibility impacts to about a 40% decrease in some cases.

2) Since the NDDH modeling did not consider speciation of PM_{10} emissions, ENSR introduced a PM_{10} speciation input into the CALPUFF modeling in accordance with technical advice provided by other BART protocols such as the VISTAS BART protocol, available at http://www.vistas-sesarm.org/documents/BARTModelingProtocol_rev3.2_31Aug06.pdf, and PM_{10} speciation guidance from the Federal Land Managers available at a link on the VISTAS web site (http://www.vistas-sesarm.org/BART/calpuff.asp). This change to the model increased the predicted impacts because the added species have a larger extinction efficiency than the “soils” used by NDDH.

The result of the refinements to the CALPUFF BART modeling for Heskett Unit 2 was a worst-year 98th percentile deciview change from background of 0.421 at TRNP and 0.399 at LWA. These values are below the 0.5 dv threshold which is used to determine if a BART-eligible source is contributing to regional haze at a Class I area. NDDH therefore concluded that Heskett Unit 2 is not a BART-subject source.

Since the selection of background visibility and a more conservative treatment of PM_{10} speciation are consistent with NDDH policy, the comments below relate to the selected grid spacing refinement ENSR employed.

It is noteworthy to consider that a third refinement, the use of the new IMPROVE equation, was not available to ENSR in 2006, but is now available as "Method 8" in CALPOST and is recognized now as an approved technique by the Federal Land Managers (see slide 4 of the presentation at http://www.cleanairinfo.com/regionalstatelocalmodelingworkshop/archive/2009/presentations/04%20Weds%20AM/RSL-FLM-05-13-09E.pdf). ENSR's experience with this more accurate method is an expected substantial decrease in the visibility impairment that is not reflected in the modeling analysis conducted in 2006.

EPA and FLM concerns with the CALPUFF Grid Spacing Issue

NDDH received a letter dated August 4, 2008 from EPA Region 8 in which the agency expressed some concern regarding the process for exempting Heskett Unit 2 from BART. In the letter, EPA stated:

> "We have concerns with ENSR's CALPUFF modeling. They reduce the CALMET/CALPUFF grid size from 3 km to 1 km. EPA has recently seen data indicating that CALPUFF may inappropriately reduce predicted concentrations with such grid size manipulation…Given that ENSR's refined results move Heskett from "subject-to-BART" to "exempt", a more robust discussion is necessary regarding why NDDH found ENSR's analysis "acceptable," including an explanation of why you think this approach will not lead to underestimates of visibility impacts."

EPA's statement that "grid size manipulation" may inappropriately reduce predicted concentrations is inaccurate. The grid size adjustment that ENSR employed follows EPA guidance regarding recommended resolution of terrain features, as noted below, and it improves CALPUFF's accuracy in addressing terrain feature interactions. The latter point is supported, in particular, by CALPUFF's developer as well as by Mr. Clint Bowman of the Washington Department of Ecology, each of whom conclude that grid size reductions are technically valid and improve the accuracy of CALPUFF modeling.

EPA Model Clearinghouse Memorandum

On May 15, 2009, EPA's Model Clearinghouse ruled on the Big Stone Unit 1 BART case (South Dakota) in which the use of a 1-km grid was questioned by EPA Region 8. In a February 24, 2009 letter to the Model Clearinghouse, EPA Region 8 questioned the use of a 1-km grid for a long distance plume travel (400 km) and relatively flat terrain. EPA Region 8 therein stated its support for the use of 1-km and even smaller grid spacing in areas where complex terrain would affect plume dispersion because the "higher resolution at these distances will better characterize terrain effects and local scale meteorology." However, for the Big Stone case under consideration which lacked complex terrain and which involved multiple-day transport, EPA Region 8 suggested that a 4-km grid spacing for a BART analysis would be supportable.

In their May 15, 2009 reply, the EPA Model Clearinghouse concurred with EPA Region 8's position on the grid spacing issue. The Model Clearinghouse noted that the modeling analysis documentation did not adequately justify the need for the finer grid resolution. They also recommended that prognostic meteorological data sets should have adequate evaluation.

The BART modeling for Heskett Unit 2 differs significantly from the Big Stone case because: (a) the Heskett case involves complex terrain with features that require a 1-km grid resolution (not flat terrain); and (b) plume travel distances from Heskett to the Class I areas at issue (LWA and three units at TRNP) are much less than 400 km, such that the plume-terrain interaction is more important to simulate correctly. Because the reduced grid size forces a smaller step change in the model and a better representation of causality effects, the 1-km grid improves on independent NDDH CALPUFF evaluations that show an overprediction tendency in the range of 50-70% relative to observed 24-hour concentrations from use of 3-km grid spacing. In addition, the NDDH has thoroughly researched and studied the Rapid Update Cycle (RUC) prognostic meteorological data being used for the BART analysis. This data set was also used previously for SO_2 increment modeling using CALPUFF and was accepted after a national review of this modeling application.

Appropriate CALMET/CALPUFF Grid Size: Response to Comments

EPA provides guidance for the selection of the CALPUFF grid size in the “Frequently Asked Questions” area on the TRC CALPUFF web site (available at http://www.src.com/calpuff/FAQ-answers.htm#2.1.4). The text of this guidance states the following:

> ***2.1.4 How will I know whether my terrain elevation data is sufficiently resolved (i.e., small enough grid size) for my specific application?***
>
> *In making CALMET and CALPUFF modeling runs, the goal is to find the optimum balance between the desire to make the grid size as large as feasible in order to reduce the run times and file sizes, and the desire to make the grid size small enough that CALMET can characterize the terrain effects on the wind field. The optimum grid spacing for a particular application will depend on the size of the modeling domain and the complexity of the terrain within the domain.*
>
> *There are some obvious checks one can make. For instance, if your application involves some terrain features (hills, valleys, etc.), CALMET needs to have as least 5 (preferably 10) grids to resolve each terrain feature. So if you have a valley of particular interest that is typically 5 km wide, one might like to have a grid spacing of 0.5 to 1-km terrain and land-use data.*
>
> *Graphical analyses may also prove helpful. Consider the following sequence to develop three graphical analyses: 1) contour the gridded data at what you think will be your final resolution, say 2-km; 2) shift the origin of the grid by ½ of the grid scale (left or right, up or down), re-grid the data using twice the original grid scale, and contour the terrain heights, and 3) using the same grid origin as in the second case, re-grid the data using ½ the original grid scale as in the first case, and contour the terrain heights. Compare the three plots to see how terrain features are 'appearing' and 'disappearing', and decide whether you are comfortable with your original grid scale. One could repeat these three steps using a different initial grid scale, but we should also remember that these results are subjective in nature, so try not to over-engineer this analysis. Common sense and experience should prevail.*

The key aspect of this guidance is that CALMET needs to have at least 5 grid elements to adequately resolve terrain features. The terrain features within the TRNP South Unit are depicted in Figures 1 and 2. Figure 1 is included since it better represents the actual terrain features of TRNP, while Figure 2 depicts the actual park boundaries more accurately. Two typical areas are circled in both figures as examples of terrain features that are on the order of 5 km or less in size. This implies that a grid spacing as large as 3 km would excessively smooth out these terrain features. In compliance with the guidance provided by EPA through the TRC website’s Frequently Asked Questions, ENSR used a 1-km grid spacing for the CALPUFF modeling to improve the accuracy of the model.

We also note that EPA Region 8 has indicated its support of the use of 1-km grid spacing or even smaller for applications with complex terrain and without long travel distances. In the case of Heskett Unit 2 and Theodore Roosevelt National Park (TRNP), virtually the entire North Unit has elevations above the Unit 2 stack top, and the terrain relief within the park exceeds 220 meters (720 feet). The distance to TRNP is less than 200 km, which is well within a distance that could be covered during nocturnal travel (12 hours at 5 m/s at plume level) in which the plume would stay relatively compact and significantly interact with the complex terrain at TRNP. The use of the 1-km grid spacing for the Heskett Unit 2 analysis therefore supplies higher resolution and better characterize terrain effects and local scale meteorology to improve the objective accuracy of the CALPUFF predictions.

In addition to this guidance, the following e-mail exchange between Robert Paine of ENSR and Joe Scire of TRC (the CALPUFF model developer) further establishes the scientific credibility of using the 1-km rather than the 3-km grid spacing.

> From: Scire, Joseph [mailto:JScire@TRCSOLUTIONS.com]
>
> Sent: Wednesday, January 10, 2007 2:32 PM
>
> To: Paine, Bob
>
> Subject: RE: issue of finer grid spacing in CALMET
>
> Bob,
>
> Generally, if CALMET is using a smaller grid spacing than MM5, it should be able to pick up terrain effects that MM5 does not see, and therefore improve the quality of the wind fields. The grid resolution of MM5 should not limit what is used in CALMET. This was tested in the Wyoming project and it was shown that the winds using CALMET at finer resolution produced the channeling that MM5 missed.
>
> Also, another advantage of finer grid resolution in CALMET is the ability to characterize the land use data in a more detailed way.
>
> Joe

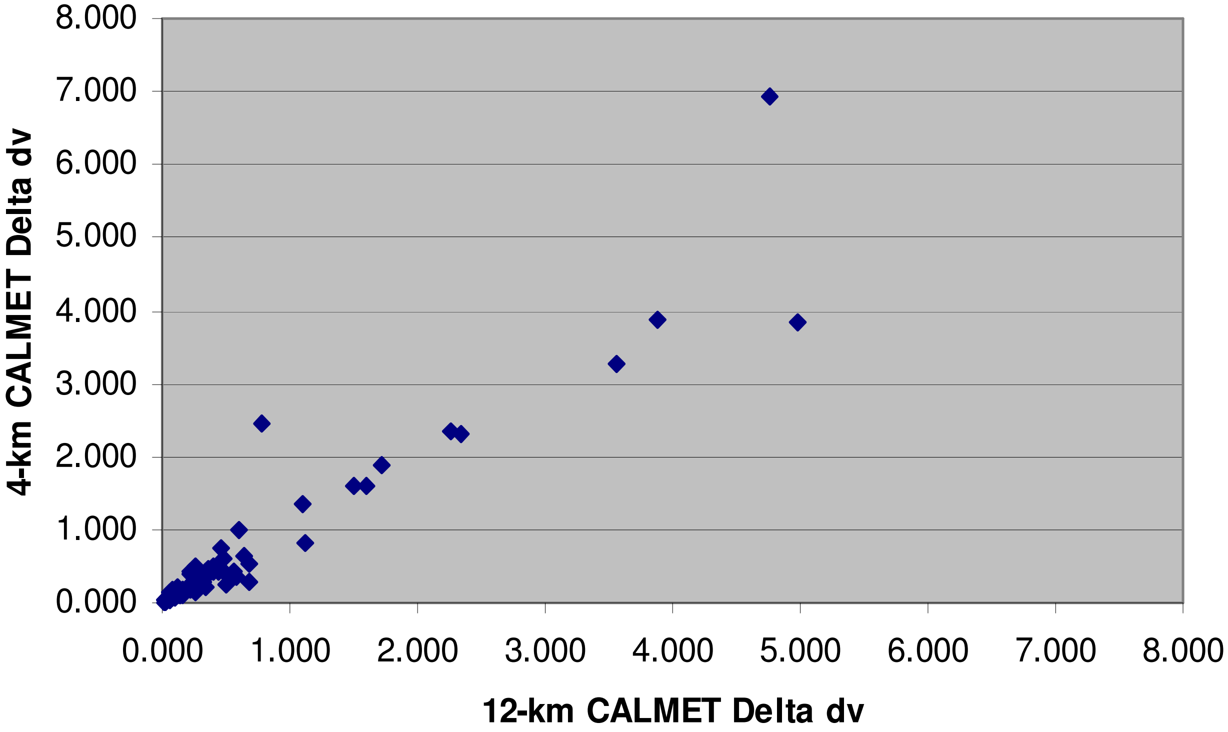
CALPUFF Modeling Bias Introduced by Smaller Grid Size?

Recently, the FLMs have suspected that lower CALPUFF predictions are routinely generated by smaller grid spacing. We surmise that this is why it is referred to in the August 4, 2008 EPA Region 8 letter to NDDH as a “grid size manipulation”. ENSR recently discussed this issue with Tim Allen of the Fish & Wildlife Service. According to Mr. Allen, his discussions in 2008 with Joe Scire indicated that the use of a finer grid spacing was neutrally biased in providing either lower or higher CALPUFF impacts.

A similar communication from Joe Scire on this issue, dated September 25, 2008, indicates that the smaller grid size would generally not be expected to introduce a routine bias in the modeling results for a large sample of modeling applications. Excerpts from Scire’s communication are provided below.

> *In CALPUFF, when using finer resolution, the model will provide a better representation of the terrain (higher peaks, lower valleys more closely representing the actual terrain), land use (higher resolution of land use variability), coastlines (a better representation of the actual land-water variation), wind flow adjustments caused by terrain (i.e., terrain channeling and slope flows) and other things too. A smaller grid size forces a smaller time step in the model and this can give a better representation of causality effects in the model.*
>
> *Regarding the issue that finer resolution always gives lower modeling predictions, this is clearly not the case. A summary of VISTAS modeling results for 26 sources at 90 source-Class I area combinations conducted previously by TRC shows this [see Figure 3]. Of the 90 cases, 47 cases showed higher max impact results with the finer grid resolution and 43 cases showed higher impacts with the coarse grid resolution. Given this result, using a fine resolution for selected Class I areas and coarse resolution for others (i.e., picking whichever produces the lower results) would probably not be deemed acceptable, since it is hard to argue the finer resolution result is better only in the cases when it produces lower impacts.*
>
> *In any given situation there may be valid reasons why the changes might be skewed more in one direction or the other, but the conclusion that finer grid resolution always decreases concentrations is not correct. As one example, coarse resolution that raises the valley floor in the model and lowers the peaks might make the flow at plume height completely different than a higher resolution run that lowers the stack base ground elevation and increases the peak elevations which may result in the plume being within the valley walls and thus subject to channeling effects. The higher resolution simulation might channel the plume into a Class I area, resulting in higher impacts, or transport it away from a Class I area and produce lower impacts (depending on where the source and Class I area are located). I’ve seen examples of both types of situations. In both cases, it could be argued the finer resolution results are more appropriate, whether they are higher or lower. But the details of the situation determine the nature of the response in the model and it will not always be the same.*

Figure 3: Comparison of Maximum Visibility Impact Predictions for Two CALPUFF Grid Sizes



In another study of the effects of grid spacing on CALPUFF results, Mr. Clint Bowman of the Washington Department of Ecology conducted a sensitivity study and presented it at EPA's 2008 modeling workshop. Bowman tested grid spacing ranging from 100 m to 12 km. He found that smaller grid size could lead to somewhat lower modeled impacts. His basic points were as follows:

- the primary effect of the finer grid spacing is to improve the terrain resolution, and this will improve the model accuracy;
- the finer grid spacing does not materially alter the peak impact location or time period;
- large grid spacing leads to artifacts in wind fields which will degrade model accuracy, while the accurate depiction of terrain-induced drainage flow is more realistic with small grid spacing; and
- the effect of slightly lower modeled impacts for a more accurate model setup with a smaller grid size is not confined to CALPUFF, but it is common to other models as well.

As ENSR has noted in various technical presentations, the issue of how grid spacing affects terrain resolution is important because there are model receptors on real terrain features (i.e., sharp peaks) that are not known to CALMET if the terrain is overly smoothed out with a coarse grid treatment. In the case of grid spacing less than the EPA recommendations noted above, the actual terrain height is provided to CALPUFF in the receptor information, but a lower hill height is presented to CALMET for the same area for purposes of wind flow adjustments. This can result in an incorrect depiction of the wind flow because it responds to the terrain information provided to CALMET. Therefore, with a smoothed version of the terrain, CALPUFF could inaccurately simulate artificial plume impacts for ground-level receptors that appear to be "flagpole" receptors relative to the terrain presented to CALMET if a coarse grid is used.

NDDH CALPUFF Evaluation

As part of the modeling analyses conducted by the NDDH on the SO_2 PSD increment question for Class I areas in North Dakota, the NDDH compared CALPUFF and available monitors with 2002 hourly emissions data from major EGUs, including Heskett Unit 2. The TRNP monitor available in 2002 was at the North Unit, for which a terrain map is shown in Figure 4. Terrain features of a size similar to that of the South Unit are present in the North Unit, justifying a grid spacing of 1 km as a more appropriate choice rather than 3 km.

The NDDH documentation of the CALPUFF model evaluation results are provided at http://www.ndhealth.gov/AQ/Dockets/Responses%20to%20Recuring%20PSD%20Issues/Responses%20to%20Recurring%20PSD%20Issues%20-%20Part%205.pdf, which involves a report of recurring issues involving the PSD increment modeling in PSD Class I areas. The NDDH analysis used more than one meteorological database, but the use of the Rapid Update Cycle (RUC) data is most closely related to the BART modeling. The results of the comparison of modeled to monitored (with a nominal background of 1.5 $\mu g/m^3$ added; Figure 23 of the NDDH report) are reproduced in Figure 5.

The relevant results, taken from the solid blue line labeled “RUC + 1.5”, indicate that the CALPUFF model as applied by the NDDH (which used a 3-km grid spacing) generally overpredicts the observed concentrations in a range of 50-70% for the peak few values. Since that margin is comparable to or exceeds the reduction in impacts obtained from reducing the grid size from 3 km to 1 km, we conclude that the smaller grid spacing would result in a better performing and more accurate CALPUFF model that still shows an overprediction tendency.

Conclusions

The initial BART modeling for Heskett Unit 2 was conducted by NDDH and it showed visibility impacts above the BART exemption threshold of 0.5 delta-dv. The EPA settlement with regard to the use of the annual average background resulted in one of the model refinements ENSR subsequently employed upon evaluation of the NDDH CALPUFF modeling. Further refinements that resulted in adjustments toward both higher and lower concentrations were applied by ENSR in two areas: (1) a finer grid spacing; and (2) the use of PM_{10} speciation, which NDDH did not use and which increased predicted visibility impacts. ENSR was not able to use a third refinement that later became available in 2008 (the new IMPROVE equation) which ENSR expects from nationwide modeling experience would have further reduced the predicted visibility impact of Heskett Unit 2.

Use of the finer grid spacing is technically justified by both the intervening complex terrain and the proximity of R.M. Heskett Station to the Class I areas. The finer 1-km grid spacing resulted in a change in impacts ranging from a slight increase to a reduction of about 40% from the 3-km spacing results. It also improved upon independent NDDH CALPUFF evaluations showing an overprediction tendency in the range of 50-70% relative to observed 24-hour concentrations with the use of 3-km grid spacing. It is evident that the use of a finer grid provides better CALPUFF accuracy and performance, still with an overall slight overprediction tendency.

For all of the reasons stated above, the concerns of the EPA and FLMs regarding the ENSR CALPUFF BART analysis have been addressed. The use of the 1-km grid will provide improved accuracy for the CALPUFF predictions. The BART exemption analysis shows that the Heskett Unit 2 regional haze impact would be below the BART contribution threshold of 0.5 delta-dv at TRNP and LWA even with the use of the old IMPROVE equation.

1.0 Introduction

1.1 Background

The North Dakota Department of Health (NDDH) has conducted CALPUFF modeling for emission sources for all BART-eligible facilities in North Dakota. This study updates and refines the CALPUFF modeling for one of these facilities, Heskett Unit 2, which is owned and operated by Montana-Dakota Utilities Co. (MDU). Heskett Unit 1, operational in 1954, has a capacity of 40 MW and is not BART-eligible since it was put into service before 1962. Unit 2, operational in 1963, has a capacity of 75 MW. Unit 2 was retrofitted to a fluidized-bed combustor in 1987, thus making it BART eligible.

In 2006, MDU asked ENSR (now AECOM) to review the NDDH BART analysis for Heskett Unit 2 and to provide an analysis that considered updates to the November 2005 NDDH BART modeling protocol. The 2006 updates focused on the following three areas:

- US EPA had announced a court settlement regarding BART modeling that allowed each state to use the annual average background visibility instead of the best 20% days' background visibility for BART analyses. This development occurred because the actual BART rule (published in the July 6, 2005, 70 Fed. Reg. 39104) stipulated that the annual average background visibility value should be used, while the preamble was inconsistent and mentioned that the 20% best days' background visibility should be used. As a result of the settlement, the NDDH adopted the annual average background visibility for the BART analysis.

- ENSR considered a more complete speciation of particulate emissions consistent with guidance provided by the National Park Service.

- ENSR adopted a 1-km CALPUFF grid spacing consistent with EPA guidance as provided in the CALPUFF FAQs regarding the resolution of terrain features with at least 5 grid elements. Other reasons for the adoption of the 1-km grid spacing have been provided to US EPA in recent correspondence.

The results of the BART modeling analysis indicated that the 98th percentile daily regional haze impact of the peak baseline daily emissions from Heskett Unit 2 would not reach the NDDH-adopted contribution level of 0.5 delta-deciview. Therefore, Heskett Unit 2 was determined to be exempt from further BART review as NDDH confirmed in a May 8, 2007 letter to MDU.

On May 15, 2009, EPA issued a Clarification Memo on CALPUFF that challenged a BART exemption analysis for the Big Stone plant in South Dakota. The clarification recommended that the grid spacing to be used for CALMET/CALPUFF analyses should be no less than 4 km.

In a more recent Clarification Memo issued on August 31, 2009, EPA issued further guidance for running CALMET.

In its recent review of the draft North Dakota Regional Haze Rule State Implementation Plan (SIP) (August 21, 2009), EPA Region 8 stated that any updates to the procedures stated in the November 2005 NDDH BART modeling protocol would need to adopt current CALPUFF modeling guidance, including the procedures discussed in the 2009 Clarification memos cited above.

This EPA position was further discussed in a conference call held among EPA, the Federal Land Managers, NDDH, and MDU with AECOM on November 17, 2009. As a result of that conference call, MDU is providing this modeling protocol document to guide an update to BART CALPUFF modeling for Heskett Unit 2.

For this update AECOM will conduct CALPUFF modeling to assess the visibility impact of Heskett Unit 2 emissions with four general areas of change to the modeling approach specified in the November 2005 NDDH BART modeling protocol, as described in the next section.

1.2 Elements of the Updated BART Modeling Analysis

The updates from the November 2005 NDDH BART modeling protocol that AECOM proposes to implement in the updated BART modeling analyses for Heskett Unit 2 are summarized below.

- In the CALMET modeling, we will adopt the recent EPA recommendations by increasing the grid size from 3 km to 4 km, and set other CALMET technical options to those stated in recent EPA Clarification memos. We will continue to set the extent of the modeling domain to 50 km outside the area denoted by the modeled source and the boundaries of the PSD Class I areas.
- For national consistency with other BART analyses, we will continue to use guidance from the National Park Service on the speciation of particulate matter emissions into several components that have different light scattering potential: coarse matter, inorganic fine matter, elemental carbon, sulfuric acid mist, and organic aerosol fine particulate.
- As a result of the EPA settlement regarding the definition of the natural visibility background and the NDDH position on this issue, we will continue to use the annual average background visibility as input to CALPOST for determining the change in visibility caused by emissions from Heskett Unit 2.
- We will use CALMET and CALPUFF versions 5.8, with all technical options as noted in the 2009 EPA Clarification Memos, as well as any applicable guidance from the March 16, 2006 EPA memo from Dennis Atkinson regarding the preferred CALPUFF dispersion option. In addition (and to be consistent with the CALPOST methods used by NDDH in their Regional Haze Rule SIP modeling), we will use the recommended new IMPROVE equation application, also known as Method 8, in the approved version of CALPOST (Version 6.221) for processing the visibility impacts at the North Dakota Class I areas. We will use inputs to CALPOST as provided in the proposed FLAG 2008 guidelines.

These modeling procedures will first be used in a reassessment of the visibility impact of the peak daily baseline emissions for the modeling period of 2000-2002 (using NDDH's RUC data). In the event Heskett Unit 2 is found to be BART-subject, the same procedures will be used to determine the visibility improvement associated with each feasible BART control option.

The BART analysis modeling updates are discussed in more detail in Section 2 below, while the references for the same are provided in Section 3.

2.0 BART Analysis Updates

Updates to the modeling procedures described in Section 1.2 will be made by AECOM to the CALMET/CALPUFF modeling for Heskett Unit 2. More details regarding this process are provided in this section.

2.1 Meteorological Processing with CALMET

One of the updates will involve the use of a 4-km grid size instead of the 3-km grid size used by NDDH. The grid size adjustment is consistent with directives in the August 31, 2009 EPA Clarification Memo and comments made by EPA and the Federal Land Managers during the November 17, 2009 conference call. The digital terrain data that will be used for this analysis will consist of 1-degree data (90-meter resolution). With this CALMET remodeling, the total grid domain will be sized to provide a 50-km buffer around this specific source as well as the PSD Class I areas. Figure 2-1 shows the proposed modeling domain.

Another update will involve changing some of the CALMET switches from the values noted in the NDDH protocol (NDDH, 2005) to those provided in the EPA Clarification Memo released on August 31, 2009. This memorandum updates the draft Interagency Workgroup on Air Quality Modeling's (IWAQM) Phase 2 summary protocol (EPA, 2009). Table 2-1 shows the changes AECOM is proposing to make to the CALMET settings consistent with the August 31, 2009 EPA Clarification Memo.

Table 2-1 Comparison of CALMET Settings Used in NDDH 2005 Protocol and in Updated Modeling

Variable	Description	NDDH 2005 Values	Updated Values
DGRIDM	Grid spacing (km)	3	4
XORIGKM	Southwest grid cell X coordinate	-380	-175

* Values for years 2000, 2001, 2002

2.2 CALPUFF Modeling Options

As with the CALMET modeling, AECOM will change some of the switches in CALPUFF from the values noted in the November 2005 NDDH BART modeling protocol to those provided in the Dennis Atkinson Dispersion Coefficient memorandum released on March 16, 2006. At that time, Mr. Atkinson was the Model Clearinghouse Director of the EPA Office of Air Quality Planning and Standards (OAQPS). In 2006, he released a memo detailing the settings to be used in CALPUFF modeling. AECOM will follow Mr. Atkinson's recommendations with the exception of the CDIV value, which has been updated by the model developer (TRC) to be 0.0. Table 2-2 shows the changes AECOM is planning to make to the CALPUFF settings, consistent with Mr. Atkinson's EPA directives.

Table 2-2 Comparison of CALPUFF Settings Used in NDDH 2005 Protocol and in Updated Modeling

Variable	Description	NDDH 2005 Values	Updated Values
NSPEC	Number of chemical species	7	9
NSE	Number of chemical species emitted	4	7
MSPLIT	Allow puff splitting (1=yes)	1	0
MDISP	Method used to compute dispersion coefficients	2	3
MPDF	PDF used for dispersion under convective conditions (1=yes)	1	0
NX	No. of X grid cells	213	79
NY	No. of Y grid cells	153	77
NZ	No. vertical layers	12	10

ZFACE	Cell face heights (m)	0.,20.,50.,90.,140.,200., 270.,370.,500.,1000.,1700., 2500.,4200.	0.,20.,40.,80.,160.,320., 640.,1200., 2000.,3000., 4000.
XORIGKM	Southwest grid cell X coordinate	-380	-175
YORIGKM	Southwest grid cell Y coordinate	140	268
IBCOMP	Southwest X-index of computational grid	20	2
JBCOMP	Southwest Y-index of computational grid	6	2
IECOMP	Northeast X-index of computational grid	213	78
JECOMP	Northeast Y-index of	153	76

Variable	Description	NDDH 2005 Values	Updated Values
	computational grid		
Dry Part. Dep.	Chemical parameters of particulate deposition species	Model defaults for which mean diameter = 6.25 m and standard deviation = 0.0 m for PMC	Model defaults for all but PMC for which mean diameter = 6.0 m and standard deviation = 2.0 m
XMAXZI	Maximum mixing height	4000	3000
IRESPLIT	Hours when puff is eligible for vertical split	Hours 0-4 and 19-23	Hour 17
ROLDMAX	Vertical puff split allowed only when the ratio of last hour's mixing height to max. mixing height experienced by the puff is smaller than this value	0.33	0.25
MDISP2	Backup method used to compute dispersion coefficients	1	3
MREG	Test options specified to see if they conform to regulatory values (1=yes)	0	1
CSPEC	Species modeled	SO2,SO4,NOX,HNO3,NO3, PMC,PMF	SO2,SO4,NOX,HNO3, NO3, EC,PMC,PMF,SOA
CDIV	Divergence criterion for dw/dz across puff used to initiate adjustment for horizontal convergence (1/s)	0.01, 0.01	0,0

2.3 Characterization of Baseline Emissions

The National Park Service has issued guidance on how to speciate particulate matter emissions into different constituents that have different light scattering EPA potential: coarse matter, inorganic fine matter, elemental carbon, sulfuric acid mist, and organic aerosol fine particulate. The guidance is located at http://www.vistas-sesarm.org/BART/calpuff.asp on the VISTAS regional planning organization web site. While NDDH did not include this guidance in its BART screening protocol, AECOM believes it should be included in this updated analysis.

Engineers from MDU have reviewed the speciation profiles and selected the data for a dry bottom PC with FGD and ESP controls spreadsheet as the most representative of the emissions from Heskett Unit 2. A series of Method 8 stack tests conducted August 24 – 26, 2000 found an average H_2SO_4 rate of 9.0 lb/hr (2.9 ppm) at full load. The resulting emissions that will be used in the CALPUFF regional haze modeling are listed in Table 2-3 (these values have not changed from the ENSR 2006 BART modeling). To simplify the modeling, the coarse and fine inorganic matter will be combined as fine matter, which has a slightly higher visibility extinction efficiency than coarse matter.

Table 2-3 Heskett Unit 2 emissions data for updated BART modeling

Component	Emission Rate (lb/hr)
SO_2	1475.5
NO_2	302.8
Coarse matter (PMC)	8.2
Inorganic fine matter (PMF)	6.3
Elemental carbon (EC)	0.2
H_2SO_4	9.0
Organic aerosols (SOA)	2.0

2.4 Natural Background Determination

Following the settlement of a court case involving how to determine natural background visibility for BART analyses, EPA determined that each state can select either the annual average or 20% best days' background. NDDH has adopted the annual average background visibility approach. The concentrations to be used in the CALPOST input for the particulate species that contribute to visibility impairment are listed in Table 2-4. In the post-processing, the various elements of the Theodore Roosevelt National Park will be considered as a single Class I area, departing from the treatment in the November 2005 NDDH BART modeling protocol. The bases for this change are reflected in EPA's comments 23, 39 and 53 pertaining to the August 21, 2009 draft NDDH Regional Haze SIP and comments provided by EPA and the Federal Land Managers during the November 17, 2009 conference call.

Table 2-4 Annual Average Natural Levels of Aerosol Components (µg/m³)

Component	Lostwood Wilderness(1)	Theodore Roosevelt NP(1)
Ammonium sulfate	0.12	0.12
Ammonium nitrate	0.10	0.10
Organic carbon mass	0.60	0.60
Elemental carbon	0.02	0.02
Soil	0.50	0.50
Coarse mass	3.00	3.00

2.5 Light Extinction and Haze Impact Calculations

The FLAG 2008 document (dated June 26, 2008) provides guidance on the recommended new IMPROVE equation application. CALPOST Version 6.221 defines this application as Method 8, Mode 5. The assessment of visibility impacts at the Class I areas will use CALPOST Method 8.

The CALPOST postprocessor will be used for the calculation of the impact of the modeled source's primary and secondary particulate matter concentrations on light extinction. In the new IMPROVE equation, the total sulfate, nitrate, and organic carbon compound concentrations are each split into two fractions, representing small and large size distributions of those components. New terms, such as sea salt (important for coastal locations), absorption by NO_2 (only used where NO_2 data are available), and site-specific Rayleigh scattering have been added to the equation. The new IMPROVE equation for calculating light extinction is shown below.

$$
\begin{aligned}
b_{ext} \quad = \quad & 2.2 \times f_S(RH) \times [\text{Small Sulfate}] + 4.8 \times f_L(RH) \times [\text{Large Sulfate}] \\
& + 2.4 \times f_S(RH) \times [\text{Small Nitrate}] + 5.1 \times f_L(RH) \times [\text{Large Nitrate}] \\
& + 2.8 \times [\text{Small Organic Mass}] + 6.1 \times [\text{Large Organic Mass}] \\
& + 10 \times [\text{Elemental Carbon}] \\
& + 1 \times [\text{Fine Soil}] \\
& + 0.6 \times [\text{Coarse Mass}] \\
& + 1.7 \times f_{SS}(RH) \times [\text{Sea Salt}] \\
& + \text{Rayleigh Scattering (Site Specific)} \\
& + 0.33 \times [NO_2\ (\text{ppb})] \ \ \{\text{or as: } 0.1755 \times [NO_2\ (\mu g/m^3)]\}
\end{aligned}
$$

Where:

[ ] indicates concentrations in $\mu g/m^3$

$f_S(RH)$ = Relative humidity adjustment factor for small sulfate and nitrate

$f_L(RH)$ = Relative humidity adjustment factor for large sulfate and nitrate

$f_{SS}(RH)$ = Relative humidity adjustment factor for sea salt

For Total Sulfate $< 20\ \mu g/m^3$:

$$[\text{Large Sulfate}] = ([\text{Total Sulfate}] / 20\ \mu g/m^3) \times [\text{Total Sulfate}]$$

For Total Sulfate $\geq 20\ \mu g/m^3$:

$$[\text{Large Sulfate}] = [\text{Total Sulfate}]$$

And:

$$[\text{Small Sulfate}] = [\text{Total Sulfate}] - [\text{Large Sulfate}]$$

To calculate large and small nitrate and organic mass, substitute ({Large, Small, Total} {Nitrate, Organic Mass}) for Sulfate.

The FLAG 2008 document provides inputs to the new IMPROVE equation for the annual average natural conditions. Inputs to the CALPOST Method 8 calculations for each Class I area are listed in Table 2-5.

Table 2-5 New IMPROVE Equation CALPOST Inputs

Component	Lostwood Wilderness(1)	Theodore Roosevelt NP(1)
Sea salt concentration (µg/m^3)	0.03	0.01
Raleigh scattering (Mm^{-1})	11	11
Monthly f_L (RH)	2.51, 2.45, 2.54, 2.06, 2.03, 2.21, 2.23, 2.05, 2.02, 2.13, 2.69, 2.67	2.47, 2.42, 2.45, 2.12, 2.14, 2.21, 2.14, 1.99, 1.99, 2.10, 2.58, 2.57
Monthly f_S (RH)	3.21, 3.15, 3.36, 2.60, 2.54, 2.86, 2.89, 2.60, 2.53, 2.72, 3.60, 3.52	3.17, 3.11, 3.22, 2.71, 2.74, 2.85, 2.73, 2.49, 2.48, 2.66, 3.42, 3.37
Monthly f_{SS} (RH)	3.77, 3.66, 3.67, 2.86, 2.79, 3.07, 3.11, 2.82, 2.80, 2.99, 3.93, 3.95	3.67, 3.56, 3.51, 2.93, 2.97, 3.09, 2.96, 2.72, 2.72, 2.93, 3.75, 3.78

1.0 Introduction

1.1 Background

The North Dakota Department of Health (NDDH) conducted CALPUFF modeling in 2005 for emission sources associated with all BART-eligible facilities in North Dakota. This study updates the CALPUFF modeling for one of these facilities, Heskett Unit 2, which is owned and operated by Montana-Dakota Utilities Co. (MDU). Heskett Unit 1, operational in 1954, has a capacity of 40 MW and is not BART-eligible since it was put into service before 1962. Unit 2, operational in 1963, has a capacity of 75 MW. Unit 2 was retrofitted to a fluidized-bed combustor in 1987, thus making it BART-eligible.

In 2006, MDU asked ENSR (now AECOM) to review the NDDH BART analysis for Heskett Unit 2 and to provide an analysis that considered updates to the November 2005 NDDH BART modeling protocol. The 2006 updates focused on the following three areas:

- US EPA had announced a court settlement regarding BART modeling that allowed each state to use the annual average background visibility instead of the best 20% days' background visibility for BART analyses. This development occurred because the actual BART rule (published in the Federal Register on July 6, 2005 at 70 Fed. Reg. 39104) stipulated that the annual average background visibility value should be used, while the preamble was inconsistent and mentioned that the 20% best days' background visibility should be used. As a result of the settlement, the NDDH adopted the annual average background visibility for the BART analysis.

- ENSR considered a more complete speciation of particulate emissions consistent with guidance provided by the National Park Service.

- ENSR adopted a 1-km CALPUFF grid spacing consistent with EPA guidance as provided in the CALPUFF FAQs regarding the resolution of terrain features with at least 5 grid elements. Support for use of 1-km grid spacing was provided to US EPA Region 8 and the Federal Land Managers in comments from AECOM dated August 12, 2009.

The results of the 2006 BART modeling analysis indicated that the 98th percentile daily regional haze impact of the peak baseline daily emissions from Heskett Unit 2 would not reach the NDDH-adopted contribution level of 0.5 delta-deciview. Therefore, Heskett Unit 2 was determined to be exempt from further BART review as NDDH confirmed in a May 8, 2007 letter to MDU.

The NDDH received EPA correspondence dated August 8, 2008 stating their concern in using a 1-km grid size and requesting a more robust discussion as to why the NDDH found the use of a 1-km grid size to be acceptable. Upon review of the EPA's comments, MDU requested AECOM develop responses to EPA's concerns. An AECOM response was filed with the NDDH on January 5, 2009.

On May 15, 2009, EPA issued a Clarification Memo on CALPUFF that challenged a BART exemption analysis for the Big Stone plant in South Dakota. The clarification recommended that the grid spacing to be used for CALMET/CALPUFF analyses should be no less than 4 km. MDU asked AECOM to update its January 5, 2009 document to take into account the issues raised in the EPA Clarification Memo. An updated AECOM response was provided to the NDDH on August 12, 2009 that included the rational for utilizing the 1-km grid size for Heskett Unit 2 in light of the May 15, 2009 EPA Clarification Memo. The

NDDH included the AECOM response as an attachment to the draft Regional Haze/BART SIP that was filed with the Federal Land Managers for review and comment in August 2009.

In a more recent Clarification Memo issued on August 31, 2009, EPA provided further guidance for running CALMET which was taken into account for recent modeling as described below.

In its recent review of the draft North Dakota Regional Haze Rule State Implementation Plan (SIP) (August 21, 2009), EPA Region 8 stated that any updates to the procedures stated in the November 2005 NDDH BART modeling protocol would need to adopt current CALPUFF modeling guidance, including the procedures discussed in the 2009 Clarification memos cited above.

This EPA position was further discussed in a conference call held among EPA, the Federal Land Managers, NDDH, and MDU with AECOM on November 17, 2009. On November 25, 2009, MDU provided NDDH a modeling protocol document to guide an update to BART CALPUFF modeling for Heskett Unit 2, consistent with both current EPA CALPUFF modeling guidance and directives provided by EPA during the November 17, 2009 conference call. The November 25, 2009 protocol was approved by the NDDH on December 1, 2009.

On December 10, 2009, EPA Region 8 also approved the November 25, 2009 protocol with the condition that one CALPUFF setting, CDIV, should be adjusted to (0.01, 0.01) instead of (0,0). While the CALPUFF model developer has advised AECOM that the setting of 0.01 is obsolete and it should be revised to be 0, the adjustment was made to demonstrate its effect upon the modeling results. To that end, the modeling results section of this report has been updated to provide predicted visibility impacts for both versions of the CALPUFF CDIV setting.

For this updated modeling analysis, AECOM conducted CALPUFF modeling in accordance with the approved protocol to assess the visibility impact of Heskett Unit 2 emissions with four general areas of change to the modeling approach specified in the November 2005 NDDH BART modeling protocol, as described in the next section.

1.2 Elements of the Refined Analysis

The updates from the November 2005 NDDH BART modeling protocol that AECOM implemented in the updated BART modeling analyses for Heskett Unit 2 are summarized below.

- In the CALMET modeling, we adopted the recent EPA recommendations by increasing the grid size from 3 km to 4 km, and set other CALMET technical options to those stated in recent EPA Clarification Memos. We set the extent of the modeling domain to 50 km outside the area denoted by the modeled source and the boundaries of the PSD Class I areas.
- For national consistency with other BART analyses, we continued to use guidance from the National Park Service on the speciation of particulate matter emissions into several components that have different light scattering potential: coarse matter, inorganic fine matter, elemental carbon, sulfuric acid mist, and organic aerosol fine particulate.
- As a result of the EPA settlement regarding the definition of the natural visibility background and the NDDH position on this issue, we used the annual average background visibility as input to CALPOST for determining the change in visibility caused by emissions from Heskett Unit 2.

- We used CALMET and CALPUFF versions 5.8, with all technical options as noted in the 2009 EPA Clarification Memos, as well as applicable guidance from the March 16, 2006 EPA memo from Dennis Atkinson regarding the preferred CALPUFF dispersion option. In addition (and to be consistent with the CALPOST methods used by NDDH in their Regional Haze Rule SIP modeling), we used the recommended new IMPROVE equation application, also known as Method 8, in the approved version of CALPOST (Version 6.221) for processing the visibility impacts at the North Dakota Class I areas. We used inputs to CALPOST as provided in the proposed FLAG 2008 guidelines.

These modeling procedures were first used in a reassessment of the visibility impact of the peak daily baseline emissions for the modeling period of 2000-2002 (using NDDH's RUC data). The results of this modeling analysis clarify whether Heskett Unit 2 is subject to BART.

The BART analysis modeling procedures are discussed in more detail in Section 2 below. Results of the modeling for baseline emissions are provided in Section 3. References are provided in Section 4.

2.0 BART Analysis Updates

Updates to the modeling procedures described in Section 1.2 were made by AECOM in the updated CALMET/CALPUFF modeling for Heskett Unit 2. More details regarding this process are provided in this section.

2.1 Meteorological Processing with CALMET

One of the updates involved the use of a 4-km grid size instead of the 3-km grid size used by NDDH. The grid size adjustment is consistent with directives in the August 31, 2009 EPA Clarification Memo and comments made by EPA and the Federal Land Managers during the November 17, 2009 conference call. The digital terrain data that was used for this analysis consisted of 1-degree data (90-meter resolution). With this CALMET remodeling, the total grid domain was sized to provide a 50-km buffer around this specific source as well as the PSD Class I areas. Figure 2-1 shows the modeling domain.

Another update involved changing some of the CALMET switches from the values noted in the NDDH protocol (NDDH, 2005) to those provided in the EPA Clarification Memo released on August 31, 2009. This memorandum updates the draft Interagency Workgroup on Air Quality Modeling's (IWAQM) Phase 2 summary protocol (EPA, 2009). Table 2-1 shows the changes AECOM applied to the CALMET settings consistent with the August 31, 2009 EPA Clarification Memo.

Table 2-1 Comparison of CALMET Settings Used in NDDH 2005 Protocol and in Updated Modeling

Variable	Description	NDDH 2005 Values	Updated Values
DGRIDM	Grid spacing (km)	3	4
XORIGKM	Southwest grid cell X coordinate	-380	-175
YORIGKM	Southwest grid cell Y coordinate	140	268
NX	No. of X grid cells	213	79
NY	No. of Y grid cells	153	77
NZ	No. vertical layers	12	10

BIAS	Layer-dependent biases modifying the weights of surface and upper air stations (BIAS(NZ))	-1.0, -0.9, -0.7, -0.4, 0.0, 0.3, 0.7, 1.0, 1.0, 1.0, 1.0, 1.0	0,0,0,0,0,0,0,0,0,0
TERRAD	Radius of influence of terrain features (km)	10	15
R1	Distance from a surface observation station at which the wind observation and the first guess field are equally weighted (km)	10	50
R2	Distance from an upper-air observation station at which the wind observation and the first guess field are equally weighted (km)	10	100
ZUPWND	Bottom and top of layer through which the domain scale winds are computed (m)	1., 2500.	1., 1000.
MNMDAV	Max. search distance (in grid cells) for spatial averaging of mixing ht. and temperature	7	1
ILEVZI	Layer of winds used in upwind averaging of mixing heights	3	1
ZIMAX	Maximum over land mixing height (m)	4000	3000
ZIMAXW	Maximum over water mixing height (m)	4000	3000

* Values for years 2000, 2001, 2002

2.2 CALPUFF Modeling Options

As with the CALMET modeling, AECOM changed some of the switches in CALPUFF from the values noted in the November 2005 NDDH BART modeling protocol to those provided in the Dennis Atkinson Dispersion Coefficient memorandum released on March 16, 2006. At that time, Mr. Atkinson was the Model Clearinghouse Director of the EPA Office of Air Quality Planning and Standards (OAQPS). In 2006, he released a memo detailing the settings to be used in CALPUFF modeling. AECOM followed Mr. Atkinson's recommendations with the exception of the CDIV value, which has been updated by the model developer (TRC) to be 0.0. Table 2-2 shows the changes AECOM made to the CALPUFF settings, consistent with Mr. Atkinson's EPA directives.

Table 2-2 Comparison of CALPUFF Settings Used in NDDH 2005 Protocol and in Updated Modeling

Variable	Description	NDDH 2005 Values	Updated Values
NSPEC	Number of chemical species	7	9
NSE	Number of chemical species emitted	4	7
MSPLIT	Allow puff splitting (1=yes)	1	0
MDISP	Method used to compute dispersion coefficients	2	3
MPDF	PDF used for dispersion under convective conditions (1=yes)	1	0
NX	No. of X grid cells	213	79
NY	No. of Y grid cells	153	77
NZ	No. vertical layers	12	10
DGRIDM	Grid spacing (km)	3	4
ZFACE	Cell face heights (m)	0.,20.,50.,90.,140.,200., 270.,370.,500.,1000.,1700., 2500.,4200.	0.,20.,40.,80.,160.,320., 640.,1200., 2000.,3000., 4000.
XORIGKM	Southwest grid cell X coordinate	-380	-175
YORIGKM	Southwest grid cell Y coordinate	140	268
IBCOMP	Southwest X-index of computational grid	20	1
JBCOMP	Southwest Y-index of computational grid	6	1
IECOMP	Northeast X-index of computational grid	213	79
JECOMP	Northeast Y-index of computational grid	153	77

Variable	Description	NDDH 2005 Values	Updated Values
Dry Part. Dep.	Chemical parameters of particulate deposition species	Model defaults for which mean diameter = 6.25 m and standard deviation = 0.0 m for PMC	Model defaults for all but PMC for which mean diameter = 6.0 m and standard deviation = 2.0 m
XMAXZI	Maximum mixing height	4000	3000
IRESPLIT	Hours when puff is eligible for vertical split	Hours 0-4 and 19-23	Hour 17
ROLDMAX	Vertical puff split allowed only when the ratio of last hour's mixing height to max. mixing height experienced by the puff is smaller than this value	0.33	0.25
MDISP2	Backup method used to compute dispersion coefficients	1	3
MREG	Test options specified to see if they conform to regulatory values (1=yes)	0	1
CSPEC	Species modeled	SO2,SO4,NOX,HNO3,NO3, PMC,PMF	SO2,SO4,NOX,HNO3, NO3, EC,PMC,PMF,SOA
CDIV	Divergence criterion for dw/dz across puff used to initiate adjustment for horizontal convergence (1/s)	0.01, 0.01	0,0

Note that CDIV was set to (0,0) because the CALPUFF model developer, Joe Scire, indicated in a December 22, 2006 e-mail to Robert Paine of AECOM (see below) that this setting is appropriate. However, EPA Region 8 has stated its preference that a CDIV of (0.01, 0.01) be used because that setting was specified in the March 16, 2006 EPA memo from Dennis Atkinson. To resolve this issue, we have conducted the modeling both ways and present two sets of results in Section 3 of this report.

To: Paine, Bob
Subject: RE: CDIV question

Bob,

The default values for CDIV has been 0.0, 0.0 going back at least six years (i.e., 2000). We may have tested other values earlier than this, but using zero for the CDIV has been the default for quite a while.

The use of the smaller value gives better protection again mass accumulation within convergence zones by compensating with increased sigma z to account for vertical movement of the air.

2.3 Characterization of Baseline Emissions

The National Park Service has issued guidance on how to speciate particulate matter emissions into different constituents that have different light scattering EPA potential: coarse matter, inorganic fine matter, elemental carbon, sulfuric acid mist, and organic aerosol fine particulate. The guidance is located at http://www.vistas-sesarm.org/BART/calpuff.asp on the VISTAS regional planning organization web site. While NDDH did not include this guidance in its BART screening protocol, AECOM believes it should be included in this updated analysis.

Engineers from MDU have reviewed the speciation profiles and selected the data for a dry bottom PC with FGD and ESP controls spreadsheet as the most representative of the emissions from Heskett Unit 2. A series of Method 8 stack tests conducted August 24 – 26, 2000 found an average H_2SO_4 rate of 9.0 lb/hr (2.9 ppm) at full load. The resulting emissions that were used in the CALPUFF regional haze modeling are listed in Table 2-3 (these values have not changed from the ENSR 2006 BART modeling). To simplify the modeling, the coarse and fine inorganic matter were combined as fine matter, which has a slightly higher visibility extinction efficiency than coarse matter.

Table 2-3 Heskett Unit 2 emissions data for updated BART modeling

Component	Emission Rate (lb/hr)
SO_2	1475.5
NO_2	302.8
Coarse matter (PMC)	8.2
Inorganic fine matter (PMF)	6.3
Elemental carbon (EC)	0.2
H_2SO_4	9.0
Organic aerosols (SOA)	2.0

2.4 Natural Background Determination

Following the settlement of a court case involving how to determine natural background visibility for BART analyses, EPA determined that each state can select either the annual average or 20% best days' background. NDDH has adopted the annual average background visibility approach. The concentrations to be used in the CALPOST input for the particulate species that contribute to visibility impairment are listed in Table 2-4. In the post-processing, the various elements of the Theodore Roosevelt National Park were considered as a single Class I area, departing from the treatment in the November 2005 NDDH BART modeling protocol. The bases for this change are reflected in EPA's comments 23, 39 and 53 pertaining to the August 21, 2009 draft NDDH Regional Haze SIP and comments provided by EPA and the Federal Land Managers during the November 17, 2009 conference call.

Table 2-4 Annual Average Natural Levels of Aerosol Components (µg/m³)

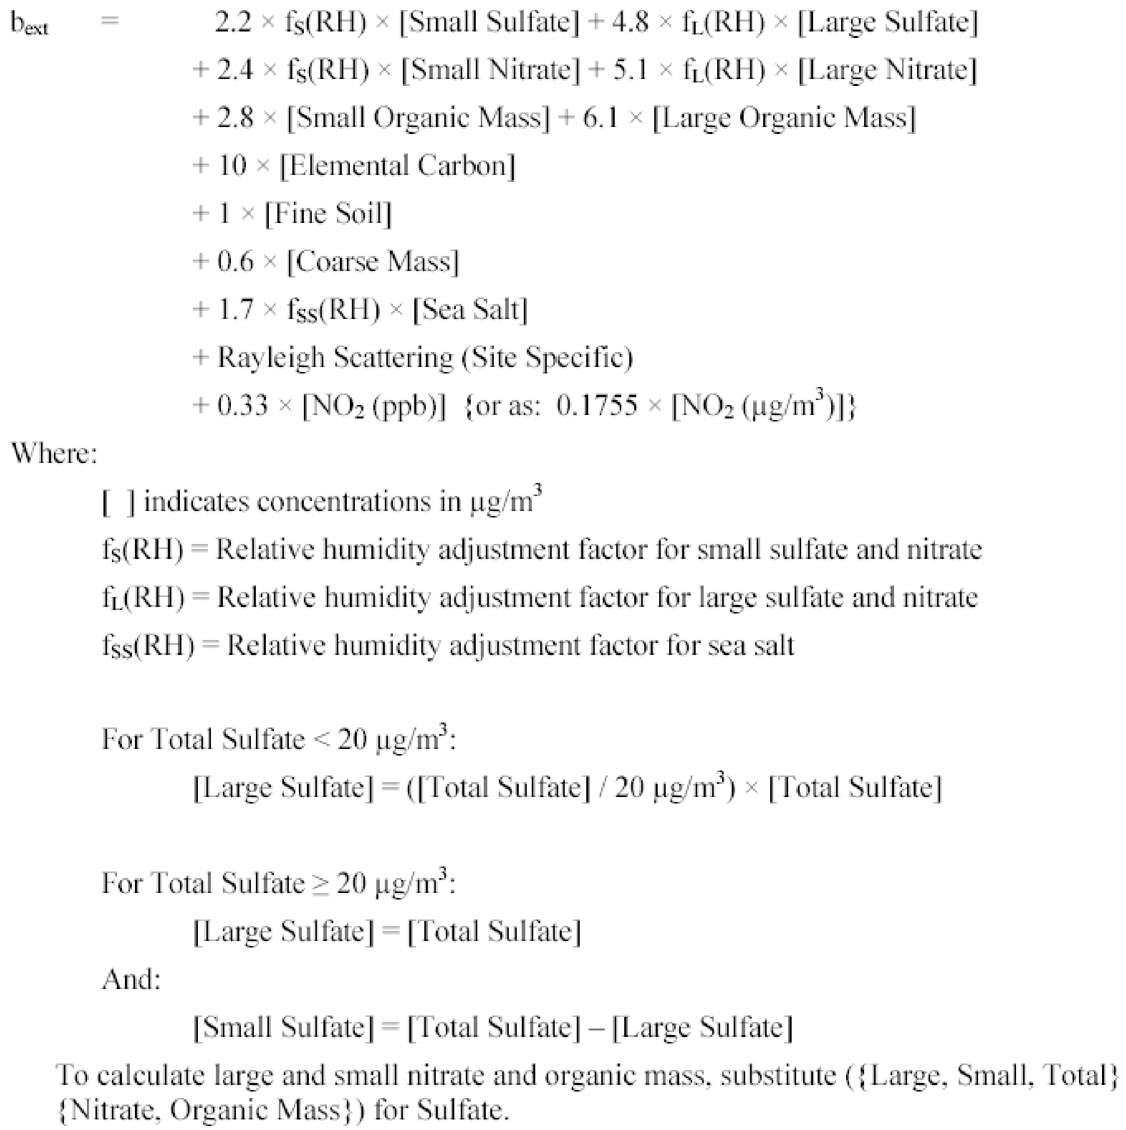
Component	Lostwood Wilderness(1)	Theodore Roosevelt NP(1)
Ammonium sulfate	0.12	0.12
Ammonium nitrate	0.10	0.10
Organic carbon mass	0.60	0.60
Elemental carbon	0.02	0.02
Soil	0.50	0.50
Coarse mass	3.00	3.00

(1) From "Federal Land Managers' Air Quality Related Values Workgroup" (FLAG, 2008), Appendix V-1, Table V.1-2.

2.5 Light Extinction and Haze Impact Calculations

The FLAG 2008 document (dated June 26, 2008) provides guidance on the recommended new IMPROVE equation application. CALPOST Version 6.221 defines this application as Method 8, Mode 5. The assessment of visibility impacts at the Class I areas will use CALPOST Method 8.

The CALPOST postprocessor will be used for the calculation of the impact of the modeled source's primary and secondary particulate matter concentrations on light extinction. In the new IMPROVE equation, the total sulfate, nitrate, and organic carbon compound concentrations are each split into two fractions, representing small and large size distributions of those components. New terms, such as sea salt (important for coastal locations), absorption by NO_2 (only used where NO_2 data are available), and site-specific Rayleigh scattering have been added to the equation. The new IMPROVE equation for calculating light extinction is shown below.



$$
\begin{aligned}
b_{ext} \quad = \quad & 2.2 \times f_S(RH) \times [\text{Small Sulfate}] + 4.8 \times f_L(RH) \times [\text{Large Sulfate}] \\
& + 2.4 \times f_S(RH) \times [\text{Small Nitrate}] + 5.1 \times f_L(RH) \times [\text{Large Nitrate}] \\
& + 2.8 \times [\text{Small Organic Mass}] + 6.1 \times [\text{Large Organic Mass}] \\
& + 10 \times [\text{Elemental Carbon}] \\
& + 1 \times [\text{Fine Soil}] \\
& + 0.6 \times [\text{Coarse Mass}] \\
& + 1.7 \times f_{SS}(RH) \times [\text{Sea Salt}] \\
& + \text{Rayleigh Scattering (Site Specific)} \\
& + 0.33 \times [NO_2\ (\text{ppb})] \quad \{\text{or as: } 0.1755 \times [NO_2\ (\mu g/m^3)]\}
\end{aligned}
$$

Where:

[ ] indicates concentrations in $\mu g/m^3$

$f_S(RH)$ = Relative humidity adjustment factor for small sulfate and nitrate

$f_L(RH)$ = Relative humidity adjustment factor for large sulfate and nitrate

$f_{SS}(RH)$ = Relative humidity adjustment factor for sea salt

For Total Sulfate $< 20\ \mu g/m^3$:

$$[\text{Large Sulfate}] = ([\text{Total Sulfate}] / 20\ \mu g/m^3) \times [\text{Total Sulfate}]$$

For Total Sulfate $\geq 20\ \mu g/m^3$:

$$[\text{Large Sulfate}] = [\text{Total Sulfate}]$$

And:

$$[\text{Small Sulfate}] = [\text{Total Sulfate}] - [\text{Large Sulfate}]$$

To calculate large and small nitrate and organic mass, substitute ({Large, Small, Total} {Nitrate, Organic Mass}) for Sulfate.

The FLAG 2008 document provides inputs to the new IMPROVE equation for the annual average natural conditions. Inputs to the CALPOST Method 8 calculations for each Class I area are listed in Table 2-5.

3.0 Updated BART Analysis Results and Conclusions

The results of the updated BART modeling for Heskett Unit 2 are provided in Table 3-1 with the use of CDIV = (0,0) and in Table 3-2 with the use of CDIV = (0.01, 0.01). The two sets of results are nearly the same, and they indicate that for the three years modeled all 98th percentile daily predictions of the change in visibility are below 0.5 deciview.

Table 3-1 Results of Updated BART Modeling with CDIV = (0, 0)

Class I Area	Met Year 2000				Met Year 2001				Met Year 2002				00-02 Peak
	Days above		MAX dv Δ B_{ext}	8th Highest Δ dv	Days above		MAX dv Δ B_{ext}	8th Highest Δ dv	Days above		MAX dv Δ B_{ext}	8th Highest Δ dv	8th Highest Δ dv
	0.5 dv Δ B_{ext}	1.0 dv Δ B_{ext}			0.5 dv Δ B_{ext}	1.0 dv Δ B_{ext}			0.5 dv Δ B_{ext}	1.0 dv Δ B_{ext}			
Lostwood W	1	0	0.69	0.19	0	0	0.38	0.23	0	0	0.31	0.11	0.23
T. Roosevelt NP	2	0	0.75	0.27	3	0	0.98	0.27	1	0	0.54	0.27	0.27

Table 3-2 Results of Updated BART Modeling with CDIV = (0.01, 0.01)

Class I Area	Met Year 2000				Met Year 2001				Met Year 2002				00-02 Peak
	Days above		MAX dv Δ B_{ext}	8th Highest Δ dv	Days above		MAX dv Δ B_{ext}	8th Highest Δ dv	Days above		MAX dv Δ B_{ext}	8th Highest Δ dv	8th Highest Δ dv
	0.5 dv Δ B_{ext}	1.0 dv Δ B_{ext}			0.5 dv Δ B_{ext}	1.0 dv Δ B_{ext}			0.5 dv Δ B_{ext}	1.0 dv Δ B_{ext}			
Lostwood W	1	0	0.82	0.20	0	0	0.40	0.23	0	0	0.32	0.11	0.23
T. Roosevelt NP	3	0	0.75	0.26	3	1	1.10	0.27	1	0	0.55	0.28	0.28

Based upon the predicted change in visibility in the two North Dakota Class I areas associated with the modeled peak daily baseline emissions reported above in either Table 3-1 or 3-2, Heskett Unit 2 is not subject to BART.

Director, Air Programs
U.S. EPA, Region 8
1595 Wynkoop Street
Denver, CO 80202-1129

Re: MDU Heskett Station Unit 2
BART Applicability

Dear ~~Ms. Videtich~~: Callie

On October 23, 2009, your staff provided comments on the draft North Dakota Regional Haze State Implementation Plan (SIP) revision. One of the comments concerned the exemption of Montana Dakota Utilities (MDU) Heskett Station Unit 2 from the BART requirements. EPA expressed concerns regarding the MDU modeling methodology, and requested that MDU remodel for BART applicability based on the latest EPA preferred model settings.

A conference call was held on November 17, 2009 with MDU, AECOM - MDU's consultant, EPA Region 8 representatives, FLM representatives and the Department to discuss the concerns. During the call, MDU agreed to remodel Heskett Unit 2 to determine BART applicability using preferred model settings identified by EPA and the FLMs. Although the Department does not necessarily agree with all of EPA's proposed model settings nor do we agree with treatment of combining the three units of TRNP as suggested by the FLMs, we did agree to allow the modeling to proceed in an effort to bring closure in addressing EPA's concerns and to meet the tight time constraints for submitting the State's RH SIP.

MDU has remodeled using the latest EPA preferred model settings and the FLMs treatment of Theodore Roosevelt National Park. The Department has reviewed MDU's updated analysis (attached) and has confirmed the modeling results. Based on the results of MDU's previous analysis and the updated analysis requested by EPA, the Department concludes MDU Heskett Station Unit 2 to be exempt from the BART requirements.

If you have any questions, please feel free to contact us.

Sincerely,

Terry O'Clair

Subject: Re: BART CALPUFF Modeling Protocol for MDU Heskett

With one exception the updated BART modeling protocol is acceptable to EPA.

The remaining issue is the CDIV switch in CALPUFF. The EPA regulatory default setting for
the Calpuff CDIV value is .01/.01 not 0/0 as the applicant has proposed.
The proposed setting should be submitted for review along with a specific request for a
regulatory change. The applicant did not give a technical reason for the setting change. If the
applicant decides to use the default setting EPA will accept the protocol.

On a non-technical issue, the narrative in the protocol describing the regulatory background
should be edited to note that EPA did not concur with the applicants 2006 exemption modeling
per a August 2008 letter from EPA.

Subject: BART CALPUFF Modeling Protocol for MDU Heskett

Kevin,

Based on discussions among MDU, EPA, FLM, and NDDH (North Dakota Dept of Health) representatives during a conference call on November 17, 2009, MDU has provided the attached, updated BART modeling protocol for MDU Heskett Unit 2. The NDDH has reviewed the protocol and finds that it address all concerns expressed during the November 17 call, and is consistent with the latest modeling guidance from EPA and FLMs.

Note that the attachments include a corrected page 2-3.

If you have any questions regarding the proposed methodology, please let me know.

Bob,

The North Dakota Department of Health has reviewed your proposed BART CALPUFF modeling protocol for MDU Heskett Station Unit 2 titled, “CALPUFF Visibility Modeling Protocol: MDU Heskett Unit 2 BART Analysis” (November 2009). We have determined that this protocol is acceptable for BART CALPUFF modeling for Heskett Unit 2.

If you have any questions, please contact me.

Steve,

I hope that you have received our updated Heskett BART modeling protocol by now. We are hoping for a quick review (by you and by any EPA and FLM reviewers) so that we can quickly proceed with the modeling. If you have an approximate schedule for the review and approval (hopefully), let me know. We are hoping to be doing final modeling this week.

Subject: Re: Heskett Unit 2

Tom:

Based on our review of AECOM's December 17, 2009 "Updated BART Modeling Results for R.M. Heskett Station Unit 2," our preliminary conclusions are that an EPA-approved protocol was used, and the results indicate that Heskett Unit 2's impact was less than the subject-to-BART threshold of 0.5 deciviews. Therefore, it appears appropriate for the State to determine that the source is not subject to BART. However, the source may still qualify for potential emission reductions under the Reasonable Progress requirements of the Regional Haze Rule. In addition, please note that we can only reach a final decision regarding the modeling and its results, and any other aspect of the Regional Haze SIP, through our own notice and comment rulemaking.

Thanks for your follow-up on this one......Amy

FILE

Cris Miller, P.E.
Environmental Coordinator
Basin Electric Power Cooperative
1717 E. Interstate Avenue
Bismarck, ND 58503

Dear Mr. Miller:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Basin Electric Leland Olds Generating Station Units 1 and 2 are BART-eligible sources. Completed visibility modeling for the Leland Olds Station (Units 1 and 2 combined) indicates that the maximum 98th percentile delta-deciview prediction for the facility exceeds the BART screening threshold of 0.5 deciviews. Therefore, Leland Olds Units 1 and 2 are subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Leland Olds Generating Station. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188. We look forward to working with you to develop appropriate BART control strategies for Leland Olds Units 1 and 2.

Sincerely,

Steve Weber for

FILE

John Graves, P.E.
Environmental Manager
Minnkota Power Cooperative, Inc.
P.O. Box 13200
Grand Forks, ND 58208

Dear Mr. Graves:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Minnkota Milton R. Young Generating Station Units 1 and 2 are BART-eligible sources. Completed visibility modeling for Milton R. Young Station (Units 1 and 2 combined) indicates that the maximum 98th percentile delta-deciview prediction for the facility exceeds the BART screening threshold of 0.5 deciviews. Therefore, Milton R. Young Units 1 and 2 are subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Milton R. Young Generating Station. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188. We look forward to working with you to develop appropriate BART control strategies for Milton R. Young Units 1 and 2.

Sincerely,

Steve Weber for

Terry L. O'Clair, P.E.
Director
Division of Air Quality

FILE

Mr. Jay Skabo
Environmental Coordinator
Montana-Dakota Utilities
400 North Fourth Street
Bismarck, ND 58501

Dear Mr. Skabo:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Montana-Dakota Utilities Heskett Unit 2 is a BART-eligible source. Completed visibility modeling for the Heskett Station Unit 2 indicates that the maximum 98th percentile delta-deciview prediction for the facility exceeds the BART screening threshold of 0.5 deciviews. Therefore, Heskett Unit 2 is subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Heskett Station Unit 2. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188. We look forward to working with you to develop an appropriate BART control strategy for Heskett Unit 2.

Sincerely,

Steve Weber for

Terry L. O'Clair, P.E.
Director
Division of Air Quality

Ms. Dianne Stockdill
Environmental Coordinator
Great River Energy
2875 Third Street SW
Underwood, ND 58576

Dear Ms. Stockdill:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Great River Energy Coal Creek Generating Station Units 1 and 2 are BART-eligible sources. Completed visibility modeling for the Coal Creek Station (Units 1 and 2 combined) indicates that the maximum 98th percentile delta-deciview prediction for the facility exceeds the BART screening threshold of 0.5 deciviews. Therefore, Coal Creek Units 1 and 2 are subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Coal Creek Generating Station. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188. We look forward to working with you to develop appropriate BART control strategies for Coal Creek Units 1 and 2.

Sincerely,

Steve Weber for

Terry L. O'Clair, P.E.
Director
Division of Air Quality

Mr. Steve Smokey
Environmental Coordinator
Great River Energy
4001 Highway 200A
Stanton, ND 58571

Dear Mr. Smokey:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Great River Energy Stanton Generating Station Unit 1 is a BART-eligible source. Completed visibility modeling for Stanton Station Unit 1 indicates that the maximum 98th percentile delta-deciview prediction for the facility exceeds the BART screening threshold of 0.5 deciviews. Therefore, Stanton Unit 1 is subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Stanton Station Unit 1. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188. We look forward to working with you to develop an appropriate BART control strategy for Stanton Station Unit 1.

Sincerely,

Steve Weber for

Terry L. O'Clair, P.E.
Director
Division of Air Quality

FILE

Mr. Ron Day
Manager, Health, Safety & Environment
Tesoro Refinery & Marketing Co.
900 Old Red Trail NE
Mandan, ND 58554

Dear Mr. Day:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Tesoro Mandan Refinery CO furnace is a BART-eligible source. Completed visibility modeling for the CO furnace indicates that the maximum 98th percentile delta-deciview prediction for the facility is below the BART screening threshold of 0.5 deciviews. Therefore, the CO furnace is not subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Mandan Refinery CO furnace. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188.

Sincerely,

Steve Weber for

Terry L. O'Clair, P.E.

OtterTail Power Company
P.O. Box 496
Fergus Falls, MN 56538-0496

Re: BART Permit to Construct

Dear Mr. Graumann:

The North Dakota Regional Haze State Implementation Plan (SIP) will require the OtterTail Power Company to reduce NO_x emissions at the Coyote Station, which is located near the City of Beulah in Mercer County. Enclosed is Permit to Construct No. 10008, which establishes the revised NO_x emission limit for the Coyote Station. A public comment period was held regarding the SIP from December 8, 2009 to January 8, 2010, during which comments were received by the Department and considered in our determination. Please note that Condition II.A.2 requires installation of the equipment necessary to meet the new NO_x limit by July 1, 2018 and compliance with the limit by July 1, 2019.

If you have any questions, please contact me at (701)328-5188.

Sincerely,

Terry O'Clair

AIR POLLUTION CONTROL
PERMIT TO CONSTRUCT

Pursuant to Chapter 23-25 of the North Dakota Century Code, and the Air Pollution Control Rules of the State of North Dakota (Article 33-15 of the North Dakota Administrative Code), a Permit to Construct is hereby issued for modifications at the following source:

I. **General Information**:

A. **Permit to Construct Number**: PTC10008

B. **Source**:

1. **Name**: Coyote Station
2. **Location**: Sec. 10, S½ of S ½ of Sec. 3 and W½ of Sec. 11, T143N, R88W, North Dakota, Mercer County
3. **Source Type**: Fossil-fuel fired steam electric unit with a nominal heat input of 5,800 million British thermal units per hour (10^6 Btu/hr).

C. **Owner Names**:
Montana-Dakota Utilities Co.
NorthWestern Public Service Company
Northern Municipal Power Agency
(Minnkota Power Cooperative, Inc.)
Otter Tail Power Company

D. **Operator**:

1. **Name**: Otter Tail Power Company
2. **Address**:
215 South Cascade Street
P.O. Box 496
Fergus Falls, MN 56538-0496

II. Permit Conditions:

This Permit to Construct establishes a revised nitrogen oxide (NO_x) emission limit for the main boiler at the Coyote Station (EUI 1) if, and when, EPA approves that limit as part of the Regional Haze SIP. The permit allows the construction and initial operation of new or modified air pollution control equipment and process modifications at the source to comply with the revised NO_x limit. If new emissions units are created, then a new Permit to Construct may be required in accordance with NDAC 33-15-14-02. The source shall be operated in accordance with the terms of this Permit to Construct and the Title V Permit to Operate until a revised Title V Permit to Operate is issued. The source is subject to all applicable rules, regulations, and orders now or hereafter in effect to the North Dakota Department of Health and to the conditions specified below:

A. Special Conditions:

1. **Emission Limits**: The term "12-month rolling average," as used in this permit to demonstrate compliance with the limit in Condition II.A.1.a. shall be determined by calculating an arithmetic average of all operating hourly outlet NO_x emissions rates as measured and calculated by the CEMS for the current month and the previous 11 months. A new 12-month rolling average shall be calculated by the 30th day following the end of each month. Each 12-month rolling average rate shall include start-up, shutdown, emergency and malfunction periods unless those periods are exempt by this permit.

   a. The permittee shall not discharge or cause the discharge of nitrogen oxides (NO_x) into the atmosphere from EUI 1 (main boiler) in excess of 0.50 pounds per million British thermal units ($lb/10^6$ Btu) on a 12-month rolling average basis.

   b. The NO_x emission limit applies at all times including startup, shutdown, emergency and malfunction.

2. **Compliance Date**: Installation of the new or modified equipment shall be completed by July 1, 2018. Compliance with the revised NO_x emission limit shall begin by July 1, 2019.

3. **Continuous Emission Monitoring (CEM)**: The emissions from EUI 1 shall be measured by continuous emission monitors (CEM) for NO_x and CO_2, The monitoring requirements under Condition II.A.4 shall be the compliance determination method for NO_x.

4. **Monitoring Requirements and Conditions**:

a. Requirements:

Testing and monitoring protocols used to demonstrate compliance with the emission limits of Condition II.A.1 above shall be as follows:

Table 1
Monitoring Requirements by Pollutant/Parameter

Pollutant/Parameter	**Monitoring Requirement (Method)**	**Condition Number (II.A. ...)**
NO_x (lb/10^6 Btu)	CEM	4.b.(1), 4.b.(2), 4.b.(3) & 4.b.(4)
CO_2	CEM	4.b(1), 4.b.(2), 4.b.(3) & 4.b.(4)

b. Emission Monitoring Conditions:

(1) The monitoring shall be in accordance with the applicable requirements of the Acid Rain Program, 40 CFR 72 and 40 CFR 75. Emissions are calculated using 40 CFR Part 75.

(2) The Department may require additional performance audits of the CEM systems.

(3) When a failure of a continuous emission monitoring system occurs, an alternative method, acceptable to the Department, for measuring or estimating emissions must be undertaken as soon as possible. The procedures outlined in 40 CFR 75, Subpart D for substitution are considered an acceptable method for the emission rate limit. Timely repair of the emission monitoring system must be made.

(4) The permittee shall maintain and operate air pollution control monitoring equipment in a manner consistent with the manufacturer's recommended equipment in a manner consistent with the manufacturer's recommended procedures on a site-specific QA/QC Plan required by 40 CFR 75. The permittee shall have the QA/QC Plan available on-site and provide the Department with a copy when requested.

5. **Recordkeeping Requirements**: The permittee shall maintain compliance monitoring records for Unit 1 as outlined in Table 2 – Monitoring Records that includes the following information:

a. A copy of the sample analysis report(s), including the date that the sample analysis was performed; the company, entity, or person that performed the analysis; and the testing techniques or methods used.

b. The records of quality assurance for emissions measuring systems including but not limited to quality control activities, audits and calibration drifts as required by the applicable test method.

c. A copy of all field data sheets from the emissions testing.

d. A record shall be kept of all major maintenance activities conducted on the emissions units or air pollution control equipment.

Table 2
Monitoring Records

Pollutant/Parameter	**Compliance Monitoring Record**
NO_x (lb/10^6 Btu)	CEM Data
CO_2	CEM Data

e. In addition to requirements outlined in Condition II.A.5, recordkeeping for EUI 1 shall be in accordance with the applicable requirements of the North Dakota Air Pollution Control Rules and the Acid Rain Program, 40 CFR 72 and 40 CFR 75.

f. The permittee shall retain records of all required compliance monitoring data and support information for a period of at least five years from the date of the compliance monitoring sampling, measurement, report, or application. Support information includes all maintenance records of the emission units and all original strip-chart recordings/computer printouts and calibrations of the continuous compliance monitoring instrumentation, and copies of all reports required by the permit.

6. **Reporting**:

a. Reporting for Unit 1 shall be in accordance with the applicable requirements of the North Dakota Air Pollution Control Rules and the Acid Rain Program, 40 CFR 72 and 40 CFR 75.

b. Quarterly excess emissions reports for Unit 1 shall be submitted no later than the 30th day of the following the end of each calendar quarter. Excess emissions are defined as emissions which exceed the emission limit for EUI 1 as outlined in Condition II.A.1.a. Excess emissions shall be reported for the following:

Parameter	Reporting Period
NO_x lb/10^6 Btu	12-month rolling average

c. The permittee shall submit a semi-annual report for all monitoring records required under Condition II.A.5 on forms supplied or approved by the Department. All instances of deviations from the permit must be identified in the report. A monitoring report shall be submitted within 45 days after June 30 and December 31 of each year.

d. 1) The permittee shall submit an annual compliance certification report within 45 days after December 31 of each year on forms supplied or approved by the Department.

2) For emissions units where the method of compliance monitoring is demonstrated by either an EPA Test Method or portable analyzer, the test report shall be submitted to the Department within 60 days after completion of the test.

3) The permittee shall submit an annual emission inventory report on forms supplied or approved by the Department . This report shall be submitted by March 15 of each year. Insignificant units/activities listed in this permit do not need to be included in the report.

4) The permittee shall notify the Department within 15 days of the actual startup date of the equipment required to meet the NO_x permit limit.

B. **General Conditions**:

1. The permit shall in no way permit or authorize the maintenance of a public nuisance or danger to public health or safety.

2. The permittee shall comply with all State and Federal environmental laws and rules. In addition, the permittee shall comply with all local building, fire, zoning, and other applicable ordinances, codes, rules and regulations.

3. All reasonable precautions shall be taken by the permittee to prevent and/or minimize fugitive emissions during the construction period.

4. The permittee shall at all times, including periods of startup, shutdown, malfunction, maintain and operate EUI 1 and all other emission units including associated air pollution equipment and fugitive dust suppression

operations in a manner consistent with good air pollution control practices for minimizing emissions.

5. Any duly authorized officer, employee or agent of the North Dakota Department of Health may enter and inspect any property, premise or place at which the source listed in Item I.B. of this permit is or will be located at any time for the purpose of ascertaining the state of compliance with the North Dakota Air Pollution Control Rules and the conditions of this permit.

6. The conditions of this permit herein become, upon the effective date of this permit, enforceable by the Department pursuant to any remedies it now has or may in the future have, under the North Dakota Air Pollution Control Law, NDCC Chapter 23-25. Each and every condition of this permit is a material part thereof, and is not severable.

ENVIRON UNIVERSITY of CALIFORNIA Riverside UNC CAROLINA ENVIRONMENTAL PROGRAM

- It is acceptable to assume that all measured sulfate is in the form of ammonium sulfate [$(NH_4)_2SO_4$] and all particulate nitrate is in the form of ammonium nitrate [NH_4NO_3].

To facilitate tracking the progress toward visibility goals, two important visibility parameters are required for each Class I area:

- *Baseline Conditions:* "Baseline Conditions" represent visibility for the B20% and W20% days for the initial five-year baseline period of the regional haze program. Baseline Conditions are calculated using monitoring data collected during the 2000-2004 five-year period and are the starting point in 2004 for the uniform rate of progress (URP) glide path to Natural Conditions in 2064 (U.S. EPA, 2003b).
- *Natural Conditions:* "Natural Conditions," the RHR goal for 2064 for the Federally mandated Class I areas, represent estimates of natural visibility conditions for the B20% and W20% days at a given Class I area.

3.3.1 Calculation of Baseline Conditions

Baseline Conditions for Class I areas are calculated using fine and coarse PM concentrations measured at Interagency Monitoring of Protected Visual Environments (IMPROVE) monitors (Malm et al., 2000). Each Class I area in the WRAP domain has an associated IMPROVE PM monitor. The IMPROVE monitors do not measure visibility directly, but instead measure speciated fine particulate ($PM_{2.5}$) and total $PM_{2.5}$ and PM_{10} mass concentrations from which visibility is calculated using the IMPROVE aerosol extinction equation, discussed later.

Visibility conditions are estimated starting with the IMPROVE 24-h average PM mass measurements related to six PM components of light extinction:

- Sulfate [$(NH_4)_2SO_4$]
- Particulate nitrate [NH_4NO_3]
- Organic matter [OMC]
- Light-absorbing carbon [LAC] or elemental carbon [EC]
- Soil
- Coarse matter [CM]

The IMPROVE monitors do not directly measure some of these species, so assumptions are made as to how the IMPROVE measurements can be adjusted and combined to obtain these six components. For example, sulfate and particulate nitrate are assumed to be completely neutralized by ammonium and only the fine mode ($PM_{2.5}$) is speciated to obtain sulfate and nitrate measurements (that is, any coarse-mode sulfate and nitrate in the real atmosphere may be present in the IMPROVE CM measurement). Concentrations for the above six components of light extinction in the IMPROVE aerosol extinction equation are obtained from the IMPROVE measured species using the formulas shown in Table 3-1.

Table 3-1. Definition of IMPROVE components from measured species.

IMPROVE Component	Calculation of Component from IMPROVE Measured Species
Sulfate	1.375 x (3 x S)
Nitrate	1.29 x NO_3^-
OMC	1.4 x OC
LAC	EC
Soil	(2.2 x Al) + (2.49 x Si) + (1.63 x Ca) + (2.42 x Fe) + (1.94 x Ti)
CM	MT – MF

where

- S is elemental sulfur as determined from proton-induced x-ray emissions (PIXE) analysis of the IMPROVE Module A. To estimate the mass of the sulfate ion ($SO_4^=$), S is multiplied by 3 to account for the presence of oxygen. If S is missing then the sulfate (SO_4) measured by ion chromatography analysis of Module B is used to replace (3 x S). For the IMPROVE aerosol extinction calculation, sulfate is assumed to be completely neutralized by ammonium (1.375 x SO_4).
- NO_3^- is the particulate nitrate measured by ion chromatography analysis of Module B. For the IMPROVE aerosol extinction calculation, it is assumed to be completely neutralized by ammonium (1.29 x NO_3).
- The IMPROVE organic carbon (OC) measurements are multiplied by 1.4 to obtain organic matter (OMC), which adjusts the OC mass for other elements assumed to be associated with OC.
- Elemental carbon (EC) is also referred to as light-absorbing carbon (LAC).
- Soil is determined as a sum of the masses of those elements (measured by PIXE) predominantly associated with soil (Al, Si, Ca, Fe, K, and Ti), adjusted to account for oxygen associated with the common oxide forms. Because K is also a product of the combustion of vegetation, it is represented in the formula by 0.6 x Fe and is not shown explicitly.
- MT and MF are total PM_{10} and $PM_{2.5}$ mass, respectively.

Associated with each PM species is an extinction efficiency that converts concentrations (in $\mu g/m^3$) to light extinction (in inverse megameters, Mm^{-1}), as listed below. Sulfate and nitrate are hygroscopic, so relative humidity (RH) adjustment factors, f(RH), are used to increase the particles' extinction efficiency with increasing RH; this accounts for the particles' taking on water and having greater light scattering. Note that some organic matter (OMC) compounds may also have hygroscopic properties, but the IMPROVE aerosol extinction equation assumes OMC is nonhygroscopic.

$$\beta_{Sulfate} = 3 \times f(RH) \times [sulfate]$$
$$\beta_{Nitrate} = 3 \times f(RH) \times [nitrate]$$
$$\beta_{OMC} = 4 \times [OMC]$$
$$\beta_{EC} = 10 \times [EC]$$
$$\beta_{Soil} = 1 \times [soil]$$
$$\beta_{CM} = 0.6 \times [CM]$$

The total light extinction (β_{ext}) is assumed to be the sum of the light extinctions due to the six PM species listed above plus Rayleigh (blue sky) background extinction (β_{Ray}), which is assumed to be 10 Mm^{-1}. This is reflected in the IMPROVE extinction equation:

$$\beta_{ext} = \beta_{Ray} + \beta_{Sulfate} + \beta_{Nitrate} + \beta_{EC} + \beta_{OMC} + \beta_{Soil} + \beta_{CM}$$

The total light extinction (β_{ext}) in Mm^{-1} is related to visual range (VR) in kilometers using the following relationship:

$$VR = 3912 / \beta_{ext}$$

The RHR requires that visibility be expressed in terms of a haze index (HI) in units of deciview (dv), which is calculated as follows:

$$HI = 10 \ln(\beta_{ext}/10)$$

The equations above, with measurements from the associated IMPROVE monitor, are used to estimate the daily average visibility at each Class I area for each IMPROVE monitored day. For each year from the 2000-2004 baseline period, these daily average visibility values are then ranked from highest to lowest. The "worst days" visibility for each of the five years in the baseline period is defined as the average visibility across the 20% worst-visibility days (highest deciview values); similarly, the "best days" visibility is defined as the average visibility across the 20% best-visibility days (lowest deciview values) for each year. The Baseline Conditions for the best and worst days are defined as the five-year average of the B20% visibility days and of the W20% visibility days, respectively, across the five-year baseline period.

The set of equations given above for relating measured PM species to visibility (light extinction) are referred to as the "Old IMPROVE" equation. The IMPROVE Steering Committee has developed a "New IMPROVE" equation that they believe better represents the fit between measured PM species concentrations and visibility impairment. Although conceptually similar to the Old IMPROVE equation, the New IMPROVE equation includes updates to many of the parameters and the addition of extinctions due to NO_2 absorption and sea salt. We performed 2018 visibility projections and comparisons with the URP glide path goals using both the New and Old IMPROVE equations. The reader is referred elsewhere for details on the New IMPROVE extinction equation (e.g., EPA, 2006a,b).

BART Determination
for
Leland Olds Station Units 1 and 2

I. Source Description

A. Owner/Operator: Basin Electric Power Cooperative
B. Source Type: Electric Utility Steam Generating Unit
C. BART Eligible Units

1. Unit 1 boiler
2. Unit 2 boiler
3. Auxiliary Boiler
4. Fire Pump
5. Materials Handling Equipment

   a. Unit 2 - coal bunkers and conveyors
   b. Unit 2 - transfer conveyors
   c. Main flyash silo
   d. 100 ton flyash silo
   e. Coal unloading facility
   f. Agglomerator
   g. Coal unloading silo

D. Unit Description

1. Unit 1:

Generator Nameplate Capacity: 216 MWe
Boiler Rating: 2622 x 10^6 Btu/hr
Startup: 1966
Fuel: North Dakota Lignite (80-100%)
: PRB Subbituminous (0-20%)
Firing Method: Wall-fired
Existing Air Pollution Control Equipment: Low NO_x burners (1995) and electrostatic precipitator

2. Unit 2:

Generator Nameplate Capacity: 440 MWe
Boiler Rating: 5130 x 10^6 Btu/hr
Startup: 1975
Fuel: North Dakota Lignite (80-100%)

: PRB Subbituminious (0-20%)
Firing Method: Cyclone
Existing Air Pollution Control Equipment: Electrostatic precipitator

3. Auxiliary Boiler:

   Boiler Rating: 51.6 x 10^6 Btu/hr
   Fuel: #2 fuel oil

4. Fire Pump:

   Rating: 200 Bhp
   Fuel: Diesel fuel

5. Materials Handling Equipment:

   a. Unit 2 coal bunkers and conveyors:
      Existing Air Pollution Control Equipment: Rotoclones

   b. Unit 2 transfer conveyors:
      Existing Air Pollution Control Equipment: Rotoclones

   c. Main Flyash Silo:
      Existing Air Pollution Control Equipment: Baghouse

   d. 100 Ton Flyash Silo:
      Existing Air Pollution Control Equipment: Baghouse
   e. Coal Unloading Facility:
      Existing Air Pollution Control Equipment: Baghouse

   f. Agglomerator:
      Existing Air Pollution Control Equipment: Baghouse

   g. Coal Unloading Silo:
      Existing Air Pollution Control Equipment: Baghouse

E. Emissions

BART Eligible Unit	**Pollutant**	**2000**	**2001**	**2002**	**2003**	**2004**	**2000-2004 Avg.**

II. Site Characteristics

The Leland Olds Station is located on the banks of the Missouri River in eastern Mercer county near the town of Stanton, North Dakota. The original design of Unit 1 only incorporated a multiclone for air pollution control, the electrostatic precipitator was added in the 1970's. Unit 2 was built with an electrostatic precipitator. Because of the original design and the close proximity of the Missouri River, there are some space constraints at the facility. Basin Electric has not indicated that the space constraints are insurmountable. Therefore, site constraints are an economic issue when evaluating the various control alternatives. Basin Electric has prepared a comprehensive BART analysis which can be found in Appendix C of the SIP.

III. BART Evaluation of Unit 1

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

Wet Scrubber
Spray Dryer
Circulating Dry Scrubber
Flash Dryer Absorber
Powerspan ECO®
Fuel Switching
Coal Cleaning

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning: Coal cleaning and coal washing have never been used commercially on North Dakota lignite. Coal washing can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. Since this facility is located on the banks of the Missouri River, water pollution is a major concern. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that has required coal cleaning. Therefore, these options were not considered further.

K-Fuel® is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels® process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Although Evergreen Energy, Inc. indicates the technology has been tested on lignite, there is no indication that lignite from the Freedom Mine was tested. Evergreen's website indicates that it has idled its Wyoming plant and directed its capital and management resources to supporting a new design. The use of the K-Fuel® process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Therefore, the Department does not consider coal cleaning or the K-Fuel® process available or technically and economically feasible.

The Department considers the Powerspan ECO® technology not to be commercially available since no full size plant has been installed or is operating at this time. All other technologies or alternatives are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Based on the information provided by Basin Electric, the Department has calculated the uncontrolled emission rate as follows:

Sulfur content = 1.13%
HHV = 6548 Btu/lb
Emission Factor = 35(s) lb/ton

The emission factor 35(s) is used to conservatively estimate the uncontrolled emission rate. During the Department's periodic review of SO_2 PSD increment consumption, emission factors for the Leland Olds Station were was extensively addressed[3]. Based on actual continuous emissions monitoring data an emission factor of 37.4(s) was established for Unit 1 and 38.7(s) for Unit 2. Using the lower emission factor of 35(s) results in a higher cost effectiveness and a lower controlled emission rate. As shown in Step 6, the emission factor does not affect the decision regarding the type of control technology selected since the most effective technology is selected as BART.

E = (35)(1.13%)(10^6)÷(2000 lb/ton)(6548 Btu/lb)
E = 3.02 lb/10^6 Btu
E = (2622 x 10^6 Btu/hr)(3.02 lb/10^6 Btu)
E = 7918.4 lb/hr
E = 34,683 tons/yr

Alternative	**Control Efficiency (%)**	**Inlet Loading (tons/yr)**	**Emissions**	
			(tons/yr)	**(lb/10^6 Btu)**
Wet Scrubber.	95	34,683	1734	0.15
Circulating Dry Scrubber	93	34,683	2428	0.21
Spray Dryer	90	34,683	3468	0.30
Flash Dryer Absorber	90	34,683	3468	0.30
Fuel Switching	≤77	34,683	7977	0.69

[a] New wet scrubbers generally achieve SO_2 removal efficiencies of 95%[4,5]. Higher efficiencies may be achieved with higher sulfur eastern coals, however, North Dakota (Fort Union) lignite is

much lower in sulfur content (1.13% for this analysis compared to 2.45% for interior bituminous coal[7]). EPA[6] indicates "Chlorine content improves the SO_2 removal ..." North Dakota lignite has some of the lowest chlorine levels of all the U.S. coals[7]. Based on the low chlorine content and lower sulfur content, lower SO_2 removal efficiencies would be expected on a power plant that burns North Dakota lignite than one that combusts eastern coal. In recent BACT assessments [8,9,10] for proposed power plants in North Dakota, the analyses indicated the efficiency of wet scrubbers would be 95% for North Dakota lignite. During three separate comment periods, no comments were received regarding the projected efficiency of a wet scrubber. The proposed BACT limits, and thus efficiency, will have to be met at all times including startup, shutdown and malfunction. The Department has determined that 95% removal efficiency is a reasonable upper limit that can be met on a continuous basis for a power plant combusting North Dakota lignite and using a wet scrubber.

Based on the future potential-to-emit, the cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($)***	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Wet FGD	32,949	19,310,000	586	353***
Circulating Dry Scrubber**	32,255	20,720,000	636	----
Spray Dryer	31,215	18,700,000	599	

Note: Flash Dryer Absorber not included since it costs more than a spray dryer with no additional emissions reduction.

* Costs provided by Basin Electric.
** Inferior option
*** Incremental cost from spray dryer to wet FGD.

Step 4: Evaluate Impacts and Document Results

Basin Electric has evaluated the energy and non-air quality effects of each option. The Department has determined that these effects will not preclude the selection of either a wet scrubber or spray dryer.

Step 5: Evaluate Visibility Results

The two primary alternatives are a wet scrubber operating at 95% removal efficiency and a spray dryer operating at 90% efficiency. The effects on visibility shown in the following tables are based on Basin Electric's estimate of SO_2 reductions. The Department estimates that the scrubbers will actually reduce emissions less than Basin Electric estimated since

Basin included SO_2 removed in the bottom ash in their calculation of emissions removed by the scrubber. The visibility impact results are therefore conservative (overestimate the improvement).

2002	Lostwood W. A.	0.544	0.396	0.148
Average	Lostwood W. A.			0.124
Overall Average				0.151

Step 6: Select BART

The cost effectiveness is reasonable for all technologies evaluated and the incremental cost from one technology to another is not excessive. There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The unit has no existing air pollution control equipment for removing sulfur dioxide and the plant is expected to have a remaining useful life of at least 20 years. The degree of visibility improvement achieved by selecting a wet scrubber operating at 95% control efficiency versus a spray dryer operating at 90% control efficiency does not exceed 0.083 deciviews (90th percentile) or 0.198 deciviews (98% percentile) at any Class I area for the 2000-2002 time frame. Although the amount of visibility improvement achieved by selecting a wet scrubber versus a spray dryer or circulating dry scrubber is small, the Department believes the cost effectiveness and incremental cost of a new wet scrubber is very low. The Department has determined that BART is represented by the use of a wet scrubber. Based on an annual average controlled emission rate of 0.15 lb/10^6 Btu, the expected maximum 30-day rolling average emission rate is 0.19 lb/10^6 Btu. By allowing Basin Electric to comply with either the percent reduction requirement or the lb/10^6 Btu limitation, the presumptive levels for plants larger than 750 MWe can be established as the BART limit. BART is proposed as an emission reduction efficiency of 95% of the inlet sulfur dioxide concentration to the scrubber or 0.15 lb/10^6 Btu on a 30-day rolling average basis.

B. Filterable Particulate Matter

Step 1: Identify All Available Technologies

New Baghouse
New Electrostatic Precipitator
Compact Hybrid Particulate Collector (CoHPAC)
Existing Electrostatic Precipitator

Step 2: Eliminate Technically Infeasible Options

All technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

		Emissions	
Alternative	**Control Efficiency**	**(tons/yr)**	**(lb/106 Btu)**
Baghouse	99.7+	108	0.013
New ESP	99.7	125	0.015
CoHPAC	99.7	125	0.015
Baseline (Existing ESP)	≈99.2	332*	0.040

* Based on the Department’s estimate of baseline emissions (2001-2002).

Alternative	**Emissions* Reduction (tpy)**	**Annualized ** Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Baghouse	224	3,260,000	14,554	46,294***
New ESP	207	2,630,000	12,705	----
CoHPAC	207	2,473,000	11,947	----
Baseline (Existing ESP)	0	0	---	

* Reductions from the baseline emission rate.
** Costs provided by Basin Electric.
*** Baghouse compared to CoHPAC.

Step 4: Evaluate Impacts and Document the Results

Basin Electric has evaluated the energy and non-air quality effects of each option. The Department has determined that the effects will not preclude the selection of any of the options.

Step 5: Evaluate Visibility Impacts

The different alternatives were not modeled because of the high cost effectiveness. However, the baseline emission rate was modeled. The results are as follows:

Unit 1 Delta Deciview PM			
Year	**Unit**	**90th Percentile**	**98th Percentile**
2000	TRNP-SU	0.0037	0.0048
2001	TRNP-SU	0.0006	0.0103
2002	TRNP-SU	0.0046	0.0119
Average	TRNP-SU	0.0030	0.0090
2000	TRNP-NU	0.0010	0.0098
2001	TRNP-NU	0.0013	0.0068
2002	TRNP-NU	0.0021	0.0371
Average	TRNP-NU	0.0015	0.0179
2000	Elkhorn Ranch	0.0020	0.0118
2001	Elkhorn Ranch	0.0004	0.0015
2002	Elkhorn Ranch	0.0040	0.0102
Average	Elkhorn Ranch	0.0021	0.0078
200	Lostwood W.A	0.0071	0.0111
2001	Lostwood W.A.	0.0059	0.0211
2002	Lostwood W.A.	0.0001	0.0053
Average	Lostwood W.A.	0.0044	0.0125
Overall Average		0.0028	0.0118

Step 6: Select BART

The alternative (excluding the baseline alternative) with the least cost for reducing filterable particulate emissions is the CoHPAC system. This system has a cost effectiveness of $11,947 per ton of particulate when compared to the current emission control system (ESP operating at approximately 99.2% efficiency). The Department considers this cost to be excessive.

There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The unit is equipped with an electrostatic precipitator that is achieving 99.2%, or greater, control efficiency. The plant is expected to have a remaining useful life of at least 20 years.

If all of the particulate emitted was eliminated, the most improvement in visibility at any Class I area would be approximately 0.0044 deciviews based on the three year average of the 90th percentile value (0.0125 deciviews based on the 98th percentile). The Department considers this amount of improvement to be negligible. Since none of the control technologies will eliminate all of the particulate matter emissions, the visibility improvement will be even less.

After considering all of the factors, the Department proposes that BART for filterable particulate matter is no additional controls. Since current actual emissions are less than the current allowable emissions, the Department proposes that BART is represented by an emission limit of 0.07 lb/10^6 Btu (average of 3 test runs).

C. Condensible Particulate Matter (PM_{10}).

Condensible particulate matter is made up of both organic and inorganic substances. Organic condensible particulate matter will be made up of organic substances, such as volatile organic compounds, which are in a gaseous state through the air pollution control devices but will eventually turn to a solid or liquid state. The primary inorganic substance expected from the boiler is sulfuric acid mist, with lesser amounts of hydrogen fluoride and ammonium sulfate.

Since sulfuric acid mist is the largest component of condensible particulate matter, controlling it will control most of the condensible particulate matter. The options for controlling sulfuric acid mist are the same options for controlling sulfur dioxide (see Section III.A.). Previously, BART for sulfur dioxide was determined to be represented by wet scrubber. This technology will achieve a 40-60% reduction as sulfuric acid mist emissions.

The control of volatile organic compounds at power plants is generally achieved through good combustion practices. The Department is not aware of any BACT determination at a power plant that resulted in any control technology being used. BACT has been found to be good combustion practices which are already in use since it minimizes the amount of fuel to generate electricity.

Basin Electric has indicated that the emission rate of condensible particulate matter could be as low as 0.0029 lb/10^6 Btu. AP-42, Compilation of Air Pollutant Emission Factors[2], suggests it could be as high as 0.02 lb/10^6 Btu. In either case, the emission rate is less than the current emissions of filterable particulate matter. The emissions of filterable particulate matter were determined to have a negligible impact on visibility.

Having considered all the factors, the Department has determined that BART for condensible particulate matter is represented by good sulfur dioxide control and good combustion control. Since the primary constituent of condensible particulate matter is sulfuric acid mist which is controlled proportionately to the sulfur dioxide controlled, the BART limit for sulfur dioxide can act as a surrogate for condensible particulate matter along with good combustion practices.

D. Nitrogen Oxides (NO_x)

Step 1: Identify All Available Technologies

Selective Catalytic Reduction (SCR)
Electro-Catalytic Oxidation (ECO)®
Selective Non-Catalytic Reduction (SNCR)
Hydrocarbon Enhanced SNCR (HE-SNCR)
Rich Reagent Injection (RRI)
Rotomix (ROFA + SNCR)
Conventional Gas Reburn (CGR)
CGR + SNCR w/separated overfire air (SOFA)
Coal Reburn
Coal Reburn + SNCR
Fuel-lean Gas Reburn (FLGR)
FLGR + SNCR
Rotating Overfire Air (ROFA)
Separated Overfire Air (SOFA)
New Low NO_x Burners (LNB)
Combustion Improvements

Step 2: Eliminate Technically Infeasible Options

The Department agrees with Basin Electric determination that high dust SCR is not technically feasible at this time. However, the Department believes low dust or tail end SCR has a good probability of successful application on Unit 1 (see discussion in Appendix B.5). ECO® and coal reburn plus SNCR have not been demonstrated on a pulverized coal-fired boiler and are considered technically infeasible. Rich reagent injection was developed for cyclone boilers and has not been demonstrated for other types of units. Therefore, RRI is considered technically infeasible for Unit 1.

Step 3: Evaluate Control Effectiveness of Remaining Control Technologies

Based on the historic baseline emissions, the Department's estimated emissions using the various technologies would be as follows:

Alternative	Control Efficiency (%)*	Emissions**	
		(tons/yr)	$lb/10^6$ Btu)
SCR w/reheat	80	593	0.057
Coal Reburn + Boosted SOFA	48.7	1,522	0.146
Coal Reburn + SOFA	46.2	1,596	0.153
SNCR + Boosted SOFA	45.1	1,629	0.156
SNCR + Basic SOFA	42.0	1,721	0.165
SNCR + Close-coupled OFA	24.5	2,240	0.215
Boosted SOFA	24.3	2,246	0.216
SOFA	19.4	2,391	0.230
Baseline		2,967	0.285

* Control efficiency provided in Basin Electric's analysis except for SCR. In the ANPR for the Four Corners Power Plant, EPA noted that the Arizona DEQ had determined that an SCR efficiency of 75% was appropriate for a unit with LNB. Leland Olds Unit 1 is equipped with LNB. EPA also indicated they believed 80% for SCR was appropriate.

** Calculated from the historic baseline. The historic baseline was used since the increased sulfur in the coal will not affect NO_x emissions. The emission rate is an annual average rate.

The estimated costs for the various technologies are as follows:

Alternative	Emissions Reduction (tpy)	Annualized Cost ($)	Cost Effectiveness ($/ton)	Incremental Cost ($/ton)
SCR w/reheat (low dust)	2,225	19,797,000 - 28,431,000	8,339 - 12,397	13,741 - 23,034***
SCR w/reheat (tail-end)	2,374	21,517,000- 31,011,000*	9,061 - 13,628	15,592 - 25,812***
Coal Reburn + Boosted SOFA	1,445	7,032,000	4,866	14,176
Coal Reburn + SOFA	1,371	5,983,000	4,364	80,727
SNCR + Boosted SOFA	1,338	3,819,000	2,854	7,826

Alternative	**Emissions Reduction (tpy)**	**Annualized Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
SNCR + Basic SOFA	1,246	3,099,000	2,487	3,737*
SNCR + Close coupled OFA	727	3,361,000	4,623	
Boosted SOFA	721	1,137,000	1,577	6,848
SOFA	576	144,000	250	250

* Department estimate based on Unit 2 cost estimate.
** SNCR + Basic SOFA compared to Boasted SOFA.
*** Incremental cost of SCR versus coal reburn + boosted SOFA.

SCR technology has never been applied to a boiler that combusts North Dakota lignite There are many unknowns that will affect the cost of either LDSCR or TESCR at the Leland Olds Station including:

1) The catalyst deactivation rate
2) Catalyst volume required
3) Catalyst surface area required
4) Required reagent injection rate
5) Expected reagent slip
6) Whether formation of ammonium bisulfate and/or ammonium sulfate will be at an acceptable rate
7) An appropriate catalyst maintenance plan

All of these will affect either the initial construction cost and/or annual operation and maintenance costs. The amount of catalyst required will affect the initial capital cost as well as the replacement cost. The life of the catalyst and the amount of reagent required will have a large impact on the annual operating cost. If a wet electrostatic precipitator is required to control ammonium bisulfate/ammonium sulfate emissions, both the initial capital cost and operation and maintenance costs will rise dramatically. Given the many unknowns with North Dakota Lignite, estimating the cost of an SCR system is extremely difficult and subject to many different opinions regarding estimating procedures. The Department believes pilot scale testing would prove to be very beneficial in addressing the items of concern and provide a more detailed professionally reliable cost estimate. However, the BART process cannot mandate pilot testing be conducted to determine costs. The Department believes the cost estimate provided by Basin Electric for Unit 2 without pilot testing, although not ideal, will suffice based on the information that is available at the current time.

Step 4: Evaluate Impacts and Document Results

There are no energy or environmental impacts that would preclude the selection of any of the alternatives.

Step 5: Evaluate Visibility Impacts

The Department considers the cost effectiveness and/or incremental cost effectiveness of the top four alternatives to be excessive. Basin Electric has modeled a no controls option and the SNCR + Basic SOFA option. The results are as follows:

Unit 1
Delta Deciview

Average	Lostwood W.A.	1.247	1.133	0.114
Overall Average		1.170	1.065	0.105

Step 6: Select BART

The Department considers the cost effectiveness and/or incremental cost of the top four options to be excessive. The Department proposes that BART is represented by SNCR plus basic SOFA. Basin Electric has indicated that Unit 1 can achieve an emission limit around 0.166-0.168 lb/10^6 Btu on an annual average basis. A thirty-day rolling average emission rate is expected to be at least 5-15% higher than the annual average emission rate. Unit 1 is a wall-fired unit fired primarily on lignite. In the BART Guideline (40 CFR 51, Appendix Y) EPA established a presumptive level for these units at 0.29 lb/10^6 Btu (30 d.r.a.). The Department proposes that BART is an emission limit of 0.19 lb/10^6 Btu on a 30-day rolling average basis.

V. BART Evaluation of Unit II

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

Wet Scrubber
Spray Dryer
Circulating Dry Scrubber
Flash Dryer Absorber
Powerspan ECO

Fuel Switching
Coal Cleaning

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning: Coal cleaning and coal washing have never been used commercially on North Dakota lignite. Coal washing can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. Since this facility is located on the banks of the Missouri River, water pollution is a major concern. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that has required coal cleaning.

K-Fuel® is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels® process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Although Evergreen Energy, Inc. indicates the technology has been tested on lignite, there is no indication that lignite from the Freedom Mine was tested. Evergreen's website indicates that it has idled its Wyoming plant and directed its capital and management resources to supporting a new design. The use of the K-Fuel® process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Therefore, the Department does not consider coal cleaning or the K-Fuel® process available or technically and economically feasible.

The Department considers the Powerspan ECO technology not to be commercially available since no full size plant has been installed or is operating at this time. All other technologies or alternatives are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Based on a potential-to-emit of 3.02 lb/10^6 Btu (see Section III.A.), the potential mass emission rate is:

E = $(3.02 \times 10^6$ lb/10^6 Btu$)(5130 \times 10^6$ Btu/hr$)$
E = 14592.6 lb/hr
E = 67,858 tons/yr

Alternative	Control Efficiency (%)	Inlet Loading (tons/yr)	Emissions	
			(tons/yr)	(lb/10^6 Btu)[a.]
Wet Scrubber	95	67,858	3,393	0.15
Circulating Dry Scrubber	93	67,858	4,750	0.21
Spray Dryer	90	67,858	6,786	0.30
Flash Dryer Absorber	90	67,858	6,786	0.30
Fuel Switching	≈77	67,858	15,607	0.69

[a.] Annual Average Emission Rate

Alternative	Emissions Reductions (tons/yr)	Annualized Cost ($)	Cost Effectiveness ($/ton)	Incremental Cost ($/ton)
Wet Scrubber	64,465	29,840,000	463	1,099[a]
CDS	63,108	35,580,000	564	
Spray Dryer	61,072	32,890,000	539	
Flash Dryer	61.072	32,430,000	531	
Fuel Switching	<52,251	13,490,000	258	

[a.] Incremental cost difference between wet scrubbing and fuel switching. All other alternatives are inferior to the wet scrubber.

Step 4: Evaluate Impacts and Document Results

Basin Electric has evaluated the energy and non-air quality effects of each option. The Department has determined that these effects will not preclude the selection of any of the available options. Basin Electric has selected the wet scrubber alternative as BART for this unit. A wet scrubber is the most efficient control option. Therefore, no evaluation of costs is necessary.

Step 5: Evaluate Visibility Results

Basin Electric has selected a wet scrubber operating at 95% control efficiency as BART. The BART Guideline states that if a source commits to a BART determination that consists of the most stringent controls available, then there is no need to complete the remaining steps. Basin has committed to the most stringent controls available and the lowest possible emission rate. Although modeling is not required, Basin Electric has modeled the use of a wet scrubber on Unit 2. The results are shown in the following table.

Unit 2

Average	Lostwood W.A.	3.395	1.029	2.366
Overall Average		3.038	0.931	2.106

Step 6: Select BART

After considering the cost of compliance, the energy and non-air quality environmental impacts, the remaining useful life (> 20 years) and the degree of visibility improvement, the Department proposes that BART is represented by a wet scrubber. Based on an annual controlled emission rate of 0.15 lb/10^6 Btu, a maximum 30-day rolling average emission rate of 0.19 lb/10^6 Btu is expected. By allowing Basin Electric to comply with either a percent reduction or a lb/10^6 Btu limitation, the presumptive emission limits for plants larger than 750 MWe can be established. The Department proposes that BART is 95% reduction efficiency from the inlet of the scrubber to the outlet of the scrubber, or 0.15 lb/10^6 Btu, on a 30-day rolling average basis.

B. Filterable Particulate Matter (PM/PM_{10})

Step 1: Identify All Available Technologies

New Baghouse
New Electrostatic Precipitator
Compact Hybrid Particulate Collector (CoHPAC)
Existing Electrostatic Precipitator

Step 2: Eliminate Technically Infeasible Options

All technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Alternative	Control Efficiency (%)	Emissions* (tons/yr)	Emissions* (lb/106 Btu)
Baghouse	99.7+	239	0.013
New ESP	99.7	277	0.015
CoHPAC	99.7	277	0.015
Baseline (Existing ESP)	≈ 99.3	627*	0.034

* Based on the Department's estimate of baseline emissions (2001-2002).

Alternative	Emissions* Reduction (tpy)	Annualized Cost** ($)	Cost Effectiveness ($/ton)	Incremental Cost ($/ton)
Baghouse	388	5,892,000	15,186	44,265***
New ESP	350	4,948,000	14,137	
CoHPAC	350	4,210,000	12,029	
Baseline	0	0	---	

* Reductions from baseline emission rate.
** Costs provided by Basin Electric.
*** CoHPAC compared to a baghouse.

Step 4: Evaluate Impacts and Document Results

Basin Electric has evaluated the energy and non-air quality environmental impacts associated with each alternative and determined that these impacts would not prelude the selection of any of the alternatives as BART. The Department agrees with this determination.

Step 5: Evaluate Visibility Results

The different alternatives were not modeled because of the high cost effectiveness. However, the baseline emission rate was modeled. The results are as follows:

Unit 2 Delta Deciview PM			
Year	**Unit**	**90th Percentile**	**98th Percentile**
2000	TRNP-SU	0.0018	0.0070
2001	TRNP-SU	0.0013	0.0084
2002	TRNP-SU	0.0068	0.0158
Average	TRNP-SU	0.0033	0.0104
2000	TRNP-NU	0.0037	0.0053
2001	TRNP-NU	0.0007	0.0059
2002	TRNP-NU	0.0006	0.0293
Average	TRNP-NU	0.0017	0.0135
2000	Elkhorn Ranch	0.0028	0.0040
2001	Elkhorn Ranch	0.0055	0.0069
2002	Elkhorn Ranch	0.0048	0.0121
Average	Elkhorn Ranch	0.0044	0.0076
2000	Lostwood W. A.	0.0139	0.0249
2001	Lostwood W. A.	0.0015	0.0258
2001	Lostwood W. A.	0.0013	0.0274
Average	Lostwood W.A.	0.0056	0.0260
Overall Average		0.0038	0.0144

Step 6: Select BART

The alternative (excluding the baseline alternative) with the least cost for reducing filter particulate matter emissions is the CoHPAC system which has a cost effectiveness of $12,029 per ton when compared to the current emission control systems (ESP operating at 99.3% control efficiency). The Department considers this cost to be excessive. There are no energy or non-air quality impacts that would preclude the selection of any of the feasible control options.

The unit is equipped with an electrostatic precipitator that is achieving 99.3% control efficiency. The average emission rate for this unit for 2000-2004 was 0.025 lb/10^6 Btu. The plant is expected to have a remaining useful life of at least 20 years.

If all of the particulate matter emitted was eliminated, the most improvement in visibility at any Class I area would be 0.0056 deciviews based on the 90th percentile (0.0260 deciviews based on 98th percentile). The Department considers this amount of improvement to be negligible. Since none of the control alternatives will eliminate all of the particulate matter emissions, the visibility improvement will even be less.

After considering all of the factors, the Department proposes that BART for filterable particulate matter is no additional controls. Since the current actual emissions are less than the current allowable emissions, the Department proposes that BART is represented by an emission limit of 0.07 lb/10^6 Btu (average of three test runs).

C. Condensible Particulate Matter (PM_{10})

See the discussion for Unit 1 in Section III.C. Any additional control technology for controlling condensible particulate matter will result in less than a 0.0056 deciview improvement at any Class I area. The Department considers the use of a wet scrubber and good combustion practices to represent BART for condensible particulate matter from Unit 2. The BART limit for sulfur dioxide (95% reduction) and good combustion practices will act as a surrogate for condensible particulate matter.

D. Nitrogen Oxides

Step 1: Identify All Available Technologies

Selective Catalytic Reduction (SCR)
Electro-Catalytic Oxidation (ECO)®
Selective Non-Catalytic Reduction (SNCR)
Hydrocarbon Enhanced - SNCR with or without Advanced Separated Overfire Air (ASOFA)
Rich Reagent Injection (RRI) + SNCR + ASOFA
Rotomix (ROFA + SNCR)
Conventional Gas Reburn plus SNCR (CGB + SNCR)
Coal Reburn
Coal Reburn + SNCR
Fuel Lean Gas Reburn (FLGR)
Seperated Overfire Air (SOFA)
Advanced SOFA (ASOFA)
Rotating Overfire Air (ROFA)
Combustion Improvements
Oxygen Enhanced Combustion (OEC)

Step 2: Eliminate Technically Infeasible Options

The Department does not consider high dust SCR to be technically feasible at this time. However, the Department believes low dust or tail end SCR has a good probability of successful application on Unit 2 (see discussion in Appendix B.5). Basin Electric has determined the following technologies are also technically infeasible:

ECO
HE-SNCR
Rotamix
CGR + SNCR
Coal Reburn + SNCR
FLGR + SNCR
OEC

The Department agrees with Basin Electric's determination regarding technical feasibility. ROFA and SOFA are similar and only SOFA will be evaluated further.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Based on the historic baseline emissions, the expected emissions are as follows:

Alternative	**Control Efficiency* (%)**	**Emissions****	
		(tons/yr)	**(lb/10^6 Btu)**
SCR w/reheat + ASOFA	90	1,202	0.07
RRI + SNCR + ASOFA	60.3	4,773	0.266
SNCR + ASOFA	54.5	5,470	0.305
Coal Reburn + ASOFA	51.8	5,795	0.323
SNCR	37	7,574	0.422
ASOFA	28	8,657	0.482
SOFA/ROFA	<28	>8,657	>0.482
Baseline		12,023	0.67

*Control efficiency specified by Basin Electric in their analysis.
**Based on historic baseline emissions. The lb/10^6 Btu emission rate is an annual average.

The estimated costs for the most efficient alternatives are as follows:

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($/ton)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Low Dust SCR + ASOFA	10,821	40,326,000 - 57,914,000	3,727 - 5,352	6,420 - 11,356
Tail-end SCR + ASOFA	10,821	43,830,000-63,170,000	4,050-5,838	7,401-12,817
RRI + SNCR + ASOFA	7,250	17,400,000	2,400	9,369
SNCR + ASOFA	6,553	10,870,000	1,659	3,021**
*Coal Reburn + ASOFA	6,228	14,860,000	2,386	
ASOFA	3,366	1,241,000	369	369

Note: See discussion for Unit 1 regarding the accuracy of the cost estimate for SCR.

* Inferior alternative since it costs more than SCNR + ASOFA with less emissions reduction.
** Incremental cost difference between SCNCR + ASOFA and ASOFA.

Step 4: Evaluate Impacts and Document Results

Basin Electric has not identified any environmental or energy impact that would preclude of the use of any of the previously evaluated emission control alternatives.

Step 5: Evaluate Visibility Impacts

The top three alternatives were evaluated with respect to the impact on visibility impairment. The results are as follows:

Unit 2

Step 6: Select BART

The Department considers both the cost effectiveness and incremental cost of SCR to be excessive. SCR will only produce an average of 0.066 decivews improvement in the North Dakota Class I areas based on the 90th percentile (0.319 decivews based on the 98th percentile) versus RRI + ASOFA + SNCR. Because the single source modeling under the BART guidelines overestimates the visibility improvement in North Dakota by a factor of 5-7 (see Section 7.4.2 of SIP), the Department conducted modeling which included all sources of emissions in the modeling inventory to determine the true impact on visibility of SCR + ASOFA versus SNCR + ASOFA. The average improvement in visibility for the 20% worst days was only 0.01 decivews at both TRNP and LWA. The Department considers this amount of improvement to be negligible. Based on the excessive cost and negligible visibility improvement, SCR was eliminated as a BART alternative.

RRI + SNCR + ASOFA and SNCR + ASOFA are both considered to have reasonable cost effectiveness. However, the incremental cost ($9,369/ton) going from SNCR + ASOFA to RRI + SNCR + ASOFA is considered excessive. Use of RRI + SNCR + ASOFA will only increase visibility improvement by an average of 0.012 deciviews (90th percentile) or 0.058 deciviews (98th percentile) during the 2000-2002 time period. Given the high incremental cost and negligible visibility improvement, RRI + ASOFA + SNCR was eliminated as a BART alternative.

After considering all of the factors, the Department proposes that BACT is represented by SNCR + ASOFA. With SNCR + ASOFA, an emission rate of 0.305 lb/10^6 Btu on an annual average basis is expected. Basin

Electric believes that an emission rate of 0.35 lb/10^6 Btu is achievable based on a 30-day rolling average. The Department's experience with power plants suggest that the maximum 30-day rolling average NO_x emission rate is 5-15% higher than the annual average emission rate. Therefore, the Department proposes that BART is an emission limit of 0.35 lb/10^6 Btu on a 30-day rolling average basis.

V. BART Evaluation for Auxiliary Boiler

The auxiliary boiler is a #2 fuel-oil fired boiler with a nominal rating of 51.6 x 10^6 Btu/hr. The auxiliary boiler is only used when both units at the Leland Olds Station are down. During the baseline period (2000-2004), the unit was operated approximately 3.6 hours per year. The annual average emissions from the unit for this period were:

NO_x	0.01 tons
SO_2	0.03 tons
PM	0.001 tons

Based on the small quantity of emissions, it is apparent that no add-on control equipment will be cost effective. Any reduction in emissions will have a virtually no effect on visibility impairment. Therefore, the Department proposes that BART is no additional controls. The current permit limits the fuel used in the boiler to #2 fuel oil. BART is the use of #2 fuel oil.

VI. BART Evaluation for Emergency Fire Pump

The emergency fire pump, is driven by a 200 horsepower diesel engine. The pump is used for emergency purposes only and most of the emissions generated are due to testing and maintenance activities. During the baseline period (2000-2004), the engine operated 4.3 hours per year and the actual annual emissions were:

NO_x	0.0002 tons
SO_2	0.0003 tons
PM	0.00001 tons

Based on the small quantity of emissions, no add-on control equipment will be cost effective. Any reduction of emissions will not affect visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VII. BART Evaluation for Materials Handling Sources

The materials handling sources at Leland Olds Station that emit to the atmosphere are as follows:

EUI	Description	Existing Control Equipment	Current Emission Limit (lb/hr)	Baseline Emissions (tons/yr)
M7	Unit 2 East bunker conveyor	Rotoclone	1.0	0.82*
M8	Unit 2 West bunker conveyor	Rotoclone	1.0	0.82*
M9	Unit 2 Bunker house transfer conveyor (west)	Rotoclone	1.0	0.82*
M10	Unit 2 Bunker house transfer conveyor (east)	Rotoclone	1.0	0.82*
M11	Main flyash silo	Baghouse	0.26	1.0
M12	100 Ton flyash silo	Baghouse	0.1	0.01
M13	Coal unloading facility	Baghouse	16.97	12.4
M14	Agglomerator	Baghouse	0.06	0.04
M16	Coal unloading silo	Baghouse	0.26	0.19

*Department estimate

Based on the small quantity emissions from those sources that are controlled by rotoclones (M7-M10), it is apparent that no additional control equipment will be cost effective. The other materials handling units are controlled using a baghouse which is considered the most efficient control device. Therefore, the Department proposes that BART for the materials handling units is no additional controls and the current emission limit for the units is BART.

VIII. Summary

Source Unit	**Proposed* BART Limit/Work Practice**				**Emissions Reduction** (tons/yr)**		
	PM	**SO2**	**NOx**	**Units**	**PM**	**SO2**	**NOx**
Unit 1 Boiler	0.07	0.15 or 95% reduction	0.19	lb/106 Btu	0	15,290	757
Unit 2 Boiler	0.07	0.15 or 95% reduction	0.35	lb/106 Btu	0	28,297	4,519
Auxiliary Boiler	Use #2 Fuel Oil			N/A	0	0	0
Fire Pump	Use low sulfur diesel fuel			N/A	0	0	0
M7	1.0	---	---	lb/hr	0	---	---
M8	1.0	---	---	lb/hr	0	---	---

Source Unit	Proposed* BART Limit/Work Practice				Emissions Reduction** (tons/yr)		
	PM	**SO2**	**NOx**	**Units**	**PM**	**SO2**	**NOx**
M9	1.0	---	---	lb/hr	0	---	---
M10	1.0	---	---	lb/hr	0	---	---
M11	0.26	---	---	lb/hr	0	---	---
M12	0.1	---	---	lb/hr	0	---	---
M13	16.97	---	---	lb/hr	0	---	---
M14	0.06	---	---	lb/hr	0	---	---
M16	0.26	---	---	lb/hr	0	---	---
Total						43,587	5,276

* PM limit is the average of three 2-hour test runs. SO_2 and NO_x limits are a 30-day rolling average.

** Reductions from 2000-2004 average emission rate assuming 30-day rolling average equals the annual average emission rate.

IX. Permit to Construct

The emission limits, monitoring, recordkeeping and reporting requirements will be included in a federally enforceable Air Pollution Control Permit to Construct that will be issued to the owner/operator of the facility. The Permit to Construct is included in Appendix D.

A. Monitoring

1. Monitoring for SO_2 and NO_x will be accomplished using the continuous emission monitors required by 40 CFR 75 for the Acid Rain Program. Monitoring for particulate matter shall be in accordance with 40 CFR 64, Compliance Assurance Monitoring. If the owner/operator of the BART-eligible unit chooses to comply with the SO_2 percent reduction requirements, monitoring of the SO_2 inlet rate to the scrubber shall be accomplished by either:

   a. A continuous emission monitor that complies with the requirements of 40 CFR 75; or

   b. Coal sampling in accordance with Method 19 of 40 CFR 60, Appendix A plus development of an emission factor based on actual stack testing.

2. For purposes of determining compliance with the SO_2 reduction requirement, the reduction efficiency shall be determined as follows:

$$\% \text{ Reduction} = \frac{\text{Inlet } SO_2 \text{ Rate} - \text{Outlet } SO_2 \text{ Rate}}{\text{Inlet } SO_2 \text{ Rate}} \times 100$$

Where:

Inlet SO_2 Rate is in units of lb/10^6 Btu, lb/hr or ppmvd @ 3% O_2.
Outlet SO_2 Rate is in the same units as the inlet SO_2 rate.

3. The owner/operator will be allowed to average emissions (bubble) for SO_2 and/or NO_x for the two units using the following formulas:

$$\text{Average AER} = \frac{[(AER_1)(HI_1)+(AER_2)(HI_2)]}{(HI_1 + HI_2)}$$

$$\text{Average ER} = \frac{[(ER_1)(HI_1)+(ER_2)(HI_2)]}{(HI_1 + HI_2)}$$

Where:

AER = Allowable Emission Rate (lb/MMBtu or % Reduction)

ER_1 = Actual Emission Rate (lb/MMBtu or % Reduction) of Unit 1
ER_2 = Actual Emission Rate (lb/MMBtu or % Reduction) of Unit 2
HI_1 = Actual Heat Input (MMBtu) of Unit 1
HI_2 = Actual Heat Input (MMBtu) of Unit 2

Notes: ER is a 30-day rolling average.
HI is a 30-day rolling average.
30-day rolling average for the 30 successive boiler operating days (must be on a consistent basis of lb/MMBtu or % reduction).

B. Recordkeeping and Reporting

The owner/operator will be required to conduct recordkeeping and reporting as required by NDAC 33-15-14-06, Title V Permit to Operate and NDAC 33-15-21, Acid Rain Program (40 CFR 72, 75 and 76).

BART Determination
For
Coal Creek Station Units 1 and 2

12/1/09

I. Source Description

A. Owner/Operator: Great River Energy (GRE)

B. Source Type: Fossil-fuel fired steam electric plant of more than 250 million British thermal units (Btu) per hour heat input and having a total generating capacity in excess of 750 megawatts.

C. BART Eligible Units

1. EU 1 - Unit 1 boiler
2. EU 2 - Unit 2 boiler
3. EU 3 - Auxiliary boiler No. 91
4. EU 4 - Auxiliary boiler No. 92
5. EU 5 - Emergency generator
6. EU 6 - Fire pump engine
7. EU 7 through EU 26 material handling units, including coal and lime handling operations and flyash silos
    a. EU 7 - Lignite transfer house
    b. EU 8 - Lignite emergency reclaim system
    c. EU 9 - Lignite yard storage silos
    d. EU 10 - Lignite yard storage silos
    e. EU 11 - Crusher building (Two 1,500 ton per hour crushers)
    f. EU 12 - Generation building coal hopper
    g. EU 13 - Falkirk Mining Company mine silo base

      h. EU 14 - Generation building coal hopper

      i. EU 15 - Generation building coal hopper

      j. EU 16 - Generation building coal hopper

      k. EU 17 - Generation building coal hopper

      l. EU 19 - Scrubber building flyash silo

      m. EU 20 - Truck air slide flyash silo

      n. EU 21 - Truck air slide flyash silo

      o. EU 22 - Water treatment building

      p. EU 23 - Scrubber building lime handling system

      q. EU 24 - Scrubber building lime handling system

      r. EU 25 - Flyash railroad marketing silo

      s. EU 26 - Flyash dome

   8. FS 1 through FS 5 - Fugitive sources

      a. FS 1 - Cooling Towers No. 91, No. 92, and No. 93

      b. FS 2 - Boombelt conveyor (stackout)

      c. FS 3 - Conveyor 909 (stackout)

      d. FS 4 - Scrubber building flyash silo (stackout)

      e. FS 5 - Coal pile maintenance

D. Unit Description

   1. EU 1 - Unit 1 boiler:

      Generator Nameplate Capacity: 550 MWe

      Boiler Rating: 6,015 x 10^6 Btu/hour

      Startup: 1979

Fuel: North Dakota lignite

Firing Method: Tangential-fired pulverized coal (PC) unit

Existing Air Pollution Equipment:

Electrostatic precipitator (ESP)
Low NO_x burners (LNB) and separated over fire air (SOFA)
Wet scrubber

2. EU 2 - Unit 2 boiler

Generator Nameplate Capacity: 550 MWe

Boiler Rating: 6,022 x 10^6 Btu/hour

Startup: 1980

Fuel: North Dakota lignite

Firing method: Tangential-fired pulverized coal (PC) unit

Existing Air Pollution Equipment:

Electrostatic precipitator (ESP)
Low NO_x burners (LNB) and separated over fire air (SOFA)
Wet scrubber

3. EU 3 - Auxiliary boiler No. 91

Boiler rating: 172 x 10^6 Btu/hour

Fuel: Residual oil, distillate fuel oils, or any combination of these fuels

Existing air pollution equipment: None

4. EU 4 - Auxiliary boiler No. 92

Boiler rating: 172 x 10^6 Btu/hour

Fuel: Residual oil, distillate fuel oils, or any combination of these fuels

Existing air pollution equipment: None

5. EU 5 - Emergency generator

Rating: 3,500 bhp

Fuel: No. 2 fuel oil or a blend of No. 1 and No. 2 fuel oil

Existing air pollution equipment: None

6. EU 6 - Fire pump engine

Rating: 200 bhp

Fuel: No. 2 fuel oil or a blend of No. 1 and No. 2 fuel oil

Existing air pollution equipment: None

7. EU 7 through EU 26 - Material handling units, including lime handling operations and flyash silos

Existing air pollution equipment: Fabric filters/bag houses

8. FS 1 through FS 5 - Fugitive sources

Existing air pollution equipment: None - fugitive emissions

II. Site Characteristics

The Coal Creek Station is a two-unit, 1,100 gross megawatt (MW) mine-to-mouth power plant consisting primarily of two steam generators and associated coal and ash handling systems. Unit 1 and Unit 2 are identical Combustion Engineering boilers firing pulverized lignite coal tangentially from a maximum of 64 firing points each. Unit 1 has a heat input capacity of 6,015 x 10^6 Btu/hr; Unit 2 is rated at 6,022 x 10^6 Btu/hr. Particulate matter from each boiler is controlled by a 99.5% efficient electrostatic precipitator (ESP) consisting of 48 transformer rectifier (TR) sets. A four-module flue gas desulfurization (FGD) system for each boiler removes approximately 90% of the sulfur dioxide from 60% of the flue gas. Each boiler is served by a 655 foot high stack.

Unit 1 began commercial operation in 1979 and Unit 2 in 1980. The facility is located in south central McLean County about five miles south of the town of Underwood, North Dakota and three miles west of US Highway 83. Coal Creek Station receives its lignite from the Falkirk Mine that is operated by the Falkirk Mining Company, a subsidiary of the North American Coal Corporation. Approximately 8,130,000 tons of lignite coal and approximately 165,000 gallons of oil were combusted in 2006.

III. BART Evaluation of Unit 1 and Unit 2

The BART guidelines apply to Units 1 and 2 because they are part of a fossil-fuel steam electric plant with a total generating capacity in excess of 750 megawatts, they are rated at more than 250 million Btu per hour heat input, and they have potential emissions of 250 tons or more per year of a visibility-impairing pollutant, specifically SO_2, NO_x and PM_{10}.

Since Units 1 and 2 are identical, the following evaluation will use values derived by averaging the historical data for each unit and then make a single BART determination that will be applicable to each unit.

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

Coal Cleaning/Washing
K-Fuel®
TurboSorp®
Coal Drying
Dry Sorbent Injection
Spray Dryer

Wet Scrubber Modification
Wet Scrubber Replacement

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning/Washing: Coal cleaning and coal washing have never been used commercially on North Dakota lignite. Coal washing can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that have required coal cleaning.

K-Fuel® is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Evergreen's website indicates that it has idled its Wyoming plant and directed its capital and management resources to supporting a new design. Although Evergreen Energy, Inc. indicates the technology has been tested on lignite, there is no indication that lignite from the Center Mine was tested. The use of the K-Fuel® process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Therefore, the Department does not consider coal cleaning or the K-Fuel® and will be submitted to this Department at the end of the approved burn period process available or technically and economically feasible.

TurboSorp®: Although the GRE analysis concluded otherwise, the Department considers TurboSorp® dry flue gas desulfurization technology to be technically feasible because it employs the proven technology of circulating dry scrubbers. Additional information on this technology is found at:
http://www.eucetsa.net/eucetsa/webPages.do?pageID=200913.

Coal Drying: Coal drying of lignite has been demonstrated to be technically feasible through pilot projects at this facility. Furthermore, dried lignite is the primary fuel for another ND facility, the GRE Spiritwood Station, that received a permit to construct September 14, 2007.

In addition to coal drying, the remaining control technologies, dry sorbent injection, spray dryer, and wet scrubber (modification or replacement), are considered to be technically feasible. GRE has elected to install coal drying equipment independent of the SO_2 control chosen.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Baseline SO_2 Emissions Controlled (past): Based on average actual controlled annual emissions when combusting lignite (undried) for a 24 month period (2003-2004) with 27% bypass: (13,817 [Unit 1, 2003] + 13,547 [Unit 2, 2003] + 15,742 [Unit 1, 2004] + 11,469 [Unit 2, 2004])/4 = 13,644 ton/yr average baseline controlled SO_2 emissions with 27% bypass and undried coal.

Applying the 68% overall control efficiency of the existing scrubber yields: [(13,644 ton/yr)/(1-0.68)] = 42,638 ton/yr uncontrolled baseline SO_2 emissions.

The 42,638 ton/yr uncontrolled baseline SO_2 emissions are based on past undried coal with an average 2003-2004 sulfur content of 0.61%. The evaluation of alternative SO_2 cleaning equipment will be based on future undried coal with an expected worst case (98 percentile) sulfur content of 1.10%, as predicted for Falkirk coal and provided by GRE. Therefore, the uncontrolled baseline SO_2 emissions above must be adjusted to the future sulfur content so that an apples to apples comparison will correctly determine emission reductions expected to result from employing the alternative equipment. The 42,638 ton/yr uncontrolled baseline SO_2 emissions is adjusted as follows: (42,638 ton/yr)(1.1%/0.61%) = 76,888 ton/yr uncontrolled baseline SO_2 emissions for undried coal with future sulfur content.

For the purposes of this analysis, the adjustment to future coal was considered necessary only for SO_2 and the related condensible particulate matter and sulfuric acid mist emissions due to the increased sulfur content expected in future coal. For all other pollutants, this analysis does not adust to future coal due to the negligible impact on emissions. No adjustment to the baseline was made for coal drying because the Permit to Construct is not expected to require dried lignite or limit moisture content.

Note: TurboSorp® is a registered trademark for Babcock Power Environmental's circulating dry scrubber. The Department considers circulating dry scrubbers to be technically feasible. Circulating dry scrubbers will generally achieve SO_2 removal efficiencies similar to spray dryer absorbers but less than wet scrubbers. Other BART analyses projected a removal efficiency of 93% with higher costs than a new wet scrubber. Since a circulating dry scrubber will have a lower removal efficiency than a wet scrubber or upgrades to the existing wet scrubber (95% and 94%, respectively) and will cost more than a new wet scrubber or upgrades to the existing wet scrubber, a circulating dry scrubber is an inferior option and is not considered further.

Future Case

Alternative	**Control Efficiency (%)**	**Baseline Uncontrolled Emissions (tons/yr)***	**Controlled Emissions***	
			(tons/yr)	**(lb/10^6 Btu)****
Wet Scrubber Replacement***	95	76,888	3,844	0.146
Wet Scrubber Modification***	95	76,888	3,844	0.146
Spray Dryer***	90	76,888	7,689	0.292
Existing Scrubber & 0% Bypass	83.1	76,888	12,994	0.493
Dry Sorbent Injection***	70	76,888	23,066	0.875
Existing Scrubber & 27% Bypass	68****	76,888	24,604*****	--

*	Future lignite at 1.10% (GRE-predicted worst-case sulfur content for Falkirk Mine lignite. As a result, Department baseline future emission estimates are somewhat higher than GRE's estimates)
**	Annual
***	0% bypass
****	Current control rate
*****	Current controlled emissions = 76,888(1-0.68) = 24,604 tpy

Step 4: Evaluate Impacts and Document Results

Costs of Compliance: Based on the past emissions adjusted for the sulfur content of future coal, the cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($)***	**Cost Effectiveness($/ton)**	**Incremental Cost ($/ton)**
Wet Scrubber Replacement	20,760	30,760,000	1,482	24,987
Wet Scrubber Modification	20,760	11,520,000	555	--
Spray Dryer**	16,915	29,220,000	1,727	--
Existing Scrubber 0% Bypass	11,610	9,840,000	848	N/A
Dry Sorbent Injection**	1,538	12,520,000	8,140	N/A

*	Costs provided by GRE
**	Inferior option to wet scrubber modifications
N/A	Not applicable since the cost effectiveness of the less efficient alternative is more than the more efficient alternative

The incremental cost associated with wet scrubber replacement ($24,987/ton) as compared to wet scrubber modification represents an excessively high cost relative to the emission reduction obtained.

Energy and Non-air Quality Effects: GRE has evaluated the energy and non-air quality effects of each option. Although the Department has determined that the information presented by GRE concerning these effects does not appear to preclude the selection of any of the five alternatives above, the possible economic impacts due to extensive process downtime associated with scrubber replacement and dry sorbent injection may be significant negative factors for their selection.

Step 5: Evaluate Visibility Results

The three primary alternatives and associated removal efficiencies are a wet scrubber replacement (95%), wet scrubber modification (95%) and spray dryer (90%). GRE estimated the effects on visibility due to SO_2 reductions (GRE BART Analysis, pages 47-51). Although these estimates were based on 94% SO_2 control for the wet scrubber modification, GRE subsequently agreed to 95% control for that option.

Step 6: Select BART

While the cost effectiveness is reasonable for all technologies evaluated except dry sorbent injection, the incremental cost associated with wet scrubber replacement is excessive.

There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The units have existing wet scrubbers for removing sulfur dioxide and the plant is expected to have a remaining useful life of at least 20 years. With identical levels of SO_2 control, wet scrubber replacement involves additional cost with no improvement in visibility at any Class I area when compared to wet scrubber modification.

The Department proposes that BART is scrubbing 100% of the flue gas stream, the use of wet scrubber modifications to achieve a minimum control efficiency of 95% (30-day rolling average) on the inlet sulfur dioxide concentration to the scrubber or 0.15 lb/10^6 Btu (30-day rolling average). Unit 1 and Unit 2 emissions may be averaged provided the average does not exceed the limit.

B. Filterable Particulate Matter

Step 1: Identify All Available Technologies

Multiclone
Replacement Dry Electrostatic Precipitator (ESP)
Polishing Wet ESP
Baghouse

Step 2: Eliminate Technically Infeasible Options

The multiclone is considered technically infeasible because it has not been successfully demonstrated at a similar plant. All remaining technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Alternative	**Control Efficiency**	**Emissions**	
		(tons/yr)	**(lb/10^6 Btu)***
Replacement Dry ESP	99.75	388	0.015
Polishing Wet ESP	99.75	388	0.015
Baghouse	99.75	388	0.015
Baseline (Existing ESP)	99.50	775	0.030

* Based on potential-to-emit (see page 15-16 of GRE's analysis).

Step 4: Evaluate Impacts and Document Results

Costs of Compliance: Based on historic baseline emissions, the cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction* (tpy)**	**Annualized Cost** ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost*** ($/ton)**
Replacement Dry ESP	387	10,060,000	25,995	N/A
Polishing Wet ESP	387	1,920,000	4,961	N/A
Baghouse	387	7,670,000	19,819	N/A
Baseline (Existing ESP)	0	0	---	---

* Reductions from the baseline emission rate
** Costs provided by GRE
*** As compared to the baseline
N/A Not applicable since the all alternatives are equally efficient

Energy and Non-air Quality Effects: GRE has evaluated the energy and non-air quality effects of each option. The Department has determined that the information presented by GRE concerning these effects does not appear to preclude the selection of any of the alternatives above.

Step 5: Evaluate Visibility Impacts

The reduction in PM_{10} emissions that could be expected to be realized by implementing any of the three alternatives would produce a visibility improvement of less than 0.027 Δ-dV (98th percentile), a negligible improvement for the additional cost required.

Energy and Non-air Quality Effects: There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options.

Step 6: Select BART

The units have an existing dry ESP for removing filterable particulate matter and the plant is expected to have a remaining useful life of at least 20 years. Pre-BART modeling showed that PM from Units 1 and 2 contribute negligibly to visibility impairment as compared to sulfates and nitrates. The alternative (excluding the baseline alternative) with the least cost for reducing filterable particulate emissions is the polishing wet ESP. This system has a cost effectiveness of $4,961 per ton of particulate when compared to the current emission control system (ESP operating at 99.5% efficiency). Considering the negligible improvement in visibility that would be achieved by adding a polishing wet ESP, the Department considers this cost, as well as the costs of the more expensive options, to be excessive.

After considering all of the factors, the Department proposes that BART for filterable particulate matter is no additional controls. Current actual emissions are less than the current allowable emissions, and combusting dried lignite can be expected to further reduce particulate emissions. Based on past actual emissions and allowing for an additional margin of safety to provide a reasonable possibility for compliance, the Department proposes that BART is represented by an emission limit of 0.07 lb/10^6 Btu (average of 3 test runs).

C. Condensible Particulate Matter (PM_{10})

Condensible particulate matter is made up of both organic and inorganic substances. Organic condensible particulate matter will be made up of organic substances, such as volatile organic compounds, which are in a gaseous state through the air pollution control devices but will eventually turn to a solid or liquid state. The primary inorganic substance expected from the boiler is sulfuric acid mist, with lesser amounts of hydrogen fluoride and ammonium sulfate.

Since sulfuric acid mist is the largest component of condensible particulate matter, controlling it will control most of the condensible particulate matter. The options for controlling sulfuric acid mist are the same options for controlling sulfur dioxide (see Section III.A.). Previously, BART for sulfur dioxide was determined to be represented by the use of wet scrubber modifications to achieve a minimum SO_2 control efficiency of 95% and 100% of the flue gas stream. These changes are expected to reduce sulfuric acid mist emissions by approximately 90%. Changes that would provide additional reductions are economically infeasible considering the minimal improvement in visibility that could be achieved.

The control of volatile organic compounds at power plants is generally achieved through good combustion practices. The Department is not aware of any BACT determination at a power plant that resulted in any control technology being used. BACT has been found to be good combustion practices which are already in use since it minimizes the amount of fuel to generate electricity.

Both GRE and AP-42, Compilation of Air Pollutant Emission Factors[2], indicate the emission rate of condensible particulate matter could be expected to be 0.02 lb/10^6 Btu. This emission rate is less than the current emissions of filterable particulate matter and the emissions of filterable particulate matter were determined to have a negligible impact on visibility.

Having considered all the factors, the Department has determined that BART for condensible particulate matter is represented by good sulfur dioxide control and good combustion control. Since the primary constituent of condensible particulate matter is sulfuric acid mist which is controlled proportionately to the sulfur dioxide controlled, the BART limit for sulfur dioxide can act as a surrogate for condensible particulate matter along with a requirement for good combustion practices.

D. Nitrogen Oxides (NO_x)

Step 1: Identify All Available Technologies

External Flue Gas Recirculation
Selective Catalytic Reduction (SCR) High Dust
Electro-Catalytic Oxidation
Pahlman Process
SCR Low Dust
Low Temperature Oxidation (LTO), either Tri-No_x® or LoTOx
Selective Non-Catalytic Reduction (SNCR), No_xOut®
Modified and Additional Separated Overfire Air (SOFA)
Low NO_x Burners (LNB)

Step 2: Eliminate Technically Infeasible Options

Great River Energy has included a cost estimate for low-dust SCR, while high-dust SCR is listed as technically infeasible by GRE. The Department believes that low dust or tail end SCR has a good probability of successful application at Coal Creek and high dust SCR is technically infeasible (see discussion in Appendix B.5).

External Flue Gas Recirculation is technically infeasible due to limited space for ductwork and reduced flame temperature.

Electro-Catalytic Oxidation and the Pahlman Process considered technically infeasible because they are still in development and testing and have not been demonstrated to be commercially available. The remaining technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Remaining Control Technologies

Based on the historic baseline emissions, the Department's estimated emissions using the various technologies are as follows:

Alternative	**Control* Efficiency (%)**	**Controlled Emissions****	
		(tons/yr)	**lb/10^6 Btu)**
LTO	90	536	0.022
SCR Low Dust	80	1,071	0.043
SNCR	50	2,679	0.108
SOFA/LNB Opt 1	30	3,750	0.15
SOFA/LNB Opt 2	21	4,232	0.17
Baseline	0	5,357	0.22

* Control efficiency provided in GRE's analysis.
** Calculated from the historic baseline (2003-2004). The emission rate is an annual average rate.

Step 4: Evaluate Impacts and Document Results

Costs of Compliance: Based on historic baseline emissions, the cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction (tpy)**	**Annualized Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
LTO	4,821	58,070,000	12,045	3,589*
SCR Low Dust	4,286	56,150,000	13,101	20,678**
SNCR	2,678	22,900,000	8,551	20,766***
SOFA/LNB Opt 1	1,607	660,000	411	664****
SOFA/LNB Opt 2	1,125	340,000	302	---

* LTO compared to SCR Low Dust
** SCR Low Dust compared to SNCR
*** SNCR compared to SOFA/LNB Opt 1
**** SOFA/LNB Opt 1 compared to SOFA/LNB Opt 2

Note: SCR and SNCR estimates above include the costs associated with lost ash sales and increased landfilling requirements due to ammonia slip rendering the ash ineligible for beneficial use. Although they were included in the GRE analysis and the table above, if the sunk costs for the ash sales infrastructure are appropriately disregarded, then the annualized cost for SNCR would be $21,750,000, the cost effectiveness would be $8,122 per ton, and the incremental cost would be $19,692 per ton.

NDDAQ was unable to determine that SNCR and its associated use of ammonia will not negatively impact GRE's ash sales; in fact, there is evidence to the contrary. GRE emails dated 8/8/08 and 8/17/08 provide additional information on this issue, as does a summary of a University of Kentucky study on the matter. Furthermore, in a BART and PSD analysis for the Omaha Public Power District Nebraska City Station Unit #1 coal boiler (Construction Permit Number CP07-0049, 2/26/09 fact sheet, pg. 14), Nebraska DEQ determined SCR was not BART in part because . . ."ammonia used in the system would cause the ash to be contaminated, thereby jeopardizing the current beneficial reuse of a portion of the ash produced by NCS Unit 1."

After considering all the information available, NDDH reached the following conclusions.

- SCR and SNCR use at Coal Creek Station will likely result in ammonia in the fly ash.
- The level of ammonia in the fly ash cannot be predicted with a reasonable certainty.
- The maximum level of ammonia in fly ash that would still avoid negative impacts on the salability of the ash cannot be predicted. Levels as low as 100 ppm have made the fly ash unfit for use in concrete.[4]

The NDDH believes there is reasonable possibility that SCR or SNCR will result in a level of ammonia in the ash that could reduce or eliminate future ash sales. Lost ash sales will inflict a significant financial penalty on GRE and send ash to a landfill instead of it being used beneficially. If this ash is regulated as a hazardous waste, the financial burden will be even greater.

Energy and environmental impacts associated with the alternatives being considered include additional energy consumption (LTO, SCR), additional wastewater (LTO), ammonia slip (SCR, SNCR), potential to require ash to be landfilled (SNCR). The Department encourages the beneficial use of fly ash for making concrete. Ammonia slip associated with SNCR and SCR would preclude this beneficial use.

Step 5: Evaluate Visibility Impacts

The Department considers the incremental cost effectiveness of LTO, SCR Low Dust and SNCR to be excessive. GRE estimated the effects on visibility due to NO_x reductions (GRE BART Analysis, pages 47-51).

The following tables show the visibility impacts of the SOFA/LNB Options 1 and 2, and SNCR.

Coal Creek Station Unit 1 or 2 Delta Deciview 90th Percentile – NO_x

Step 6: Select BART

The units have existing low NO_x burners and SOFA for removing nitrogen oxides and the plant is expected to have a remaining useful life of at least 20 years. The Department considers the incremental cost of the top three options to be excessive. If fly ash sales are not lost due to the use of SNCR, the cost for this alternative is not considered excessive. However, the maximum improvement in visibility for SNCR versus SOFA/LNB Option 1 is 0.105 deciviews based on the 98th percentile (0.027 deciviews based on the 90th percentile). The Department has found that the single source BART modeling overpredicts the amount of visibility improvement by a factor of 5-7 (see Section 7.4.2 of SIP). The Department considers the amount of visibility improvement from the use of SCNR versus SOFA/LNB Option 1 to be inconsequential. Because of the potential for lost sales of fly ash, the negative environmental effects of having to dispose of the fly ash instead of recycling it into concrete, and the very small amount of visibility improvement from the use of SNCR, this option is rejected as BART. The Department proposes that BART is represented by modified and additional SOFA plus LNB (Option 1). GRE has indicated the feasibility of, and the manufacturer has guaranteed, an emission limit of 0.15 $lb/10^6$ Btu on an annual average basis. An achievable thirty-day rolling average emission rate is expected to be slightly higher at 0.17 $lb/10^6$ Btu. The Department proposes that BART is 0.17 $lb/10^6$ Btu on a 30-day rolling average basis. Unit 1 and Unit 2 emissions may be averaged provided the average does not exceed the limit.

IV. BART Evaluation for Auxiliary Boilers No. 91 and No. 92

Auxiliary boilers No. 91 and No. 92 are distillate and residual oil-fired boilers with a nominal rating of 172 x 10^6 Btu/hr. The auxiliary boilers are only used when both units at the Coal Creek Station are down. During the baseline period (2000-2004), the auxiliary boilers were operated an average of 11.2 hours per unit per year. The annual average emissions per unit for this period were:

NO_x	0.09 tons
SO_2	0.19 tons
PM	0.08 tons

Based on the small quantity of emissions, it is apparent that no add-on control equipment will be cost effective. Any reduction in emissions will have a virtually no effect on visibility impairment. Therefore, the Department proposes that BART is no additional controls and the currently permitted fuel limitation of distillate oil, residual oil or any combination of the two.

V. BART Evaluation of Emergency Generator

The emergency generator is driven by a 3,500 horsepower diesel engine. The generator is used for emergency purposes only and most of the emissions generated are due to testing and maintenance activities. During the baseline period (2000-2004), the engine operated an average of 94.9 hours per year and the average annual emissions were:

PM	0.07 tons
NO_x	2.87 tons
SO_2	0.31 tons

Based on the small quantity of emissions, it is apparent that no add-on control equipment will be cost effective. Any reduction in emissions will have a virtually no effect on visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VI. BART Evaluation for Emergency Fire Pump

The emergency fire pump is driven by a 200 horsepower diesel engine. The pump is used for emergency purposes only and most of the emissions generated are due to testing and maintenance activities. During the baseline period (2000-2004), the engine operated an average of 14.0 hours per year and the actual annual emissions were:

PM	0.01 tons
NO_x	0.11 tons
SO_2	0.01 tons

Based on the small quantity of emissions, no add-on control equipment will be cost effective. Any reduction of emissions will not affect visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VII. BART Evaluation for Materials Handling Sources

The materials handling sources at Coal Creek Station that emit to the atmosphere are as follows:

EU – Description	Existing Control Equipment	Current PM Emission Limit (lb/hr)	Baseline PM Emissions (tons/yr)
EU 7 - Lignite transfer house	Bagfilter	3	0.07
EU 8 - Lignite emergency reclaim system	Bagfilter	3	0.00
EU 9 - Lignite yard storage silos	Bagfilter	3	0.03
EU 10 - Lignite yard storage silos	Bagfilter	3	0.03
EU 11 - Crusher building	Bagfilter	3	0.07
EU 12 - Generation building coal hopper	Bagfilter	3	0.07
EU 13 - Falkirk mining Company mine silo base	Bagfilter	3	0.07

EU – Description	**Existing Control Equipment**	**Current PM Emission Limit (lb/hr)**	**Baseline PM Emissions (tons/yr)**
EU 14 - Generation building coal hopper	Bagfilter	3	0.02
EU 15 - Generation building coal hopper	Bagfilter	3	0.02
EU 16 - Generation building coal hopper	Bagfilter	3	0.02
EU 17 - Generation building coal hopper	Bagfilter	3	0.02
EU 19 - Scrubber building flyash silo	Bagfilter	3	0.02
EU 20 - Truck air slide flyash silo	Bagfilter	3	0.05
EU 21 - Truck air slide flyash silo	Bagfilter	3	0.05
EU 22 - Water treatment building	Bagfilter	3	0.03
EU 23 - Scrubber building lime handling system	Bagfilter	3	0.02
EU 24 - Scrubber building lime handling system	Bagfilter	3	0.02
EU 25 - Flyash railroad marketing silo	Bagfilter	3	0.05
EU 26 - Flyash dome	Bagfilter	0.4 (EP 26a-26b), 0.09 (EP 26e)	0.02
EU 27 - Coal Dryer	Bagfilter	3.1	0.3*
FS 1 - Cooling towers No. 91, No. 92, and No. 93	Fugitive	--	0.02
FS 2 - Boombelt conveyor (stackout)	Fugitive	--	0.02
FS 3 - Conveyor 909 (stackout)	Fugitive	--	0.04
FS 4 - Scrubber building flyash silo (stackout)	Fugitive	--	0.04
FS 5 - Coal pile maintenance	Fugitive	--	3.77

* Department estimate based on 2005 emissions

Based on the small quantity emissions from those sources (EU 7-27) that are controlled by bagfilters, which are considered the most efficient control devices, it is apparent that no additional control equipment will be cost effective. Materials handling units (FS 1-5) are uncontrolled sources of fugitive emissions. Based on the small quantity of emissions from those sources, it is apparent that no additional control equipment will be cost effective. Any additional controls would have a neglible effect on visibility impairment. Therefore, the Department proposes that BART for the materials handling units is no additional controls and the current emission limits for the units is BART.

VIII. Summary

Source Unit	**Proposed BART Limit/Work Practice**				**Emissions Reduction (tons/yr)**		
	PM	**SO_2**	**NO_x**	**Units**	**PM**	**SO_2**	**NO_x**
Unit 1 Boiler	0.07	0.15 (30-dra) or 94% reduction	0.17 (30-dra)	$lb/10^6$ Btu	0	19,990*	1,607
Unit 2 Boiler	0.07	0.15 (30-dra) or 94% reduction	0.17 (30-dra)	$lb/10^6$ Btu	0	19,990*	1,607
Auxiliary Boiler No. 91	Continue current practices			N/A	0	0	0
Auxiliary Boiler No. 92	Continue current practices			N/A	0	0	0
Emerg. Gen.	Continue current practices			N/A	0	0	0
Fire Pump	Continue current practices			N/A	0	0	0
Material Handling EU 7-25	3	---	---	lb/hr	0	---	---
Flyash Dome EU 26	0.4 (EP 26a-26b), 0.09 (EP 26e)	---	---	lb/hr	0	---	---

Source Unit	Proposed BART Limit/Work Practice				Emissions Reduction (tons/yr)		
	PM	SO_2	NO_x	Units	PM	SO_2	NO_x
Coal Dryer EU 27	3.1	---	---	---	0	---	---
Fugitive FS 1-5	---	---	---	---	0	---	---
Total:						39,980*	3,214

* Reductions from 2000-2004 average emission rate adjusted for future fuel (dried lignite).

IX. Permit to Construct

The emission limits, monitoring, recordkeeping and reporting requirements will be included in a federally enforceable Air Pollution Control Permit to Construct that will be issued to the owner/operator of the facility. The Permit to Construct is included in Appendix D.

A. Monitoring

1. Monitoring for SO_2 and NO_x will be accomplished using the continuous emission monitors required by 40 CFR 75 for the Acid Rain Program. Monitoring for particulate matter shall be in accordance with 40 CFR 64, Compliance Assurance Monitoring. If the owner/operator of the BART-eligible unit chooses to comply with the SO_2 percent reduction requirements, monitoring of the SO_2 inlet rate loading to the scrubber shall be accomplished by either:

    a. A continuous emission monitor that complies with the requirements of 40 CFR 75; or

    b. Coal sampling in accordance with Method 19 of 40 CFR 60, Appendix A plus development of an emission factor based on actual stack testing.

2. For purposes of determining compliance with the SO_2 reduction requirement, the reduction efficiency shall be determined as follows:

$$\% \text{ Reduction} = \frac{\text{Inlet } SO_2 \text{ Rate} - \text{Outlet } SO_2 \text{ Rate}}{\text{Inlet } SO_2 \text{ Rate}} \times 100$$

Where:

Inlet SO_2 Rate is in units of lb/10^6 Btu, lb/hr or ppmvd @ 3% O_2.

Outlet SO_2 Rate is in the same units as the inlet SO_2 rate.

3. The owner/operator will be allowed to average emissions (bubble) for SO_2 and/or NO_x for the two units using the following formulas:

$$\text{Average AER} = \frac{[(AER_1)(HI_1)+(AER_2)(HI_2)]}{(HI_1 + HI_2)}$$

$$\text{Average ER} = \frac{[(ER_1)(HI_1)+(ER_2)(HI_2)]}{(HI_1 + HI_2)}$$

Where:

AER = Allowable Emission Rate (lb/MMBtu or % Reduction)
ER_1 = Actual Emission Rate (lb/MMBtu or % Reduction) of Unit 1
ER_2 = Actual Emission Rate (lb/MMBtu or % Reduction) of Unit 2
HI_1 = Actual Heat Input (MMBtu) of Unit 1
HI_2 = Actual Heat Input (MMBtu) of Unit 2

Notes: ER is a 30-day rolling average.
HI is a 30-day rolling average.
30-day rolling average is determined in accordance with 40 CFR 60, Subpart Da, for the 30 successive boiler operating days (must be on a consistent basis of lb/MMBtu or % reduction).

B. Recordkeeping and Reporting

The owner/operator will be required to conduct recordkeeping and reporting as required by NDAC 33-15-14-06, Title V Permit to Operate and NDAC 33-15-21, Acid Rain Program (40 CFR 72, 75 and 76).

BART Determination
For
Coal Creek Station Units 1 and 2

2/10/10

I. Source Description

A. Owner/Operator: Great River Energy (GRE)

B. Source Type: Fossil-fuel fired steam electric plant of more than 250 million British thermal units (Btu) per hour heat input and having a total generating capacity in excess of 750 megawatts.

C. BART Eligible Units

1. EU 1 - Unit 1 boiler
2. EU 2 - Unit 2 boiler
3. EU 3 - Auxiliary boiler No. 91
4. EU 4 - Auxiliary boiler No. 92
5. EU 5 - Emergency generator
6. EU 6 - Fire pump engine
7. EU 7 through EU 26 material handling units, including coal and lime handling operations and flyash silos
    a. EU 7 - Lignite transfer house
    b. EU 8 - Lignite emergency reclaim system
    c. EU 9 - Lignite yard storage silos
    d. EU 10 - Lignite yard storage silos
    e. EU 11 - Crusher building (Two 1,500 ton per hour crushers)
    f. EU 12 - Generation building coal hopper
    g. EU 13 - Falkirk Mining Company mine silo base

h. EU 14 - Generation building coal hopper

i. EU 15 - Generation building coal hopper

j. EU 16 - Generation building coal hopper

k. EU 17 - Generation building coal hopper

l. EU 19 - Scrubber building flyash silo

m. EU 20 - Truck air slide flyash silo

n. EU 21 - Truck air slide flyash silo

o. EU 22 - Water treatment building

p. EU 23 - Scrubber building lime handling system

q. EU 24 - Scrubber building lime handling system

r. EU 25 - Flyash railroad marketing silo

s. EU 26 - Flyash dome

8. FS 1 through FS 5 - Fugitive sources

a. FS 1 - Cooling Towers No. 91, No. 92, and No. 93

b. FS 2 - Boombelt conveyor (stackout)

c. FS 3 - Conveyor 909 (stackout)

d. FS 4 - Scrubber building flyash silo (stackout)

e. FS 5 - Coal pile maintenance

D. Unit Description

1. EU 1 - Unit 1 boiler:

Generator Nameplate Capacity: 550 MWe

Boiler Rating: 6,015 x 10^6 Btu/hour

Startup: 1979

Fuel: North Dakota lignite

Firing Method: Tangential-fired pulverized coal (PC) unit

Existing Air Pollution Equipment:

Electrostatic precipitator (ESP)
Low NO_x burners (LNB) and separated over fire air (SOFA)
Wet scrubber

2. EU 2 - Unit 2 boiler

   Generator Nameplate Capacity: 550 MWe

   Boiler Rating: 6,022 x 10^6 Btu/hour

   Startup: 1980

   Fuel: North Dakota lignite

   Firing method: Tangential-fired pulverized coal (PC) unit

   Existing Air Pollution Equipment:

   Electrostatic precipitator (ESP)
   Low NO_x burners (LNB) and separated over fire air (SOFA)
   Wet scrubber

3. EU 3 - Auxiliary boiler No. 91

   Boiler rating: 172 x 10^6 Btu/hour

   Fuel: Residual oil, distillate fuel oils, or any combination of these fuels

   Existing air pollution equipment: None

4. EU 4 - Auxiliary boiler No. 92

   Boiler rating: 172 x 10^6 Btu/hour

   Fuel: Residual oil, distillate fuel oils, or any combination of these fuels

   Existing air pollution equipment: None

5. EU 5 - Emergency generator

Rating: 3,500 bhp

Fuel: No. 2 fuel oil or a blend of No. 1 and No. 2 fuel oil

Existing air pollution equipment: None

6. EU 6 - Fire pump engine

   Rating: 200 bhp

   Fuel: No. 2 fuel oil or a blend of No. 1 and No. 2 fuel oil

   Existing air pollution equipment: None

7. EU 7 through EU 26 - Material handling units, including lime handling operations and flyash silos

   Existing air pollution equipment: Fabric filters/bag houses

8. FS 1 through FS 5 - Fugitive sources

   Existing air pollution equipment: None - fugitive emissions

II. Site Characteristics

The Coal Creek Station is a two-unit, 1,100 gross megawatt (MW) mine-to-mouth power plant consisting primarily of two steam generators and associated coal and ash handling systems. Unit 1 and Unit 2 are identical Combustion Engineering boilers firing pulverized lignite coal tangentially from a maximum of 64 firing points each. Unit 1 has a heat input capacity of 6,015 x 10^6 Btu/hr; Unit 2 is rated at 6,022 x 10^6 Btu/hr. Particulate matter from each boiler is controlled by a 99.5% efficient electrostatic precipitator (ESP) consisting of 48 transformer rectifier (TR) sets. A four-module flue gas desulfurization (FGD) system for each boiler removes approximately 90% of the sulfur dioxide from 60% of the flue gas. Each boiler is served by a 655 foot high stack.

Unit 1 began commercial operation in 1979 and Unit 2 in 1980. The facility is located in south central McLean County about five miles south of the town of Underwood, North Dakota and three miles west of US Highway 83. Coal Creek Station receives its lignite from the Falkirk Mine that is operated by the Falkirk Mining Company, a subsidiary of the North American Coal Corporation. Approximately 8,130,000 tons of lignite coal and approximately 165,000 gallons of oil were combusted in 2006.

III. BART Evaluation of Unit 1 and Unit 2

The BART guidelines apply to Units 1 and 2 because they are part of a fossil-fuel steam electric plant with a total generating capacity in excess of 750 megawatts, they are rated at more than 250 million Btu per hour heat input, and they have potential emissions of 250 tons or more per year of a visibility-impairing pollutant, specifically SO_2, NO_x and PM_{10}.

Since Units 1 and 2 are identical, the following evaluation will use values derived by averaging the historical data for each unit and then make a single BART determination that will be applicable to each unit.

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

Coal Cleaning/Washing
K-Fuel[7]
TurboSorp[7]
Coal Drying
Dry Sorbent Injection
Spray Dryer

Wet Scrubber Modification
Wet Scrubber Replacement

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning/Washing: Coal cleaning and coal washing have never been used commercially on North Dakota lignite. Coal washing can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that have required coal cleaning.

K-Fuel^7 is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Evergreen=s website indicates that it has idled its Wyoming plant and directed its capital and management resources to supporting a new design. Although Evergreen Energy, Inc. indicates the technology has been tested on lignite, there is no indication that lignite from the Falkirk Mine was tested. The use of the K-Fuel^7 process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Therefore, the Department does not consider coal cleaning or the K-Fuel^7 and will be submitted to this Department at the end of the approved burn period process available or technically and economically feasible.

TurboSorp^7: Although the GRE analysis concluded otherwise, the Department considers TurboSorp^7 dry flue gas desulfurization technology to be technically feasible because it employs the proven technology of circulating dry scrubbers. Additional information on this technology is found at:
http://www.eucetsa.net/eucetsa/webPages.do?pageID=200913.

Coal Drying: Coal drying of lignite has been demonstrated to be technically feasible through pilot projects at this facility. Furthermore, dried lignite is the primary fuel for another ND facility, the GRE Spiritwood Station, that received a permit to construct September 14, 2007.

In addition to coal drying, the remaining control technologies, dry sorbent injection, spray dryer, and wet scrubber (modification or replacement), are considered to be technically feasible. GRE has elected to install coal drying equipment independent of the SO_2 control chosen.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Baseline SO_2 Emissions Controlled (past): Based on average actual controlled annual emissions when combusting lignite (undried) for a 24 month period (2003-2004) with 27% bypass: (13,817 [Unit 1, 2003] + 13,547 [Unit 2, 2003] + 15,742 [Unit 1, 2004] + 11,469 [Unit 2, 2004])/4 = 13,644 ton/yr average baseline controlled SO_2 emissions with 27% bypass and undried coal.

Applying the 68% overall control efficiency of the existing scrubber yields: [(13,644 ton/yr)/(1-0.68)] = 42,638 ton/yr uncontrolled baseline SO_2 emissions.

The 42,638 ton/yr uncontrolled baseline SO_2 emissions are based on past undried coal with an average 2003-2004 sulfur content of 0.61%. The evaluation of alternative SO_2 cleaning equipment will be based on future undried coal with an expected worst case (98 percentile) sulfur content of 1.10%, as predicted for Falkirk coal and provided by GRE. Therefore, the uncontrolled baseline SO_2 emissions above must be adjusted to the future sulfur content so that an apples to apples comparison will correctly determine emission reductions expected to result from employing the alternative equipment. The 42,638 ton/yr uncontrolled baseline SO_2 emissions is adjusted as follows: (42,638 ton/yr)(1.1%/0.61%) = 76,888 ton/yr uncontrolled baseline SO_2 emissions for undried coal with future sulfur content.

For the purposes of this analysis, the adjustment to future coal was considered necessary only for SO_2 and the related condensible particulate matter and sulfuric acid mist emissions due to the increased sulfur content expected in future coal. For all other pollutants, this analysis does not adjust to future coal due to the negligible impact on emissions. No adjustment to the baseline was made for coal drying because the Permit to Construct is not expected to require dried lignite or limit moisture content.

Note: TurboSorp[7] is a registered trademark for Babcock Power Environmental=s circulating dry scrubber. The Department considers circulating dry scrubbers to be technically feasible. Circulating dry scrubbers will generally achieve SO_2 removal efficiencies similar to spray dryer absorbers but less than wet scrubbers. Other BART analyses projected a removal efficiency of 93% with higher costs than a new wet scrubber. Since a circulating dry scrubber will have a lower removal efficiency than a wet scrubber or upgrades to the existing wet scrubber (95% and 94%, respectively) and will cost more than a new wet scrubber or upgrades to the existing wet scrubber, a circulating dry scrubber is an inferior option and is not considered further.

Future Case

Alternative	**Control Efficiency (%)**	**Baseline Uncontrolled Emissions (tons/yr)***	**Controlled Emissions***	
			(tons/yr)	**(lb/10^6 Btu)****
Wet Scrubber Replacement***	95	76,888	3,844	0.146
Wet Scrubber Modification***	95	76,888	3,844	0.146
Spray Dryer***	90	76,888	7,689	0.292
Existing Scrubber & 0% Bypass	83.1	76,888	12,994	0.493
Dry Sorbent Injection***	70	76,888	23,066	0.875
Existing Scrubber & 27% Bypass	68****	76,888	24,604*****	--

*	Future lignite at 1.10% (GRE-predicted worst-case sulfur content for Falkirk Mine lignite. As a result, Department baseline future emission estimates are somewhat higher than GRE=s estimates)
**	Annual
***	0% bypass
****	Current control rate
*****	Current controlled emissions = 76,888(1-0.68) = 24,604 tpy

Step 4: Evaluate Impacts and Document Results

Costs of Compliance: Based on the past emissions adjusted for the sulfur content of future coal, the cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($)***	**Cost Effectiveness($/ton)**	**Incremental Cost ($/ton)**
Wet Scrubber Replacement	20,760	30,760,000	1,482	24,987
Wet Scrubber Modification	20,760	11,520,000	555	--
Spray Dryer**	16,915	29,220,000	1,727	--
Existing Scrubber 0% Bypass	11,610	9,840,000	848	N/A
Dry Sorbent Injection**	1,538	12,520,000	8,140	N/A

*	Costs provided by GRE
**	Inferior option to wet scrubber modifications
N/A	Not applicable since the cost effectiveness of the less efficient alternative is more than the more efficient alternative

The incremental cost associated with wet scrubber replacement ($24,987/ton) as compared to wet scrubber modification represents an excessively high cost relative to the emission reduction obtained.

Energy and Non-air Quality Effects: GRE has evaluated the energy and non-air quality effects of each option. Although the Department has determined that the information presented by GRE concerning these effects does not appear to preclude the selection of any of the five alternatives above, the possible economic impacts due to extensive process downtime associated with scrubber replacement and dry sorbent injection may be significant negative factors for their selection.

Step 5: Evaluate Visibility Results

The three primary alternatives and associated removal efficiencies are a wet scrubber replacement (95%), wet scrubber modification (95%) and spray dryer (90%). GRE estimated the effects on visibility due to SO_2 reductions (GRE BART Analysis, pages 47-51). Although these estimates were based on 94% SO_2 control for the wet scrubber modification, GRE subsequently agreed to 95% control for that option.

Step 6: Select BART

While the cost effectiveness is reasonable for all technologies evaluated except dry sorbent injection, the incremental cost associated with wet scrubber replacement is excessive.

There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The units have existing wet scrubbers for removing sulfur dioxide and the plant is expected to have a remaining useful life of at least 20 years. With identical levels of SO_2 control, wet scrubber replacement involves additional cost with no improvement in visibility at any Class I area when compared to wet scrubber modification.

The Department proposes that BART is scrubbing 100% of the flue gas stream, the use of wet scrubber modifications to achieve a minimum control efficiency of 95% (30-day rolling average) on the inlet sulfur dioxide concentration to the scrubber or 0.15 lb/10^6 Btu (30-day rolling average). Unit 1 and Unit 2 emissions may be averaged provided the average does not exceed the limit.

B. Filterable Particulate Matter

Step 1: Identify All Available Technologies

Multiclone
Replacement Dry Electrostatic Precipitator (ESP)
Polishing Wet ESP
Baghouse

Step 2: Eliminate Technically Infeasible Options

The multiclone is considered technically infeasible because it has not been successfully demonstrated at a similar plant. All remaining technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Alternative	**Control Efficiency**	**Emissions**	
		(tons/yr)	**(lb/10^6 Btu)***
Replacement Dry ESP	99.75	388	0.015
Polishing Wet ESP	99.75	388	0.015
Baghouse	99.75	388	0.015
Baseline (Existing ESP)	99.50	775	0.030

* Based on potential-to-emit (see page 15-16 of GRE's analysis).

Step 4: Evaluate Impacts and Document Results

Costs of Compliance: Based on historic baseline emissions, the cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction* (tpy)**	**Annualized Cost** ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost*** ($/ton)**
Replacement Dry ESP	387	10,060,000	25,995	N/A
Polishing Wet ESP	387	1,920,000	4,961	N/A
Baghouse	387	7,670,000	19,819	N/A
Baseline (Existing ESP)	0	0	---	---

* Reductions from the baseline emission rate
** Costs provided by GRE
*** As compared to the baseline
N/A Not applicable since the all alternatives are equally efficient

Energy and Non-air Quality Effects: GRE has evaluated the energy and non-air quality effects of each option. The Department has determined that the information presented by GRE concerning these effects does not appear to preclude the selection of any of the alternatives above.

Step 5: Evaluate Visibility Impacts

The reduction in PM_{10} emissions that could be expected to be realized by implementing any of the three alternatives would produce a visibility improvement of less than 0.027 Δ-dV (98th percentile), a negligible improvement for the additional cost required.

Energy and Non-air Quality Effects: There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options.

Step 6: Select BART

The units have an existing dry ESP for removing filterable particulate matter and the plant is expected to have a remaining useful life of at least 20 years. Pre-BART modeling showed that PM from Units 1 and 2 contribute negligibly to visibility impairment as compared to sulfates and nitrates. The alternative (excluding the baseline alternative) with the least cost for reducing filterable particulate emissions is the polishing wet ESP. This system has a cost effectiveness of $4,961 per ton of particulate when compared to the current emission control system (ESP operating at 99.5% efficiency). Considering the negligible improvement in visibility that would be achieved by adding a polishing wet ESP, the Department considers this cost, as well as the costs of the more expensive options, to be excessive.

After considering all of the factors, the Department proposes that BART for filterable particulate matter is no additional controls. Current actual emissions are less than the current allowable emissions, and combusting dried lignite can be expected to further reduce particulate emissions. Based on past actual emissions and allowing for an additional margin of safety to provide a reasonable possibility for compliance, the Department proposes that BART is represented by an emission limit of 0.07 lb/10^6 Btu (average of 3 test runs).

C. Condensible Particulate Matter (PM_{10})

Condensible particulate matter is made up of both organic and inorganic substances. Organic condensible particulate matter will be made up of organic substances, such as volatile organic compounds, which are in a gaseous state through the air pollution control devices but will eventually turn to a solid or liquid state. The primary inorganic substance expected from the boiler is sulfuric acid mist, with lesser amounts of hydrogen fluoride and ammonium sulfate.

Since sulfuric acid mist is the largest component of condensible particulate matter, controlling it will control most of the condensible particulate matter. The options for controlling sulfuric acid mist are the same options for controlling sulfur dioxide (see Section III.A.). Previously, BART for sulfur dioxide was determined to be represented by the use of wet scrubber modifications to achieve a minimum SO_2 control efficiency of 95% and 100% of the flue gas stream. These changes are expected to reduce sulfuric acid mist emissions by approximately 90%. Changes that would provide additional reductions are economically infeasible considering the minimal improvement in visibility that could be achieved.

The control of volatile organic compounds at power plants is generally achieved through good combustion practices. The Department is not aware of any BACT determination at a power plant that resulted in any control technology being used. BACT has been found to be good combustion practices which are already in use since it minimizes the amount of fuel to generate electricity.

Both GRE and AP-42, Compilation of Air Pollutant Emission Factors[2], indicate the emission rate of condensible particulate matter could be expected to be 0.02 lb/10^6 Btu. This emission rate is less than the current emissions of filterable particulate matter and the emissions of filterable particulate matter were determined to have a negligible impact on visibility.

Having considered all the factors, the Department has determined that BART for condensible particulate matter is represented by good sulfur dioxide control and good combustion control. Since the primary constituent of condensible particulate matter is sulfuric acid mist which is controlled proportionately to the sulfur dioxide controlled, the BART limit for sulfur dioxide can act as a surrogate for condensible particulate matter along with a requirement for good combustion practices.

D. Nitrogen Oxides (NO_x)

Step 1: Identify All Available Technologies

External Flue Gas Recirculation
Selective Catalytic Reduction (SCR) High Dust
Electro-Catalytic Oxidation
Pahlman Process
SCR Low Dust
Low Temperature Oxidation (LTO), either Tri-No_x[7] or LoTOx
Selective Non-Catalytic Reduction (SNCR), No_xOut[7]
Modified and Additional Separated Overfire Air (SOFA)
Low NO_x Burners (LNB)

Step 2: Eliminate Technically Infeasible Options

Great River Energy has included a cost estimate for low-dust SCR, while high-dust SCR is listed as technically infeasible by GRE. The Department believes that low dust or tail end SCR has a good probability of successful application at Coal Creek and high dust SCR is technically infeasible (see discussion in Appendix B.5).

External Flue Gas Recirculation is technically infeasible due to limited space for ductwork and reduced flame temperature.

Electro-Catalytic Oxidation and the Pahlman Process considered technically infeasible because they are still in development and testing and have not been demonstrated to be commercially available. The remaining technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Remaining Control Technologies

Based on the historic baseline emissions, the Department's estimated emissions using the various technologies are as follows:

Alternative	**Control* Efficiency (%)**	**Controlled Emissions****	
		(tons/yr)	**lb/10^6 Btu)**
LTO	90	536	0.022
SCR Low Dust	80	1,071	0.043
SNCR	50	2,679	0.108
SOFA/LNB Opt 1	30	3,750	0.15
SOFA/LNB Opt 2	21	4,232	0.17
Baseline	0	5,357	0.22

* Control efficiency provided in GRE's analysis.
** Calculated from the historic baseline (2003-2004). The emission rate is an annual average rate.

Step 4: Evaluate Impacts and Document Results

Costs of Compliance: Based on historic baseline emissions, the cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction (tpy)**	**Annualized Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
LTO	4,821	58,070,000	12,045	3,589*
SCR Low Dust	4,286	56,150,000	13,101	20,678**
SNCR	2,678	22,900,000	8,551	20,766***
SOFA/LNB Opt 1	1,607	660,000	411	664****
SOFA/LNB Opt 2	1,125	340,000	302	---

* LTO compared to SCR Low Dust
** SCR Low Dust compared to SNCR
*** SNCR compared to SOFA/LNB Opt 1
**** SOFA/LNB Opt 1 compared to SOFA/LNB Opt 2

Note: SCR and SNCR estimates above include the costs associated with lost ash sales and increased landfilling requirements due to ammonia slip rendering the ash ineligible for beneficial use. Although they were included in the GRE analysis and the table above, if the sunk costs for the ash sales infrastructure are appropriately disregarded, then the annualized cost for SNCR would be $21,750,000, the cost effectiveness would be $8,122 per ton, and the incremental cost would be $19,692 per ton.

NDDH was unable to determine that SNCR and its associated use of ammonia will not negatively impact GRE's ash sales; in fact, there is considerable evidence to the contrary. GRE emails dated 8/8/08, 8/17/08 and 2/9/10 provide additional information on this issue, as does a summary of a University of Kentucky study on the matter. The 2/9/10 GRE email contains testimonials from ash marketers, buyers and end product users that provide clear evidence of actual negative impact on ash sales and use when the ash is contaminated with ammonia by SCR and SNCR systems. Furthermore, in a BART and PSD analysis for the Omaha Public Power District Nebraska City Station Unit #1 coal boiler (Construction Permit Number CP07-0049, 2/26/09 fact sheet, pg. 14), Nebraska DEQ determined SCR was not BART in part because . . ."ammonia used in the system would cause the ash to be contaminated, thereby jeopardizing the current beneficial reuse of a portion of the ash produced by NCS Unit 1."

After considering all the information available, NDDH reached the following conclusions.

- SCR and SNCR use at Coal Creek Station will likely result in ammonia in the fly ash.
- The level of ammonia in the fly ash cannot be predicted with a reasonable certainty.
- The maximum level of ammonia in fly ash that would still avoid negative impacts on the salability of the ash cannot be predicted. Levels as low as 100 ppm have made the fly ash unfit for use in concrete.[4]

The NDDH believes there is reasonable possibility that SCR or SNCR will result in a level of ammonia in the ash that could reduce or eliminate future ash sales. Lost ash sales will inflict a significant financial penalty on GRE and send ash to a landfill instead of it being used beneficially. If this ash is regulated as a hazardous waste, the financial burden will be even greater.

Energy and environmental impacts associated with the alternatives being considered include additional energy consumption (LTO, SCR), additional wastewater (LTO), ammonia slip (SCR, SNCR), potential to require ash to be landfilled (SNCR). The Department encourages the beneficial use of fly ash for making concrete. Ammonia slip associated with SNCR and SCR would preclude this beneficial use.

Step 5: Evaluate Visibility Impacts

The Department considers the incremental cost effectiveness of LTO, SCR Low Dust and SNCR to be excessive. GRE estimated the effects on visibility due to NO_x reductions (GRE BART Analysis, pages 47-51).

The following tables show the visibility impacts of the SOFA/LNB Options 1 and 2, and SNCR.

Coal Creek Station Unit 1 or 2

Step 6: Select BART

The units have existing low NO_x burners and SOFA for removing nitrogen oxides and the plant is expected to have a remaining useful life of at least 20 years. The Department considers the incremental cost of the top three options to be excessive. If fly ash sales are not lost due to the use of SNCR, the cost for this alternative is not considered excessive. However, the maximum improvement in visibility for SNCR versus SOFA/LNB Option 1 is 0.105 deciviews based on the 98th percentile (0.027 deciviews based on the 90th percentile). The Department has found that the single source BART modeling overpredicts the amount of visibility improvement by a factor of 5-7 (see Section 7.4.2 of SIP). The Department considers the amount of visibility improvement from the use of SCNR versus SOFA/LNB Option 1 to be inconsequential. Because of the potential for lost sales of fly ash, the negative environmental effects of having to dispose of the fly ash instead of recycling it into concrete, and the very small amount of visibility improvement from the use of SNCR, this option is rejected as BART. The Department proposes that BART is represented by modified and additional SOFA plus LNB (Option 1). GRE has indicated the feasibility of, and the manufacturer has guaranteed, an emission limit of 0.15 lb/10^6 Btu on an annual average basis. An achievable thirty-day rolling average emission rate is expected to be slightly higher at 0.17 lb/10^6 Btu. The Department proposes that BART is 0.17 lb/10^6 Btu on a 30-day rolling average basis. Unit 1 and Unit 2 emissions may be averaged provided the average does not exceed the limit.

IV. BART Evaluation for Auxiliary Boilers No. 91 and No. 92

Auxiliary boilers No. 91 and No. 92 are distillate and residual oil-fired boilers with a nominal rating of 172 x 10^6 Btu/hr. The auxiliary boilers are only used when both units at the Coal Creek Station are down. During the baseline period (2000-2004), the auxiliary boilers were operated an average of 11.2 hours per unit per year. The annual average emissions per unit for this period were:

NO_x	0.09 tons
SO_2	0.19 tons
PM	0.08 tons

Based on the small quantity of emissions, it is apparent that no add-on control equipment will be cost effective. Any reduction in emissions will have a virtually no effect on visibility impairment. Therefore, the Department proposes that BART is no additional controls and the currently permitted fuel limitation of distillate oil, residual oil or any combination of the two.

V. BART Evaluation of Emergency Generator

The emergency generator is driven by a 3,500 horsepower diesel engine. The generator is used for emergency purposes only and most of the emissions generated are due to testing and maintenance activities. During the baseline period (2000-2004), the engine operated an average of 94.9 hours per year and the average annual emissions were:

PM	0.07 tons
NO_x	2.87 tons
SO_2	0.31 tons

Based on the small quantity of emissions, it is apparent that no add-on control equipment will be cost effective. Any reduction in emissions will have a virtually no effect on visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VI. BART Evaluation for Emergency Fire Pump

The emergency fire pump is driven by a 200 horsepower diesel engine. The pump is used for emergency purposes only and most of the emissions generated are due to testing and maintenance activities. During the baseline period (2000-2004), the engine operated an average of 14.0 hours per year and the actual annual emissions were:

PM	0.01 tons
NO_x	0.11 tons
SO_2	0.01 tons

Based on the small quantity of emissions, no add-on control equipment will be cost effective. Any reduction of emissions will not affect visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VII. BART Evaluation for Materials Handling Sources

The materials handling sources at Coal Creek Station that emit to the atmosphere are as follows:

EU – Description	Existing Control Equipment	Current PM Emission Limit (lb/hr)	Baseline PM Emissions (tons/yr)
EU 7 - Lignite transfer house	Bagfilter	3	0.07
EU 8 - Lignite emergency reclaim system	Bagfilter	3	0.00
EU 9 - Lignite yard storage silos	Bagfilter	3	0.03
EU 10 - Lignite yard storage silos	Bagfilter	3	0.03
EU 11 - Crusher building	Bagfilter	3	0.07
EU 12 - Generation building coal hopper	Bagfilter	3	0.07
EU 13 - Falkirk mining Company mine silo base	Bagfilter	3	0.07

EU – Description	Existing Control Equipment	Current PM Emission Limit (lb/hr)	Baseline PM Emissions (tons/yr)
EU 14 - Generation building coal hopper	Bagfilter	3	0.02
EU 15 - Generation building coal hopper	Bagfilter	3	0.02
EU 16 - Generation building coal hopper	Bagfilter	3	0.02
EU 17 - Generation building coal hopper	Bagfilter	3	0.02
EU 19 - Scrubber building flyash silo	Bagfilter	3	0.02
EU 20 - Truck air slide flyash silo	Bagfilter	3	0.05
EU 21 - Truck air slide flyash silo	Bagfilter	3	0.05
EU 22 - Water treatment building	Bagfilter	3	0.03
EU 23 - Scrubber building lime handling system	Bagfilter	3	0.02
EU 24 - Scrubber building lime handling system	Bagfilter	3	0.02
EU 25 - Flyash railroad marketing silo	Bagfilter	3	0.05
EU 26 - Flyash dome	Bagfilter	0.4 (EP 26a-26b), 0.09 (EP 26e)	0.02
EU 27 - Coal Dryer	Bagfilter	3.1	0.3*
FS 1 - Cooling towers No. 91, No. 92, and No. 93	Fugitive	--	0.02
FS 2 - Boombelt conveyor (stackout)	Fugitive	--	0.02
FS 3 - Conveyor 909 (stackout)	Fugitive	--	0.04
FS 4 - Scrubber building flyash silo (stackout)	Fugitive	--	0.04
FS 5 - Coal pile maintenance	Fugitive	--	3.77

* Department estimate based on 2005 emissions

Based on the small quantity emissions from those sources (EU 7-27) that are controlled by bagfilters, which are considered the most efficient control devices, it is apparent that no additional control equipment will be cost effective. Materials handling units (FS 1-5) are uncontrolled sources of fugitive emissions. Based on the small quantity of emissions from those sources, it is apparent that no additional control equipment will be cost effective. Any additional controls would have a neglible effect on visibility impairment. Therefore, the Department proposes that BART for the materials handling units is no additional controls and the current emission limits for the units is BART.

VIII. Summary

Source Unit	**Proposed BART Limit/Work Practice**				**Emissions Reduction (tons/yr)**		
	PM	**SO_2**	**NO_x**	**Units**	**PM**	**SO_2**	**NO_x**
Unit 1 Boiler	0.07	0.15 (30-dra) or 95% reduction	0.17 (30-dra)	lb/10^6 Btu	0	19,990*	1,607
Unit 2 Boiler	0.07	0.15 (30-dra) or 95% reduction	0.17 (30-dra)	lb/10^6 Btu	0	19,990*	1,607
Auxiliary Boiler No. 91	Continue current practices			N/A	0	0	0
Auxiliary Boiler No. 92	Continue current practices			N/A	0	0	0
Emerg. Gen.	Continue current practices			N/A	0	0	0
Fire Pump	Continue current practices			N/A	0	0	0
Material Handling EU 7-25	3	---	---	lb/hr	0	---	---
Flyash Dome EU 26	0.4 (EP 26a-26b), 0.09 (EP 26e)	---	---	lb/hr	0	---	---

Source Unit	Proposed BART Limit/Work Practice				Emissions Reduction (tons/yr)		
	PM	SO_2	NO_x	Units	PM	SO_2	NO_x
Coal Dryer EU 27	3.1	---	---	---	0	---	---
Fugitive FS 1-5	---	---	---	---	0	---	---
Total:						39,980*	3,214

* Reductions from 2000-2004 average emission rate adjusted for future fuel (dried lignite).

IX. Permit to Construct

The emission limits, monitoring, recordkeeping and reporting requirements will be included in a federally enforceable Air Pollution Control Permit to Construct that will be issued to the owner/operator of the facility. The Permit to Construct is included in Appendix D.

A. Monitoring

1. Monitoring for SO_2 and NO_x will be accomplished using the continuous emission monitors required by 40 CFR 75 for the Acid Rain Program. Monitoring for particulate matter shall be in accordance with 40 CFR 64, Compliance Assurance Monitoring. If the owner/operator of the BART-eligible unit chooses to comply with the SO_2 percent reduction requirements, monitoring of the SO_2 inlet rate loading to the scrubber shall be accomplished by either:

   a. A continuous emission monitor that complies with the requirements of 40 CFR 75; or

   b. Coal sampling in accordance with Method 19 of 40 CFR 60, Appendix A plus development of an emission factor based on actual stack testing.

2. For purposes of determining compliance with the SO_2 reduction requirement, the reduction efficiency shall be determined as follows:

$$\% \text{ Reduction} = \frac{\text{Inlet } SO_2 \text{ Rate} - \text{Outlet } SO_2 \text{ Rate}}{\text{Inlet } SO_2 \text{ Rate}} \times 100$$

Where:

Inlet SO_2 Rate is in units of lb/10^6 Btu, lb/hr or ppmvd @ 3% O_2.

Outlet SO_2 Rate is in the same units as the inlet SO_2 rate.

3. The owner/operator will be allowed to average emissions (bubble) for SO_2 and/or NO_x for the two units using the following formulas:

$$\text{Average AER} = \frac{[(AER_1)(HI_1)+(AER_2)(HI_2)]}{(HI_1 + HI_2)}$$

$$\text{Average ER} = \frac{[(ER_1)(HI_1)+(ER_2)(HI_2)]}{(HI_1 + HI_2)}$$

Where:

AER = Allowable Emission Rate (lb/MMBtu or % Reduction)
ER_1 = Actual Emission Rate (lb/MMBtu or % Reduction) of Unit 1
ER_2 = Actual Emission Rate (lb/MMBtu or % Reduction) of Unit 2
HI_1 = Actual Heat Input (MMBtu) of Unit 1
HI_2 = Actual Heat Input (MMBtu) of Unit 2

Notes: ER is a 30-day rolling average.
HI is a 30-day rolling average.
30-day rolling average is determined in accordance with 40 CFR 60, Subpart Da, for the 30 successive boiler operating days (must be on a consistent basis of lb/MMBtu or % reduction).

B. Recordkeeping and Reporting

The owner/operator will be required to conduct recordkeeping and reporting as required by NDAC 33-15-14-06, Title V Permit to Operate and NDAC 33-15-21, Acid Rain Program (40 CFR 72, 75 and 76).

BART Determination
for
Stanton Station Unit 1

11/18/09

I. <u>Source Description</u>

A. Owner/Operator: Great River Energy

B. Source Type: Electric Utility Steam Generating Unit

C. BART Eligible Units
  1. Unit 1 boiler
  2. Auxiliary Boiler
  3. Emergency Diesel Generator
  4. Emergency Fire Pump Engine
  5. Materials Handling Equipment
    a. Unit 1 coal bunker
    b. Flyash silo

D. Unit Description

  1. Unit 1:
     Generator Nameplate Capacity: 188 MWe
     Boiler Rating: 1,800 x 10^6 Btu/hr
     Startup: 1966
     Fuel: North Dakota Lignite, PRB Subbituminous
     Firing Method: Wall-fired
     Existing Air Pollution Control Equipment: Low NO_x burners and an electrostatic precipitator

  2. Auxiliary Boiler:
     Boiler Rating: 38 x 10^6 Btu/hr
     Fuel: #2 fuel oil

  3. Emergency Diesel Generator
     Rating: 10.35 x 10^6 Btu/hr
     Fuel: #2 fuel oil

  4. Emergency Fire Pump Engine:
     Rating: 370 horsepower
     Fuel: #2 fuel oil

  5. Materials Handling Equipment:

    a. Unit 1 coal bunker
       Existing Air Pollution Control Equipment: Baghouse

b. Flyash Silo:
Existing Air Pollution Control Equipment: Baghouse

** Projected emission rates when burning PRB coal (see discussion in Section IV.A. of this analysis for sulfur dioxide and Section IV.D. of this analysis for nitrogen oxides). For PM, it is assumed that PM emissions from the combustion of PRB coal are the same as for lignite coal.

*** Based on 500 hours per year of operation.

**** Department estimate.

II. Site Characteristics

The Stanton Station is located on the banks of the Missouri River in eastern Mercer County near the town of Stanton, North Dakota.

III. BART Evaluation of Unit 1 When Combusting Lignite Coal

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

- Wet Scrubber
- Spray Dryer / Fabric Filter (SD/FF)
- Circulating Dry Scrubber
- Wet Scrubber with a 10% bypass
- Dry Sorbent Injection / Fabric Filter (DSI/FF)
- Dry Sorbent Injection / Existing ESP (DSI/ESP)
- Powerspan ECO7
- Coal Cleaning
- Pahlman Process^{TM}
- K-Fuel7

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning: Coal cleaning and coal washing have never been used commercially on North Dakota lignite. Coal washing can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. Since this facility is located on the banks of the Missouri River, water pollution is a major concern. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that has required coal cleaning.

K-Fuel7 is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Evergreen's website indicates that it has idled its Wyoming plant and directed its capital and management resources to supporting a new design. Although Evergreen Energy, Inc. indicates the technology has been tested on lignite, there is no indication that lignite from North Dakota was tested. The use of the K-Fuel process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Therefore, the Department does not consider coal cleaning or the K-Fuel process available or technically and economically feasible.

A circulating dry scrubber is not considered commercially available by Great River Energy. However, the Department is including this as an available technology. Costs for a circulating dry scrubber are estimated based on cost estimates included in other BART analyses.

The Department considers the Powerspan ECO technology and the Pahlman Process not to be commercially available since no full size plant has been installed or is operating at this time. All other technologies or alternatives are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

The Department has calculated the baseline SO_2 emission rate when burning lignite by utilizing the highest calendar year average SO_2 emission rate of 1.81 lb/million Btu from 2000-2004 and multiplying this value by the highest heat input for any two consecutive years for the 2000-2004 period. This results in a baseline SO_2 emission rate as follows:

Heat input (2001) = 9.965×10^{12} Btu

Heat input (2002) = 1.075×10^{13} Btu

Average heat input = $(9.965 \times 10^{12} + 1.075 \times 10^{13}) / 2$
= 1.036×10^{13} Btu

Baseline SO_2 emission rate when combusting lignite coal
= 1.036×10^{13} Btu (1.81 lb/million Btu)(1 ton/2000 lb) = 9,376 tons/year

The control effectiveness of all remaining control technologies are shown in the following table.

Alternative	**Control Efficiency (%)**	**Inlet Loading (tons/yr)**	**Controlled Emissions**	
			(tons/yr)	**(lb/10^6 Btu)**
Wet Scrubber	95	9,376	469	0.091
Circulating Dry Scrubber	93	9,376	656	0.127
SD/FF	90	9,376	938	0.181
Flash Dryer Absorber	90	9,376	938	0.181

Alternative	**Control Efficiency (%)**	**Inlet Loading (tons/yr)**	**Controlled Emissions**	
			(tons/yr)	**(lb/10^6 Btu)**
Wet Scrubber with 10% bypass	86	9,376	1,313	0.263
DSI/FF	55	9,376	4,219	0.817
DSI/ESP	35	9,376	6,094	1.18

The cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($)***	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Wet Scrubber	8,907	13,180,000	1,480	4,179****
Circulating Dry Scrubber	8,720	14,220,000***	1,631	10,638
SD/FF	8,438	11,220,000	1,330	850**
Wet Scrubber with 10% bypass	8,063	9,490,000	1,177	365
DSI/FF	5,157	8,430,000	1,635	2,789
DSI/ESP	3,282	3,200,000	975	---

Note: Flash Dryer Absorber not included since it costs more than a spray dryer with no additional emissions reduction.

* Costs provided by Great River Energy (except as noted).
** The incremental cost shown is the incremental cost of SD/FF compared to DSI/FF.
*** The cost is estimated based on other BART analyses.
**** The incremental cost shown is the incremental cost of a wet scrubber compared to SD/FF.

Step 4: Evaluate Impacts and Document Results

Great River Energy has evaluated the energy and non-air quality effects of each option. The Department has determined that these effects will not preclude the selection of any of the control equipment.

Step 5: Evaluate Visibility Results

The two primary alternatives are a wet scrubber operating at 95% removal efficiency and a spray dryer operating at 90% efficiency. The effects on visibility for each of these two control options at the Theodore Roosevelt National Park, South Unit (TRNP-SU), Theodore Roosevelt National Park, North Unit (TRNP-NU), Theodore Roosevelt National Park, Elkhorn Ranch (TRNP-Elkhorn Ranch) and the Lostwood Wilderness Area (Lostwood WA) are shown in the following tables.

Unit 1 - Lignite Coal Combustion

Average	Lostwood WA			0.055
	Overall Average			0.064

Step 6: Select BART

There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The incremental cost of greater than $10,600 per ton of sulfur dioxide removed for a circulating dry scrubber compared to a spray dryer is considered excessive and a circulating dry scrubber is removed from further consideration as BART.

The unit has no existing air pollution control equipment for removing sulfur dioxide and the plant is expected to have a remaining useful life of at least 20 years. The degree of visibility improvement achieved by selecting a wet scrubber operating at 95% control efficiency versus a spray dryer operating at 90% control efficiency does not exceed 0.028 deciviews (90th percentile) or 0.112 deciviews (98% percentile) at any Class I area for the 2000-2002 time frame. Although the amount of visibility improvement achieved by selecting a wet scrubber versus a spray dryer is small, the Department has placed the primary emphasis on the cost of each option. The incremental cost from a spray dryer to a wet scrubber is $4,179 per ton of SO_2 removed. The Department does not consider this incremental cost to be excessive. However, wet scrubbing does have additional environmental impacts when compared to a spray dryer with a fabric filter as outlined below:

- A wet scrubber is estimated by GRE to use as much as 20% more water or approximately 15 million gallons per year of additional water.
- It is assumed that a wet scrubber system will require additional on-site ponding. GRE has identified two potential areas on site that could be used for the additional ponding. The areas include the existing ash pile, which would have to be excavated and moved, or the abandoned ash disposal area adjacent to the river, which reportedly has geotechnical deficiencies.
- Dry scrubbers are purported to achieve a higher mercury control efficiency on lignite and PRB as compared to a wet scrubber. In addition, future mercury control requirements could result in high concentrations of mercury in the ponds and prove problematic to discharge.

Based upon the additional environmental impacts and the fact that a wet scrubber will remove at best an additional 469 tons/year of SO_2 (with a small corresponding visibility improvement) beyond the control achieved by a spray dryer, the Department proposes BART as a spray dryer with a fabric filter.

The highest calendar year average SO_2 emission rate is approximately 1.81 lb/MM Btu for the 2000-2004 period when combusting lignite at Stanton Station Unit 1. Utilizing a 90% control efficiency for the spray dryer and fabric filter results in an annual average controlled emission rate of approximately 0.181 lb/MM Btu. Based upon historical SO_2 emissions data for spray dryers and fabric filters at North Dakota facilities, the Department has determined that an increase of 33% is warranted to adjust from an annual average SO_2 emission rate to a 30-day rolling average SO_2 emission rate. Multiplying the annual average emission rate of 0.181 lb/MM Btu by a factor of 1.33 (an increase of 33%) yields a 30-day rolling average SO_2 emission rate of 0.24 lb/MM Btu. Therefore, BART for SO_2 when combusting lignite coal is an SO_2 emission limit of 0.24 lb/million Btu heat input (on a 30 day rolling average) or a reduction efficiency of 90% (on a 30 day rolling average) on the inlet SO_2 concentration to the pollution control equipment.

B. Filterable Particulate Matter

Step 1: Identify All Available Technologies

New Baghouse
New Electrostatic Precipitator (ESP)
New Wet ESP
Existing ESP

Step 2: Eliminate Technically Infeasible Options

All technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Alternative	Control Efficiency	Emissions (tons/yr)	Emissions (lb/10^6 Btu)
Baghouse	99.7+	72.5	0.015
New ESP	99.7	72.5	0.015
Wet ESP	99.7	72.5	0.015
Baseline (Existing ESP)*	.99.5	90.5	0.019

* Based on the average of 2000 and 2001 emissions.

Alternative	Emissions Reduction (tpy)*	Annualized Cost ($)**	Cost Effectiveness ($/ton)
Baghouse	18	4,980,000	276,670
New ESP	18	5,800,000	322,220
Wet ESP	18	2,030,000	112,780
Baseline (Existing ESP)	0	0	---

* Reductions from the baseline emission rate.
** Costs provided by Great River Energy.

Step 4: Evaluate Impacts and Document the Results

Great River Energy has evaluated the energy and non-air quality effects of each option. The Department has determined that the effects will not preclude the selection of any of the options.

Step 5: Evaluate Visibility Impacts

Modeling was conducted to determine the visibility impairment at the PM emission limit of 0.1 lb/million Btu and an emission limit of 0.015 lb/million Btu. The visibility improvement in deciviews which results from reducing PM emissions from 0.1 lb/million Btu to 0.015 lb/million Btu is shown in the following table.

Unit 1 - Lignite Coal Combustion PM Delta Deciview			
Year	**Unit**	**90th Percentile**	**98th Percentile**
2000	TRNP-SU	0.005	0.008
2001	TRNP-SU	0.001	0.002
2002	TRNP-SU	0.006	0.021
Average		0.004	0.01
2000	TRNP-NU	0.001	0.011
2001	TRNP-NU	0.005	0.006
2002	TRNP-NU	0.001	0.019
Average		0.002	0.012
2000	TRNP-Elkhorn Ranch	0.001	0.013
2001	TRNP-Elkhorn Ranch	<0.001	0.002
2002	TRNP-Elkhorn Ranch	0.001	0.01
Average		<0.001	0.008
2000	LWA	0.005	0.011
2001	LWA	0.007	0.007
2002	LWA	0.005	0.003
Average		0.006	0.007
Overall Average		0.003	0.009

Step 6: Select BART

The alternative (excluding the baseline alternative) with the least cost for reducing filterable particulate emissions is a wet ESP. This system has a cost effectiveness of approximately $113,000 per ton of particulate when compared to the current emission control system (ESP operating at 99.5% efficiency). The Department considers this cost to be excessive.

There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The unit is equipped with an electrostatic precipitator that is achieving 99.5% Control efficiency. The plant is expected to have a remaining useful life of at least 20 years.

If the particulate emitted was reduced from the allowable emission limit of 0.1 lb/million Btu to 0.015 lb/million Btu, the most improvement in visibility at any Class I area would be approximately 0.006 deciviews (90th percentile) based on the three year average (0.008 deciviews based on the 98th percentile). The Department considers this amount of improvement to be insignificant.

After considering all of the factors, the Department proposes that BART for filterable particulate matter when combusting lignite coal is no additional controls. Since current actual emissions are less than the current allowable emissions and emissions lower than the current allowable can be achieved by the existing control equipment, the Department proposes that BART is represented by an emission limit of 0.07 lb/10^6 Btu.

C. Condensible Particulate Matter (PM_{10}).

Condensible particulate matter is made up of both organic and inorganic substances. Organic condensible particulate matter will be made up of organic substances, such as volatile organic compounds, which are in a gaseous state through the air pollution control devices but will eventually turn to a solid or liquid state. The primary inorganic substance expected from the boiler is sulfuric acid mist, with lesser amounts of hydrogen fluoride and ammonium sulfate.

Since sulfuric acid mist is the largest component of condensible particulate matter, controlling it will control most of the condensible particulate matter. The options for controlling sulfuric acid mist are the same options for controlling sulfur dioxide (see Section III.A.). Previously, BART for sulfur dioxide was determined to be represented by a spray dryer.

The control of volatile organic compounds at power plants is generally achieved through good combustion practices. The Department is not aware of any BACT determination at a power plant that resulted in any control technology being used. BACT has been found to be good combustion practices which are already in use since it minimizes the amount of fuel to generate electricity.

AP-42, Compilation of Air Pollutant Emission Factors[2], suggests that the emission rate of condensible PM could be as high as 0.02 lb/10^6 Btu. This emission rate is approximately equal to the current emissions of filterable particulate matter. The emissions of filterable particulate matter were determined to have a negligible impact on visibility.

Having considered all the factors, the Department has determined that BART for condensible particulate matter when combusting lignite coal is represented by good sulfur dioxide control and good combustion control. Since the primary constituent of condensible particulate matter is sulfuric acid mist which is controlled proportionately to the sulfur dioxide controlled, the BART limit for sulfur dioxide can act as a surrogate for condensible particulate matter along with a requirement for good combustion practices.

D. Nitrogen Oxides (NO_x)

Step 1: Identify All Available Technologies

Selective Catalytic Reduction (SCR)
Low Temperature Oxidation (LTO)
Non Selective Catalytic Reduction (NSCR)
Electro-Catalytic Oxidation (ECO)
Selective Non-Catalytic Reduction (SNCR)
Rich Reagent Injection (RRI)
Flue Gas Recirculation (FGR)
Overfire Air (OFA)
Low NO_x Burners (LNB)
Pahlman Process

Step 2: Eliminate Technically Infeasible Options

After significant review, it is the Department=s position that high-dust SCR for control of emissions from the combustion of North Dakota lignite at electric utility steam generating units is not technically feasible at this time (see discussion in Appendix B.5). Great River Energy has included a cost estimate for low-dust SCR, while high-dust SCR is listed as technically infeasible by GRE.

ECO, NSCR and the Pahlman Process have not been demonstrated on a pulverized coal-fired boiler and are considered technically infeasible.

Rich reagent injection was developed for cyclone boilers and has not been demonstrated for other types of units. Therefore, RRI is considered technically infeasible for Unit 1 since it is not a cyclone boiler.

Flue gas recirculation is not considered a technically feasible control option due to the space constraints at the facility. The space constraints do not allow for the additional ductwork and blower required to recirculate the flue gas.

Step 3: Evaluate Control Effectiveness of Remaining Control Technologies

Based on the historic baseline emissions, the Department=s estimated emissions using the various technologies would be as follows:

Alternative	**Control Efficiency (%)***	**Emissions**	
		(tons/yr)	**(lb/10^6 Btu)**
SCR with reheat	90	210	0.044
LTO	90	210	0.044
LNB + OFA + SNCR	45	1,156	0.239
SNCR	33	1,401	0.29
LNB + OFA	26	1,546	0.32
Baseline**	---	2,137	0.44

* Control efficiency provided in Great River Energy=s analysis.
** Based on the average of 2002 and 2003 emissions.

The estimated costs for the various technologies are as follows:

Alternative	**Emissions Reduction (tpy)**	**Annualized Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
SCR with reheat	1,929	12,490,000	6,475	10,032*
LTO	1,929	44,780,000	23,217	45,439
LNB + OFA + SNCR	983	3,000,000	3,052	6,923**
SNCR	738	2,700,000	3,658	16,551
LNB + OFA	593	300,000	504	---
Baseline	2,137	---	---	---

* The incremental cost shown is the incremental cost of SCR with reheat as compared to LNB + OFA + SNCR.
** The incremental cost show is the incremental cost of LNB + OFA + SNCR as compared to LNB + OFA.

Step 4: Evaluate Impacts and Document Results

There are no energy or environmental impacts that would preclude the selection of any of the alternatives.

Step 5: Evaluate Visibility Impacts

The Department considers the incremental cost effectiveness of the top two alternatives to be excessive. Modeling has been conducted assuming control with a spray dryer and LNB (current control for NO_x) and additional modeling has been conducted assuming control with OFA and SNCR in addition to the spray dryer and LNB. The difference in visibility impact between the two control scenarios is shown in the following tables.

Unit 1 - Lignite Coal Combustion Delta Deciview 90th Percentile

Average		0.425	0.339	0.086
Overall Average		0.417	0.340	0.077

Step 6: Select BART

The Department considered the incremental cost of the top two options to be excessive. The Department proposes that BART is represented by low-NO_x burners (LNB) plus over-fire air (OFA) plus selective non-catalytic reduction (SNCR). The Department proposes that BART for NO_x when combusting lignite coal is an emission limit of 0.29 lb/million Btu on a 30-day rolling average basis.

IV. BART Evaluation of Unit 1 when Burning PRB

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

Wet Scrubber
Spray Dryer / Fabric Filter (SD/FF)
Circulating Dry Scrubber
Flash Dryer Absorber
Wet Scrubber with a 10% bypass
Dry Sorbent Injection / Fabric Filter (DSI/FF)
Dry Sorbent Injection / Existing ESP (DSI/ESP)
Powerspan ECO
Coal Cleaning
Pahlman Process

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning: Coal cleaning can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. Since this facility is located on the banks of the Missouri River, water pollution is a major concern. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that has required coal cleaning.

K-Fuel is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Evergreen's website indicates that it has idled its Wyoming plant and directed its capital and management resources to supporting a new design. The use of the K-Fuel process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Based upon the above, the Department does not consider coal cleaning or the K-Fuel process available or technically and economically feasible.

A circulating dry scrubber is not considered commercially available by Great River Energy. However, the Department is including this as an available technology. Costs for a circulating dry scrubber are estimated based on cost estimates included another BART analysis.

The Department considers the Powerspan ECO technology and the Pahlman Process not to be commercially available since no full size plant has been installed or is operating at this time. All other technologies or alternatives are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Actual SO_2 emissions from Unit 1 at the Stanton Station were approximately 0.44 lb/million Btu heat input for calendar year 2006. However, Great River Energy has indicated that the mine from which the current PRB coal is received has a contractual arrangement with Great River to supply coal with a sulfur content which equates to an SO_2 emission limit no greater than 0.8 lb/million Btu heat input with a financial penalty if the sulfur content is greater than this amount. The mine uses a sulfur reject value of 1.2 lb/million Btu heat input.

Great River Energy has indicated that the contract for PRB coal from the existing mine expires in 2009 and has indicated that other potential PRB coal mines have PRB coal average sulfur contents of 0.34% sulfur, 0.64% sulfur and 0.80% sulfur, which equates to the following SO_2 emission rates:

SO_2 emission rate = 35S lb/ton*

* From EPA Publication AP-42, Section 1.1, Table 1.1-3, where S is the coal sulfur content.

SO_2 emission rate (at 0.34% sulfur PRB coal)
= 35 (0.34) lb/ton (1 ton/2,000 lb)(l lb / 9,350 Btu)
= 0.64 lb/million Btu heat input

SO_2 emission rate (at 0.64% sulfur PRB coal)
= 35 (0.64) lb/ton (1 ton/2,000 lb)(l lb / 8,750 Btu)
= 1.28 lb/million Btu heat input

SO_2 emission rate (at 0.80% sulfur PRB coal)
= 35 (0.80) lb/ton (1 ton/2,000 lb)(l lb / 8,750 Btu)
= 1.60 lb/million Btu heat input

For purposes of this analysis, an SO_2 emission rate of 1.2 lb/million Btu will be used to calculate uncontrolled emissions when combusting PRB coal. Baseline SO_2 emissions when combusting PRB coal are calculated using the heat inputs for calendar years 2001 and 2002, which are the same calendar years which were used to establish the baseline emission rate for SO_2 when combusting lignite coal. Baseline SO_2 emissions when combusting PRB coal assuming an SO_2 emission rate of 1.2 lb/million Btu are calculated as follows:

Heat input (2001) = 9.965×10^{12} Btu

Heat input (2002) = 1.075×10^{13} Btu

Average heat input = $(9.965 \times 10^{12} + 1.075 \times 10^{13}) / 2$
= 1.036×10^{13} Btu

Baseline SO_2 emission rate when combusting PRB coal
= 1.036×10^{13} Btu (1.2 lb/million Btu)(1 ton/2000 lb)
= <u>6,216 tons/year</u>

The control effectiveness of all remaining control technologies assuming an SO_2 emission rate of 1.2 lb/million Btu are shown in the following table.

Alternative	Control Efficiency (%)	Inlet Loading (tons/yr)	Controlled Emissions	
			(tons/yr)	(lb/10^6 Btu)
Wet Scrubber	95	6,216	311	0.06
Circulating Dry Scrubber	93	6,216	435	0.084
SD/FF	90	6,216	622	0.12
Flash Dryer Absorber	90	6,216	622	0.12
Wet Scrubber with 10% bypass	86	6,216	870	0.168
DSI/FF	55	6,216	2,797	0.54
DSI/ESP	35	6,216	4,040	0.78

The cost effectiveness and incremental costs for the various alternatives assuming an SO_2 emission rate of 1.2 lb/million Btu are shown in the following table.

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($)***	**Cost Effectiveness($/ton)**	**Incremental Cost ($/ton)**
Wet Scrubber	5,905	13,180,000	2,232	6,302****
Circulating Dry Scrubber	5,781	14,220,000***	2,460	16,043
SD/FF	5,594	11,220,000	2,006	1,283**
Wet Scrubber with 10% bypass	5,346	9,490,000	1,775	550
DSI/FF	3,419	8,430,000	2,466	4,208
DSI/ESP	2,176	3,200,000	1,471	---

Note: Flash Dryer Absorber is not included since it costs more than a spray dryer with no additional emissions reduction.

* Costs provided by Great River Energy

** The incremental cost shown is the incremental cost of SD/FF compared to DSI/FF.

*** The cost is estimated based on costs included in the BART analysis for the Leland Olds Station.

**** The incremental cost shown is the incremental cost of a wet scrubber compared to SD/FF.

Given that a lower SO_2 emission rate of 0.64 lb/million Btu is possible in the future, baseline SO_2 emissions at this emission rate are calculated as follows:

Baseline SO_2 emission rate when combusting PRB coal
= 1.036 x 10^{13} Btu (0.64 lb/million Btu)(1 ton/2000 lb)
= <u>3,315 tons/year</u>

The control effectiveness of all remaining control technologies assuming an SO_2 emission rate of 0.64 lb/million Btu are shown in the following table.

Alternative	**Control Efficiency (%)**	**Inlet Loading (tons/yr)**	**Controlled Emissions**	
			(tons/yr)	**(lb/10^6 Btu)**
Wet Scrubber	95	3,315	166	0.032
Circulating Dry Scrubber	93	3,315	232	0.045
SD/FF	90	3,315	332	0.064

Alternative	**Control Efficiency (%)**	**Inlet Loading (tons/yr)**	**Controlled Emissions**	
			(tons/yr)	**($lb/10^6$ Btu)**
Flash Dryer Absorber	90	3,315	332	0.064
Wet Scrubber with 10% bypass	86	3,315	464	0.090
DSI/FF	55	3,315	1,492	0.288
DSI/ESP	35	2,215	2,155	0.416

The cost effectiveness and incremental costs for the various alternatives assuming an SO_2 emission rate of 0.64 lb/million Btu are shown in the following table.

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($)***	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Wet Scrubber	3,149	13,180,000	4,185	11,807****
Circulating Dry Scrubber	3,083	14,220,000***	4,612	30,000
SD/FF	2,983	11,220,000	3,761	2,405**
Wet Scrubber with 10% bypass	2,851	9,490,000	3,329	1,031
DSI/FF	1,823	8,430,000	4,624	7,888
DSI/ESP	1,160	3,200,000	2,759	---

Note: Flash Dryer Absorber is not included since it costs more than a spray dryer with no additional emissions reduction.

* Costs provided by Great River Energy

** The incremental cost shown is the incremental cost of SD/FF compared to DSI/FF.

*** The cost is estimated based on costs included in the BART analysis for the Leland Olds Station.

**** The incremental cost shown is the incremental cost of a wet scrubber compared to SD/FF.

Step 4: Evaluate Impacts and Document Results

Great River Energy has evaluated the energy and non-air quality effects of each option. The Department has determined that these effects will not preclude the selection of any of the control equipment.

Step 5: Evaluate Visibility Results

The two primary alternatives are a wet scrubber operating at 95% removal efficiency and a spray dryer operating at 90% efficiency. The effects on visibility for each of these two control options at the Theodore Roosevelt National Park, South Unit (TRNP-SU), Theodore Roosevelt National Park, North Unit (TRNP-NU), Theodore Roosevelt National Park, Elkhorn Ranch (TRNP-Elkhorn Ranch) and the Lostwood Wilderness Area (Lostwood WA) were modeled when combusting lignite but not PRB. The degree of visibility improvement achieved by selecting a wet scrubber versus a spray dryer when combusting lignite does not exceed 0.028 deciviews (90th percentile) or 0.112 deciviews (98th percentile). The degree of incremental visibility improvement when combusting PRB is expected to be less than the incremental improvement when combusting lignite due to the lower SO_2 emission rates expected when combusting PRB.

Step 6: Select BART

There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The incremental cost of greater than $16,000 per ton of SO_2 removed for a circulating dry scrubber compared to a spray dryer is considered excessive and a circulating dry scrubber is removed from further consideration as BART.

The unit has no existing air pollution control equipment for removing sulfur dioxide and the plant is expected to have a remaining useful life of at least 20 years. The degree of visibility improvement achieved by selecting a wet scrubber operating at 95% control efficiency versus a spray dryer operating at 90% control efficiency is expected to be minimal. Although the amount of visibility improvement achieved by selecting a wet scrubber versus a spray dryer is small, the Department has placed the primary emphasis on the cost of each option. The incremental cost from a spray dryer to a wet scrubber is $6,302 per ton of SO_2 removed (assuming an uncontrolled emission rate of 1.2 lb/million Btu) and $11,807 per ton of SO_2 removed (assuming an uncontrolled emission rate of 0.64 lb/million Btu). The Department does not consider the incremental cost of $6,302 per ton to be excessive but does consider the incremental cost of $11,807 per ton to be excessive. Wet scrubbing does have additional environmental impacts as outlined below:

- A wet scrubber is estimated by GRE to use as much as 20% more water or approximately 15 million gallons per year of additional water.
- It is assumed that a wet scrubber system will require additional on-site ponding. GRE has identified two potential areas on site that could be used for the additional ponding. The areas include the existing ash pile, which would have to be

excavated and moved, or the abandoned ash disposal area adjacent to the river, which reportedly has geotechnical deficiencies.

- Dry scrubbers are purported to achieve a higher mercury control efficiency on lignite and PRB as compared to a wet scrubber. In addition, future mercury control requirements could result in high concentrations of mercury in the ponds and prove problematic to discharge.

Based upon the additional environmental impacts and the fact that a wet scrubber will only remove at best an additional 311 tons/year of SO_2 (with a small corresponding visibility improvement) beyond the control achieved by a spray dryer, the Department proposes BART as a spray dryer with a fabric filter.

The calendar year average SO_2 emission rate used in the analysis is 1.2 lb/MM Btu when combusting PRB at Stanton Station Unit 1. As indicated previously, this is considered to be a reasonable estimate of the future annual average SO_2 emission rate when combusting PRB coal at Stanton Station Unit 1. Utilizing a 90% control efficiency for the spray dryer and fabric filter results in an annual average controlled SO_2 emission rate of approximately 0.12 lb/MM Btu. Based upon historical SO_2 emissions data for spray dryers and fabric filters at North Dakota facilities, the Department has determined that an increase of 33% is warranted to adjust from an annual average SO_2 emission rate to a 30-day rolling average SO_2 emission rate. Multiplying the annual average emission rate of 0.12 lb/MM Btu by a factor of 1.33 (an increase of 33%) yields a 30-day rolling average SO_2 emission rate of 0.16 lb/MM Btu. Therefore, BART for SO_2 when combusting PRB coal is an SO_2 emission limit of 0.16 lb/million Btu heat input on a 30 day rolling average basis or a reduction efficiency of 90% (on a 30-day rolling average basis) on the inlet SO_2 concentration to the pollution control equipment.

B. Filterable Particulate Matter

Section III.B. of this analysis proposes BART for filterable particulate matter (PM) when combusting lignite coal as no additional controls with an emission limit of 0.07 lb/million Btu heat input. Given that the available pollution control equipment is expected to control emissions from both lignite coal and PRB coal to similar expected emission rates, a BART analysis for filterable particulate matter when combusting PRB coal is expected to yield essentially the same results as the BART analysis for filterable PM when combusting lignite coal.

The Department has proposed BART for filterable PM when combusting lignite coal as no additional controls. The Department proposes that BART for filterable PM when combusting PRB coal is also no additional controls and proposes that BART is represented by an emission limit of 0.07 lb/million Btu (average of 3 test runs).

C. Condensible Particulate Matter (PM_{10})

Section III.C. of this analysis proposes BART for condensible particulate matter (PM) when combusting lignite coal is represented by sulfur dioxide control and good combustion control. For the same reasons outlined in Section III.C. for the selection of BART for condensible PM when combusting lignite coal, the Department proposes that the BART limit for sulfur dioxide when combusting PRB coal can act as a surrogate for condensible particulate matter along with a requirement for good combustion practices.

D. Nitrogen Oxides (NO_x)

Step 1: Identify All Available Technologies

Selective Catalytic Reduction (SCR)
Low Temperature Oxidation (LTO)
Non Selective Catalytic Reduction (NSCR)
Electro-Catalytic Oxidation (ECO)
Selective Non-Catalytic Reduction (SNCR)
Rich Reagent Injection (RRI)
Flue Gas Recirculation (FGR)
Overfire Air (OFA)
Low NO_x Burners (LNB)
Pahlman Process

Step 2: Eliminate Technically Infeasible Options

After significant review, it is the Department=s position that high-dust SCR for control of emissions from the combustion of North Dakota lignite at electric utility steam generating units is not technically feasible at this time (see discussion in Appendix B.5). Great River Energy has included a cost estimate for low-dust SCR, while high-dust SCR is listed as technically infeasible by GRE. Although high-dust SCR is considered technically feasible by the Department when combusting PRB coal, the fact that lignite coal will be allowed to be combusted in the future in Unit 1 does not allow for the installation of a high-dust SCR system; therefore, a high-dust SCR system remains technically infeasible for Unit 1.

ECO, NSCR and the Pahlman Process have not been demonstrated on a pulverized coal-fired boiler and are considered technically infeasible.

Rich reagent injection was developed for cyclone boilers and has not been demonstrated for other types of units. Therefore, RRI is considered technically infeasible for Unit 1 since it is not a cyclone boiler.

Flue gas recirculation is not considered a technically feasible control option due to the space constraints at the facility. The space constraints do not allow for the additional ductwork and blower required to recirculate the flue gas.

Step 3: Evaluate Control Effectiveness of Remaining Control Technologies

Great River Energy calculated the baseline emission rate for NO_x when combusting PRB coal using an emission rate of 0.36 lb/million Btu (as compared to the baseline emission rate when burning lignite of 0.435 lb/million Btu), resulting in a baseline emission rate when combusting PRB coal of 1,740 tons/year. The Department=s estimated emissions using the various technologies would be as follows:

Alternative	**Control Efficiency (%)***	**Emissions**	
		(tons/yr)	**(lb/10^6 Btu)****
SCR with reheat	88	210	0.044
LTO	88	210	0.044
LNB + OFA + SNCR	45	946	0.196
SNCR	36	1,111	0.230
LNB + OFA	21	1,382	0.286
Baseline	---	1,740	0.36

* Control efficiencies calculated based upon the lb/million Btu emission rates provided by Great River Energy.

** Provided by Great River Energy.

The estimated costs for the various technologies are as follows:

Alternative	**Emissions Reduction (tpy)**	**Annualized Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
SCR with reheat	1,530	12,490,000	8,163	12,894*
LTO	1,530	44,780,000	29,268	60,842
LNB + OFA + SNCR	794	3,000,000	3,778	6,193**
SNCR	629	2,700,000	4,293	8,856
LNB + OFA	358	300,000	838	---
Baseline	1,740	---	---	---

* The incremental cost shown is the incremental cost of SCR with reheat as compared to LNB + OFA + SNCR.

** The incremental cost show is the incremental cost of LNB + OFA + SNCR as compared to LNB + OFA.

Step 4: Evaluate Impacts and Document Results

There are no energy or environmental impacts that would preclude the selection of any of the alternatives.

Step 5: Evaluate Visibility Impacts

The Department considers the incremental cost effectiveness of the top two alternatives to be excessive. Modeling has been conducted to estimate visibility impacts when combusting lignite but not PRB. When combusting lignite, the degree of visibility improvement achieved by selecting a low-NO_x burner plus over-fire air and SNCR over a low NO_x burner plus over-fire air was shown to be no greater than 0.027 deciviews (90th percentile) and 0.135 deciviews (98th percentile). The degree of incremental visibility improvement when combusting PRB is expected to be less than the incremental improvement when combusting lignite due to the lower NO_x emission rates expected when combusting PRB.

Step 6: Select BART

The Department considers the cost effectiveness and the incremental cost of the top two options to be excessive. The cost for the third option (LNB + OFA + SNCR) is not considered to be excessive. The Department proposes that BART is represented by low-NO_x burners (LNB) plus over-fire air (OFA) plus selective non-catalytic reduction (SNCR). The Department proposes that BART when combusting PRB coal is an emission limit of 0.23 lb/10^6 Btu on a 30-day rolling average basis.

V. BART Evaluation for Auxiliary Boiler

The auxiliary boiler is a #2 fuel-oil fired boiler with a nominal rating of 38 x 10^6 Btu/hr. The auxiliary boiler is only used when both units at the Stanton Station are down. During the baseline period (2000-2004), the unit was operated a total of 93 hours. The annual average emissions from the unit for this period were:

NO_x	0.14 tons
SO_2	0.36 tons
PM	0.02 tons

Based on the small quantity of emissions, it is apparent that no add-on control equipment will be cost effective. Any reduction in emissions will have a virtually no effect on visibility impairment. Therefore, the Department proposes that BART is no additional controls. The current permit limits the fuel used in the boiler to #2 fuel oil. BART is the use of #2 fuel oil.

VI. BART Evaluation for Emergency Diesel Generator

The emergency diesel generator has a rated heat input of 10.35 million Btu/hr. The generator is used for emergency purposes only and most of the emissions generated are due to testing and maintenance activities. Assuming 500 hours/year of operation, emissions from the unit would be as follows.

NO_x	8.0 tons
SO_2	1.3 tons
PM	0.2 tons

Based on the small quantity of emissions, no add-on control equipment will be cost effective. Any reduction of emissions will not affect visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VII. BART Evaluation for Emergency Fire Pump

The emergency fire pump is driven by a 370 horsepower diesel engine. The pump is used for emergency purposes only and most of the emissions generated are due to testing and maintenance activities. Assuming a maximum of 500 hours of operation per year, emissions would be as follows:

NO_x	2.76 tons
SO_2	0.19 tons
PM	0.2 tons

Based on the small quantity of emissions, no add-on control equipment will be cost effective. Any reduction of emissions will not affect visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VIII. BART Evaluation for Materials Handling Sources

The materials handling sources at the Stanton Station that emit to the atmosphere are as follows:

EUI	Description	Existing Control Equipment	Current Emission Limit (lb/hr)	Baseline Emissions (tons/yr)
M1	Unit 1 Coal Bunker	Baghouse	5.0*	0.6**
M3	Unit 2 West bunker conveyor	Baghouse	5.0	18.3**

* The emission limit of 5.0 lb/hr is for combined emissions from the Unit 1 and Unit 10 coal bunkers.

** Department estimate.

The materials handling units are controlled using a baghouse which is considered the most efficient control device. Therefore, the Department proposes that BART for the materials handling units is no additional controls and the current emission limit for the units is BART.

IX. Summary

The proposed BART limits and the effect on emissions is shown in the following table.

Source Unit	**Proposed BART Limit/Work Practice**				**Emissions Reduction (tons/yr)**		
	PM	**SO_2**	**NO_x**	**Units**	**PM**	**SO_2**	**NO_x**
Unit 1 Boiler (lignite)	0.07	0.24	0.29	lb/10^6 Btu	0	7,715	983
Unit 1 Boiler (PRB)	0.07	0.16	0.23	lb/10^6 Btu	0	5,594	794
Auxiliary Boiler	Use #2 Fuel Oil			N/A	0	0	0
Emergency Diesel Generator	Use #2 Fuel Oil			N/A	0	0	0
Fire Pump	Use #2 Fuel Oil			N/A	0	0	0
M1	5.0	---	---	lb/hr	0	---	---
M3	5.0	---	---	lb/hr	0	---	---
Total (lignite)					0	7,715	983
Total (PRB)					0	5,594	794

The BART analyses for SO_2 and NO_x were conducted assuming 100% lignite combustion and 100% PRB coal combustion. Since the same technologies were chosen for both fuels, any BART analysis conducted assuming a blending of lignite and PRB coal would result in the choice of the same control technologies as BART. For this reason, separate BART analyses conducted assuming a blending of coals were not necessary and were not conducted. However, to account for the scenario when both lignite coal and subbituminous coal are burned together in a 30-day averaging period, SO_2 and NO_x emissions will be limited by a weighted average emission limit when burning a combination of lignite and subbituminous coal. It should be noted that lignite and PRB coal will likely only be burned in the same 30-day averaging period during a switch from one coal to another (i.e., fuel blending is not likely to occur on an extended basis).

The modeled visibility impacts of Unit 1 when combusting lignite coal are shown in the following tables. As can be seen from the tables below, the proposed BART limits will result in average modeled visibility improvements ranging from 69-75% in the Class I areas when combusting lignite coal. The overall average improvement (90th percentile) for all Class I areas is approximately 0.2 deciviews, which equates to a 73% improvement. The overall average improvement (98th percentile) for all Class I areas is approximately 0.8 deciviews, which equates to a 70% improvement.

Modeling was not conducted to determine the visibility impacts when combusting PRB coal; however, since the proposed BART limits are lower for PRB (when compared to lignite), the visibility improvement when combusting PRB coal is expected to be greater than the visibility improvement when combusting lignite.

X. Permit to Construct

The emission limits, monitoring, recordkeeping and reporting requirements will be included in a federally enforceable Air Pollution Control Permit to Construct that will be issued to the owner/operator of the facility. The Permit to Construct is included in Appendix D.

A. Monitoring

1. Monitoring for SO_2 and NO_x will be accomplished using the continuous emission monitors required by 40 CFR 75 for the Acid Rain Program. Monitoring for particulate matter shall be in accordance with 40 CFR 64, Compliance Assurance Monitoring. If the owner/operator of the BART-eligible unit chooses to comply with the SO_2 percent reduction requirements, monitoring of the SO_2 inlet rate loading to the scrubber shall be accomplished by either:

    a. A continuous emission monitor that complies with the requirements of 40 CFR 75; or

b. Coal sampling in accordance with Method 19 of 40 CFR 60, Appendix A plus development of an emission factor based on actual stack testing.

2. For purposes of determining compliance with the SO_2 reduction requirement, the reduction efficiency shall be determined as follows:

$$\%\ \text{Reduction} = \frac{\text{Inlet } SO_2 \text{ Rate - Outlet } SO_2 \text{ Rate}}{\text{Inlet } SO_2 \text{ Rate}} \times 100$$

Where:

Inlet SO_2 Rate is in units of lb/10^6 Btu, lb/hr or ppmvd @ 3% O_2.

Outlet SO_2 Rate is in the same units as the inlet SO_2 rate.

B. Recordkeeping and Reporting

The owner/operator will be required to conduct recordkeeping and reporting as required by NDAC 33-15-14-06, Title V Permit to Operate and NDAC 33-15-21, Acid Rain Program (40 CFR 72, 75 and 76).

D. Unit Description

1. Unit 1:

Generator Nameplate Capacity: 257 MWe
Boiler Rating: 3200 x 10^6 Btu/hr
Startup: 1970
Fuel: North Dakota Lignite Firing Method: Cyclone
Existing Air Pollution Control Equipment: Electrostatic Precipitator

2. Unit 2:

   Generator Nameplate Capacity: 477 MWe
   Boiler Rating: 6300 x 10^6 Btu/hr
   Startup: 1975
   Fuel: North Dakota Lignite
   Firing Method: Cyclone
   Existing Air Pollution Control Equipment: Electrostatic precipitator and wet scrubber

3. Auxiliary Boiler:

   Boiler Rating: 78 x 10^6 Btu/hr
   Fuel: #1 or #2 fuel oil

4. Unit 1 Fire Pump:
   Rating: 237 Bhp

5. Unit 2 Fire Pump:
   Rating: 190 Bhp
   Fuel: Diesel fuel

6. Emergency Generator:
   Rating: 355 Bhp
   Fuel: Diesel fuel

7. Materials Handling Equipment:

   a. Unit 1 Crusher House and Conveyer 1C:
      Existing Air Pollution Control Equipment: Rotoclone

   b. Unit 1 Coal Silo:
      Existing Air Pollution Control Equipment: Rotoclone

   c. Unit 2 Crusher House:
      Existing Air Pollution Control Equipment: Rotoclone

II. Site Characteristics

The M.R. Young Station is located in east central Oliver County near the town of Center, North Dakota. The facility receives its lignite from BNI Coal Ltd.'s Center Mine which is located immediately adjacent to the plant. The original design of Unit 1 only incorporated a multiclone for air pollution control, the electrostatic precipitator was added in the 1970s. Unit 2 was built with an electrostatic precipitator and a wet scrubber. Because of the original design and the close proximity to Nelson Lake, there are some space constraints at the facility. Minnkota has not indicated that the space constraints are insurmountable. Therefore, site constraints are an economic issue when evaluating the various control alternatives.

III. BART Evaluation of Unit 1

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

Wet Scrubber
Spray Dryer
Circulating Dry Scrubber
Powerspan ECO®
Fuel Switching
Coal Cleaning

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning: Coal cleaning and coal washing have never been used commercially on North Dakota lignite. Coal washing can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. Since this facility is located near Nelson Lake, water pollution is a major concern. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that has required coal cleaning.

K-Fuel® is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels® process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Evergreen's website indicates that it has idled its Wyoming plant and directed its capital and management resources to supporting a new design. Although Evergreen Energy, Inc. indicates the technology has been tested on lignite, there is no indication that lignite from the Center Mine was tested. The use of the K-Fuel® process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Therefore, the Department does not consider coal cleaning or the K-Fuel® process available or technically and economically feasible.

A recent decision by the Seventh Circuit Court of Appeals on a BACT for Prairie Generating Company, LLC indicated that fuel switching was not required for mine mouth coal generating facilities. The Department believes the decision would also apply to BART determinations. Therefore, the Department did not consider coal switching.

The Department considers the Powerspan ECO® technology not to be commercially available since no full size plant has been installed or is operating at this time. All other technologies or alternatives are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Based on the information provided by Minnkota Power Coop. in their Annual Emission Inventory Reports, the Department has calculated the baseline emission rate (2001-2002) at 21,519 tons per year.

Alternative	**Control Efficiency (%)**	**Baseline Emissions (tons/yr)**	**Emissions***	
			(tons/yr)	**(lb/106 Btu)**
Wet Scrubber	95	21,519	1,076	0.10
Circulating Dry Scrubber	93	21,519	1,506	0.14
Spray Dryer	90	21,519	2,152	0.20

* Emission rate (lb/10^6 Btu) is an annual average rate. Future coal is expected to have higher sulfur content and a higher emission rate.

The cost effectiveness and incremental costs for the various alternatives are as follows:

Alternative	**Emissions Reduction (tons/yr)**	**Annualized Cost ($)***	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Wet Scrubber	20,443	22,584,000	1,105	N/A
Circulating Dry Scrubber	20,013	24,650,000	1,232	N/A
Spray Dryer	19,367	23,676,000	1,222	N/A

* Costs for wet scrubber and spray dryer provided by Minnkota. Circulating Dry Scrubber costs are the Department's estimate based on costs provided by Basin Electric for Leland Olds Unit 2.

Step 4: Evaluate Impacts and Document Results

Minnkota has evaluated the energy and non-air quality effects of each option. The Department has determined that these effects will not preclude the selection of either a wet scrubber or spray dryer.

Step 5: Evaluate Visibility Results

The alternatives are a wet scrubber operating at 95% removal efficiency, a circulating dry scrubber at 93% control and a spray dryer operating at 90% efficiency. Minnkota has proposed to install a wet scrubber operating at 95% removal efficiency. Since this is the most efficient technology, an evaluation of the impact on visibility for each alternative was not necessary. However, Minnkota did evaluate the impact on visibility for the 95% and 90% control options. The results based on the 90th and 98th percentile value are shown in the following tables.

Average	Lostwood W.A.	1.257	0.951	0.306
Overall Average		1.254	0.952	0.301

Step 6: Select BART

The cost effectiveness is reasonable for all technologies evaluated and the incremental cost from one technology to another is not excessive. There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The unit has no existing air pollution control equipment for removing sulfur dioxide and the plant is expected to have a remaining useful life of at least 20 years. Minnkota has proposed that BART is a wet scrubber operating at 95% control efficiency. The Department concurs with the use of a wet scrubber achieving a 95% reduction efficiency. Minnkota is a party to a Consent Decree which resolved alleged New Source Review violations at the M.R. Young Station. The Consent Decree states that if Minnkota installs a wet scrubber, they must comply with a 95% reduction requirement with no alternative emission rate (lb/10^6 Btu) limit. Therefore, the Department proposes that BART is a reduction efficiency of 95% of the inlet sulfur dioxide concentration to the scrubber on a 30-day rolling average basis (30 d.r.a.).

B. Filterable Particulate Matter

Step 1: Identify All Available Technologies

New Baghouse
New Electrostatic Precipitator
Compact Hybrid Particulate Collector (CoHPAC)
Existing Electrostatic Precipitator (Upgrade)

Step 2: Eliminate Technically Infeasible Options

All technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

The baseline emission rate from Unit 1 was calculated by the Department at 268 tons per year based on data for 2002-2003.

Alternative	**Control Efficiency**	**Emissions**	
		(tons/yr)	**(lb/10^6 Btu)**
Baghouse	99.7+	134	0.013
New ESP	99.7	158	0.015
CoHPAC	99.7	158	0.015
Baseline (Existing ESP)	99.0	268	0.026

Alternative	**Emissions* Reduction (tpy)**	**Annualized** Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Baghouse	134	5,284,000	39,433	37,545***
New ESP	90	4,643,000	51,589	N/A
CoHPAC	90	3,632,000	40,355	40,355
Baseline (Existing ESP)	0	1,822,000	---	

* Reductions from the baseline emission rate.
** Costs provided by Minnkota.
*** Incremental cost between baghouse and CoHPAC. New ESP is an inferior option since it costs more than CoHPAC with no additional emissions reductions.

Step 4: Evaluate Impacts and Document the Results

Minnkota has evaluated the energy and non-air quality effects of each option. The Department has determined that the effects will not preclude the selection of any of the options.

Step 5: Evaluate Visibility Impacts

The different alternatives were not modeled because of the high cost effectiveness. However, the maximum 24-hour emission rate during the baseline period was modeled. The results are as follows:

Unit 1 Delta Deciview PM			
Year	Unit	90th Percentile	98th Percentile
2000	TRNP-SU	0.0004	0.0015
2001	TRNP-SU	0.0006	0.0048
2002	TRNP-SU	0.0016	0.0023
Average	TRNP-SU	0.0007	0.0029
2000	TRNP-NU	0.0002	0.0004
2001	TRNP-NU	0.0011	0.0007
2002	TRNP-NU	0.0004	0.0059
Average	TRNP-NU	0.0006	0.0023
2000	TRNP-Elkhorn Ranch	0.0003	0.0010
2001	TRNP-Elkhorn Ranch	0.0002	0.0031
2002	TRNP-Elkhorn Ranch	0.0004	0.0020
Average	TRNP-Elkhorn Ranch	0.0003	0.0020
2000	Lostwood W. A.	0.0018	0.0007
2001	Lostwood W.A.	0.0013	0.0058
2002	Lostwood W. A.	0.0015	0.0007
Average	Lostwood W. A.	0.0015	0.0024
Overall Average		0.0013	0.0024

Step 6: Select BART

The alternative (excluding the baseline alternative) with the least cost for reducing filterable particulate emissions is the new baghouse. This system has a cost effectiveness of $39,433 per ton of particulate when compared to the current emission control system (ESP operating at 99.0% efficiency). The Department considers this cost to be excessive.

There are no energy or non-air quality environmental impacts that would preclude the selection of any of the feasible control options. The unit is equipped with an electrostatic precipitator that is achieving 99.0% Control efficiency. The plant is expected to have a remaining useful life of at least 20 years.

If all of the particulate emitted was eliminated, the most improvement in visibility at any Class I area would be approximately 0.0015 deciviews based on the 3-year average of the 90th percentile (0.0024 deciviews based on the 98th percentile). The Department considers this amount of improvement to be insignificant. Since none of the control alternatives will eliminate all of the particulate matter emissions, the visibility improvement will be even less.

After considering all of the factors, the Department proposes that BART for filterable particulate matter is no additional controls. Minnkota is under a Consent Decree which limits particulate emissions to 0.030 lb/10^6 Btu if they install a wet scrubber or 0.015 lb/10^6 if they install a dry scrubber with baghouse. Since Minnkota will install a wet scrubber, the Department proposes that BART is represented by an emission limit of 0.030 lb/10^6 Btu (average of 3 test runs).

C. Condensible Particulate Matter (PM_{10})

Condensible particulate matter is made up of both organic and inorganic substances. Organic condensible particulate matter will be made up of organic substances, such as volatile organic compounds, which are in a gaseous state through the air pollution control devices but will eventually turn to a solid or liquid state. The primary inorganic substance expected from the boiler is sulfuric acid mist, with lesser amounts of hydrogen fluoride and ammonium sulfate.

Since sulfuric acid mist is the largest component of condensible particulate matter, controlling it will control most of the condensible particulate matter. The options for controlling sulfuric acid mist are the same options for controlling sulfur dioxide (see Section III.A.). Previously, BART for sulfur dioxide was determined to be represented by a wet scrubber. This technology will achieve a 40-60% reduction as sulfuric acid mist emissions.

The control of volatile organic compounds at power plants is generally achieved through good combustion practices. The Department is not aware of any BACT determination at a power plant that resulted in any control technology being used. BACT has been found to be good combustion practices which are already in use since it minimizes the amount of fuel to generate electricity.

AP-42, Compilation of Air Pollutant Emission Factors[2], suggests the condensible particulate matter emission rate could be as high as 0.02 lb/10^6 Btu. This emission rate is less than the current emissions of filterable particulate matter. The emissions of filterable particulate matter were determined to have a negligible impact on visibility.

Having considered all the factors, the Department has determined that BART for condensible particulate matter is represented by good sulfur dioxide control and good combustion control. Since the primary constituent of condensible particulate matter is sulfuric acid mist which is controlled proportionately to the sulfur dioxide controlled, the BART limit for sulfur dioxide can act as a surrogate for condensible particulate matter along with good combustion practices.

D. Nitrogen Oxides (NO_x)

Step 1: Identify All Available Technologies

Selective Catalytic Reduction (SCR)
Electro-Catalytic Oxidation (ECO)
Selective Non-Catalytic Reduction (SNCR)
Hydrocarbon Enhanced SNCR (HE-SNCR)
Rich Reagent Injection (RRI)
Rotomix® (ROFA + SNCR)
Conventional Gas Reburn (CGR)
CGR + SNCR w/separated overfire air (SOFA)
Coal Reburn
Coal Reburn + SNCR
Fuel Lean Gas Reburn (FLGR™)
FLGR™ + SOFA
Rotating Overfire Air (ROFA)
Separated Overfire Air (SOFA)
Advanced SOFA (ASOFA)
Combustion Improvements (Included with SOFA and ASOFA)
Oxygen Enhanced Combustion (OEC)

Step 2: Eliminate Technically Infeasible Options

Minnkota believes SCR is not technically feasible at the M.R. Young Station. The Department does not consider high dust SCR to be technically feasible at this time. However, the Department believes low dust and tail end and SCR have a good probability of successful application at M.R. Young Station (see discussion in Appendix B.5). Minnkota has determined the following technologies are also technically infeasible:

ECO®
HE-SNCR
RRI
Rotomix® (ASOFA + SNCR evaluated)
CGR + SNCR
Coal Reburn + SNCR
FLGR™ + SNCR
OEC®

The Department agrees with Minnkota's determination regarding technical feasibility, except for LDSCR and TESCR. ROFA, SOFA, and ASOFA are similar and only ASOFA will be evaluated further.

Step 3: Evaluate Control Effectiveness of Remaining Control Technology

Alternative	Control Efficiency* (%)	Emissions (tons/yr)	Emissions ($lb/10^6$ Btu)
SCR w/reheat + ASOFA	90	903	0.085
SNCR + ASOFA	58.1	3,784	0.355
Gas Reburn + ASOFA	56.0	3,974	0.374
Coal Reburn + ASOFA	54.6	4,100	0.385
FLGR + ASOFA	45.9	4,886	0.460
ASOFA	39.5	5,464	0.513
SNCR	37	5,690	0.535
SOFA/ROFA	<28	6,503	0.611
Baseline	0	9,032	0.849

* Control efficiency specified by Minnkota in their analysis except for SCR. The Department believes a reduction effiency of 90% for ASOFA and SCR is more appropriate on a long-term basis.

** Based on the Department's calculation of baseline emissions. The $lb/10^6$ Btu emission rate is an annual average rate.

The estimated costs for the most efficient alternatives are as follows:

Alternative	Emissions Reduction (tpy)	Annualized Cost ($/ton)	Cost Effectiveness ($/ton)	Incremental Cost Effectiveness ($/ton)
Low Dust SCR + ASOFA	8,129	33,526,000/ 52,193,000	4,124/6,421	9,043/15,523
Tail End SCR + ASOFA*	8,129	39,307,000/ 56,095,000	4,835/6,901	11,050/16,877
SNCR + ASOFA	5,248	7,472,000	1,424	2,966***
Gas Reburn + ASOFA**	5,058	37,334,000	7,381	
Coal Reburn + ASOFA**	4,931	11,388,000	2,309	
FLGR + ASOFA	4,146	16,990,000	4,098	
ASOFA	3,568	2,489,000	698	

* Two different cost estimates are provided for SCR. This represents the range of costs provided by Minnkota for two different catalyst replacement scenarios and two different cost

bases – stand alone SCR systems for each unit and shared facilities.
** Inferior options to SNCR + ASOFA
*** Incremental cost for SNCR + ASOFA versus ASOFA

Minnkota has provided calculations of cost effectiveness and incremental cost effectiveness based on an NO_x removal efficiency of 93.8% and a baseline emission rate that is more reflective of potential emissions (the Department used 90% efficiency and historical data to calculate baseline emission rate). Minnkota used the most optimistic projections of efficiency and baseline emissions to show that LDSCR and TESCR are not cost effective even under those conditions. Minnkota's estimated costs are:

Alternative	**Emissions Reduction (tons)**	**Annualized Cost ($)***	**Cost Effectiveness ($/ton)**	**Incremental Cost Effectiveness ($/ton)**
Low Dust SCR + ASOFA	9,348/9,401	33,526,000/ 52,193,000	3,586/5,552	7,575/12,806
Tail End SCR + ASOFA	9,345/9,398	39,307,000/ 56,095,000	4,206/5,969	9,264/13,936
SNCR + ASOFA	4,025	7,472,000	1,265	---
Coal Reburn + ASOFA	4,275	11,388,000	2,037	---
FLGR + ASOFA	4,343	16,990,000	3,635	---
ASOFA	5,260	2,489,000	613	---

*Range of costs using two different catalyst replacement schedules and two different cost bases – stand alone SCR systems and shared facilities between M.R. Young 1 and 2.

SCR technology has never been applied to a boiler that combusts North Dakota lignite. There are many unknowns that will affect the cost of either LDSCR or TESCR at the M.R. Young Station including:

1) The catalyst deactivation rate
2) Catalyst volume required
3) Catalyst surface area required
4) Required reagent injection rate
5) Expected reagent slip
6) Whether formation of ammonium bisulfate and/or ammonium sulfate will be at an acceptable rate
7) An appropriate catalyst maintenance plan

All of these will affect either the initial construction cost and/or annual operation and maintenance costs. The amount of catalyst required will affect the initial capital cost as well as the replacement cost. The life of the catalyst and the amount of reagent required will have a large impact on the annual operating cost. If a wet electrostatic precipitator is required to control ammonium bisulfate/ammonium sulfate emissions, both the initial capital cost and operation and maintenance costs will rise dramatically. Given the many unknowns with North Dakota lignite, estimating the cost of an SCR system is extremely difficult and subject to many different opinions regarding estimating procedures. The Department believes pilot scale testing would prove to be very beneficial in addressing the items of concern and provide a more detailed professionally reliable cost estimate; however, the BART process cannot mandate that pilot testing be conducted to determine costs. The Department believes the cost estimate without pilot testing, although not ideal, will suffice based on the information that is available at the current time.

Step 4: Evaluate Impacts and Document Results

Minnkota has not identified any environmental impacts or energy impacts that would preclude of the use of any of the previously evaluated emission control alternatives.

Step 5: Evaluate Visibility Impacts

The Department has conducted modeling to determine the improvement in visibility for SCR + ASOFA versus SNCR + ASOFA. The results, based on the BART modeling guidelines, are as follows:

Unit 1
Delta Deciview
90th Percentile

Average	Lostwood W.A.	0.152	0.458	0.305
Overall Average		0.163	0.469	0.307

Step 6: Select BART

The cost effectiveness and incremental cost of LDSCR and TESCR is considered excessive or unreasonable. The visibility modeling results indicated only a 0.059 deciview (90th percentile) average improvement for SCR + ASOFA versus SNCR + ASOFA (0.307 deciviews based on 98th percentile). Because modeling based on the BART Guidelines (40 CFR 51, Appendix Y) overpredicts the visibility improvement in North Dakota (see Section 7.4.2), the Department conducted a modeling analysis to determine the amount of improvement when all sources are considered (cumulative analysis). The visibility will only improve 0.01 deciviews on average for the 20% worst days when SCR + ASOFA is compared to SNCR + ASOFA. The Department considers 0.01 deciviews improvement to be negligible.

The Department also considered the cost effectiveness and incremental costs of LDSCR and TESCR calculated by Minnkota. Both of these cost metrics are considered excessive over the entire range. The Department conducted dispersion modeling to determine the visibility improvement if SCR did achieve 93.8% reduction efficiency. The results indicate only a 0.011 deciview improvement in visibility on average for the 20% worst days when SCR + ASOFA is compared to SNCR + ASOFA. The amount of improvement is still negligible. Given the excessive cost and negligible visibility improvement, SCR + ASOFA is not considered BART for Unit 1.

Minnkota has proposed SNCR + ASOFA as BART. SNCR + ASOFA will achieve an emission rate of 0.355 lb/10^6 Btu on an annual average basis. The Department has determined that BART, during normal operations, is a limit of 0.36 lb/10^6 Btu on a 30-day rolling average basis.

Minnkota has requested a different limit during startup of the boiler. Minnkota's justification for the startup units is found in Section 3.5.2 of their BART analysis. Minnkota is under a Consent Decree which requires a BACT determination for nitrogen oxides. The Consent Decree (Paragraph 66) requires Minnkota to address specific limits during unit startups. Therefore, the proposed BACT and BART limit (which are identical) do not account for startups of the units. If it did, the proposed limit would be substantially higher. In order to harmonize the BACT limits with the BART limits, the Department is proposing separate BART emissions limits for NO_x during startup of Units 1 and 2.

The EPA Air Pollution Control Cost Manual[3] states "The NO_x reduction reaction occurs within a specific temperature range where adequate heat is available to drive the reaction. At lower temperatures the reaction kinetics are slow and ammonia passes through the boiler (ammonia slip). At higher temperatures the reagent oxidizes and additional NO_x is generated. The temperature window is dependent on the reagent utilized. Figure 1.3 shows the NO_x reduction efficiency for urea and ammonia SNCR at various boiler temperatures. For ammonia, the optimum temperature is from 870°C to 1100°C (1600°F to 2000°F)."

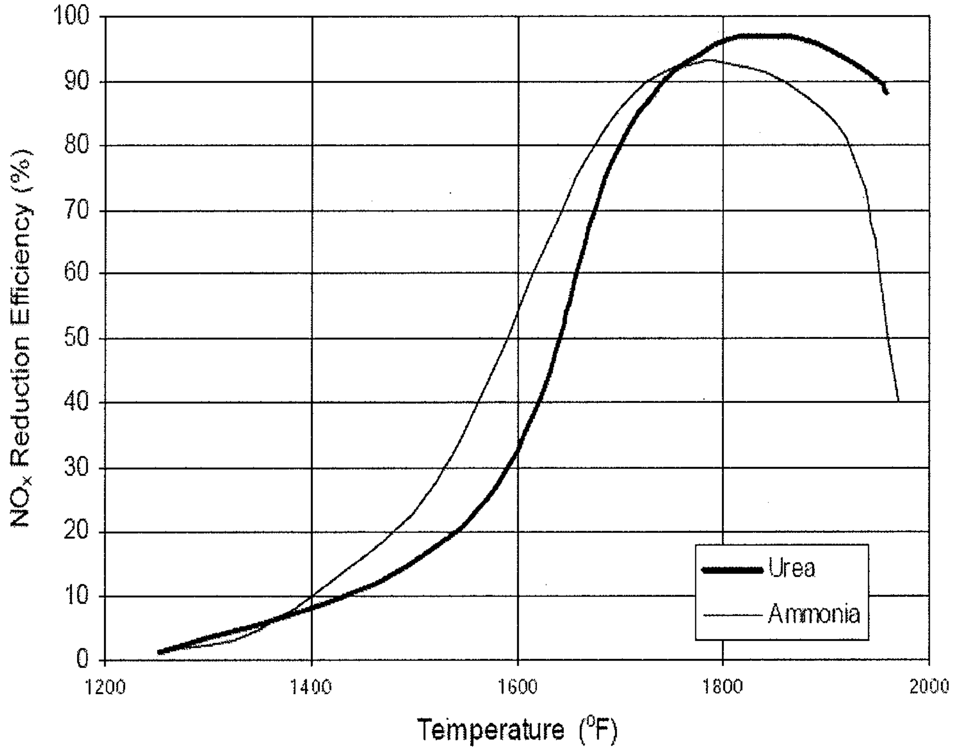

Figure 1.3: Effect of Temperature on NO_x Reduction

“ Flue gas temperature within the boiler depends on the boiler design and operating conditions. These are generally set to meet steam generation requirements and are not always ideal for the SNCR process. Flue gas temperatures in the upper furnace through the convective pass may vary by ±150°C (300°F) from one boiler to the next [1]. In addition, fluctuations in the boiler load profile affect the temperature within the boiler. At lower load profiles, the temperature within the boiler is lower. Variations in the flue gas temperature make the design and operation of an SNCR system more difficult.”

It is clear to the Department that startup of the boiler will affect the SNCR system and perhaps the overfire system also (see p. 3-42 to p. 3-42 of Minnkota’s BART analysis). Minnkota has stated that startup has lasted up to 61 hours (2.54 days) for Unit 1. Including 2.54 days of noncompliance within a 30-day rolling average emission rate calculation will make compliance extremely difficult. In recent PSD application reviews for power plants, the Department has found sufficient cause to provide alternative limits under BACT for periods of startup and shutdown. The State of Montana in the permit for the Highwood Generating Station, EPA Region 9 in the permit for the Desert Rock Energy Center and the State of Nebraska in the Ag Soy Processing plant permit also included alternative limits for NO_x during startup and shutdown.

Minnkota has recommended in the October 2006 BACT submittal an emission limit of 0.98 lb/10^6 Btu (24-hr rolling average) for periods of startup. This value is based on historical data for startups from 2001 - 2005. Based on a rated heat input of 3200 x 10^6 Btu/hr, this equates to 3136 lb/hr. The rated heat input will generally not be achieved during a startup and a lower emission limit for startup is warranted. Minnkota has proposed a reduced startup limit of 2070.2 lb/hr on a 24-hour rolling average basis (see November 11, 2007 submittal). The Department proposes that NO_x emissions be limited to 2070.2 lb/hr on a 24-hour rolling average basis during startup. The normal BART limit of 0.36 lb/10^6 Btu will apply during all other periods including malfunctions.

IV. BART Evaluation of Unit II

A. Sulfur Dioxide

Step 1: Identify All Available Technologies

New Wet Scrubber
Spray Dryer
Circulating Dry Scrubber
Flash Dryer Absorber
Powerspan ECO®

Fuel Switching
Coal Cleaning
Upgrade Existing Scrubber

Step 2: Eliminate Technically Infeasible Options

Coal Cleaning: Coal cleaning and coal washing have never been used commercially on North Dakota lignite. Coal washing can have significant environmental effects. A wet waste from the washing process must be handled properly to avoid soil and water contamination. Since this facility is located near Nelson lake, water pollution is a major concern. The Department is not aware of any BACT determinations for low sulfur western coal burning facilities that has required coal cleaning.

K-Fuel® is a proprietary process offered by Evergreen Energy, Inc. which employs both mechanical and thermal processes to increase the quality of coal by removing moisture, sulfur, nitrogen, mercury and other heavy metals.[1] The process uses steam to help break down the coal to assist in the removal of the unwanted constituent. The K-Fuels® process would require a steam generating unit which will produce additional air contaminants. In addition to these concerns, the Department has determined that the technology is not proven commercially. The first plant was scheduled for operation on subbituminous coal sometime in 2005. Although Evergreen Energy indicates the technology has been tested on lignite, there is no indication that lignite from the Freedom Mine was tested. The use of the K-Fuel® process would pose significant technical and economic risks and would require extensive research and testing to determine its feasibility.

Therefore, the Department does not consider coal cleaning or the K-Fuel® process available or technically and economically feasible.

The Department considers the Powerspan ECO® technology not to be commercially available since no full size plant has been installed or is operating at this time. All other technologies or alternatives are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Alternative	Control Efficiency (%)	Baseline Emissions (tons/yr)**	Emissions	
			(tons/yr)	($lb/10^6$ Btu)*
New Wet Scrubber	95	18,090	1,964	0.11
Upgrade Existing Scrubber	95	18,090	1,964	0.11
Circulating Dry Scrubber	93	18,090	2,749	0.16
Upgrade Existing	90	18,090	3,928	0.23

Alternative	Control Efficiency (%)	Baseline Emissions (tons/yr)**	Emissions	
			(tons/yr)	(lb/10^6 Btu)*
Scrubber				
Spray Dryer	90	18,090	3.928	0.23
Flash Dryer Absorber	90	18,090	3,928	0.23

* Annual average emission rate.
** Based on an annual average sulfur content of 0.93% and 2000-2001 operating data.

Unit 2 is equipped with a lime/flyash scrubber that achieved an average SO_2 reduction efficiency (inlet to outlet) of approximately 65% for the period 2000-2004. It is obvious that upgrading the existing scrubber to either 90% or 95% control efficiency will be the most cost effective alternative.

Alternative	Emissions Reduction (tpy)	Annualized Cost ($/ton)	Cost Effectiveness ($/ton)	Incremental Cost ($/ton)
Upgrade existing scrubber to 95%	16,126	8,414,000	522	550
Upgrade existing scrubber to 90%	14,162	7,333,000	518	N/A

Step 4: Evaluate Impacts and Document Results

Minnkota has evaluated the energy and non-air quality effects of each option. The Department has determined that these effects will not preclude the selection of any of the available options.

Step 5: Evaluate Visibility Results

The two primary alternatives are upgrading the existing scrubber to achieve a reduction efficiency of 90% or 95%. The effects on visibility shown below are based on Minnkota's estimate of SO_2 reductions.

Unit 2
Delta Deciview
90th Percentile
SO_2

Year	Unit	95% Reduction	90% Reduction	Difference
2000	TRNP-SU	0.317	0.340	0.023
2001	TRNP-SU	0.154	0.332	0.178
2002	TRNP-SU	0.442	0.497	0.055
Average	TRNP-SU	0.304	0.390	0.085
2000	TRNP-NU	0.241	0.257	0.016
2001	TRNP-NU	0.214	0.442	0.228
2002	TRNP-NU	0.359	0.419	0.051
Average	TRNP-NU	0.271	0.370	0.098
2000	Elkhorn Ranch	0.175	0.201	0.026

Step 6: Select BART

The Consent Decree that covers M.R. Young Station Unit 2 only requires 90% reduction of SO_2 emissions by the scrubber. Minnkota has proposed that BART is represented by improvements to the existing scrubber such that a 90% reduction efficiency will be achieved on a 30-day rolling average basis. Minnkota states that the costs associated with each alternative (90% or 95% reduction) are reasonable based on other regulatory analysis. The Department believes the costs are quite low and very reasonable. Minnkota has not identified any energy or non-air quality impacts that would preclude either alternative. Minnkota's choice of 90% reduction as BART is based on the visibility modeling results. The difference, according to Minnkota's results, indicate an average visibility impact reduction of only 0.082 deciviews based on the 90th percentile value (0.250 dv based on 98th percentile). However, the difference in visibility impact between the two alternatives will be as much as 0.228 deciviews based on the 90th percentile (0.479 deciviews based on 98th percentile) for year 2001 in TRNP-NU. Although the average visibility improvement is small, this factor must be considered with the other four factors.

The cost of upgrading the existing wet scrubber to achieve 95% control is very reasonable. There are no unacceptable energy and non-air quality environmental impacts, the remaining useful life is greater than 20 years, and there is a small degree of visibility improvement. The Department proposes that BART is represented by improvements to the existing wet scrubber which will achieve approximately 95% reduction in SO_2 emissions. BART is 95% reduction efficiency from the inlet of the scrubber to the outlet of the scrubber.

Data on future coal sulfur content was submitted by Minnkota in an April 18, 2007 response to comments (Table C.11). The core sample data indicates a maximum sulfur content of 5.6%, an average sulfur content of 0.93% and a standard deviation of 0.53%. Based on an average sulfur content of 0.93%, the uncontrolled emission rate would be approximately 2.26 lb/10^6 Btu. However, the unit will have to comply with the BART emission limit at all times on a 30-day rolling average basis. Adding one standard deviation to the average sulfur content yields a design sulfur content of 1.46% or an uncontrolled emission rate of 3.48 lb/10^6 Btu.

A scrubber operating at 95% removal efficiency will achieve an annual average emission rate of 0.11 lb/10^6 Btu based on average coal or 0.17 lb/10^6 Btu based on a design sulfur content of 1.46%. This is equivalent to approximately 0.15 lb/10^6 Btu to 0.23 lb/10^6 Btu on a 30-day rolling average basis. The existing scrubber is a mid 1970s design and maintaining 95% reduction continuously will be more difficult than with new designs that are 30 years more advanced. Because of the age of the scrubber and some uncertainty in the future coal sulfur content, the Department has determined that an alternative limit be incorporated into the BART limit. Minnkota has agreed to limit SO_2 emissions to no more than 0.15 $lb/10^6$ Btu. The Department has determined that BART is 95% reduction or 0.15 $lb/10^6$ Btu on a 30-day rolling average basis. This is the same as the presumptive BART level listed in 40 CFR 51, Appendix Y even though the unit is not subject to the presumptive level (i.e., plant is less than 750 MWe and existing SO_2 controls achieve greater than 50% efficiency). However, the Consent Decree requires a minimum of 90% reduction. This requirement will also be incorporated into the BART limit.

B. Filterable Particulate Matter (PM/PM_{10})

Step 1: Identify All Available Technologies

New Baghouse
New Electrostatic Precipitator
Compact Hybrid Particulate Collector (CoHPAC)
Existing Electrostatic Precipitator

Step 2: Eliminate Technically Infeasible Options

All technologies are considered technically feasible.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Alternative	**Control Efficiency (%)**	**Emissions***	
		(tons/yr)	**($lb/10^6$ Btu)**
Baghouse	99.7+	248	0.013
New ESP	99.7	286	0.015
CoHPAC	99.7	286	0.015
Baseline (Existing ESP)	≈99.0	1,135	0.060

* Based on the Department's estimate of baseline emissions.

Alternative	**Emissions* Reduction (tpy)**	**Annualized** Cost ($)**	**Cost Effectiveness ($/ton)**	**Incremental Cost ($/ton)**
Baghouse	887	8,249,000	9,300	67,553***
New ESP	849	7,520,000	8,857	---
CoHPAC	849	5,682,000	6,693	9,472
Baseline (Existing ESP)	0	2,973,000	-	-

* Reductions from baseline emission rate.
** Costs provided by Minnkota.
*** Baghouse compared to CoHPAC.

Step 4: Evaluate Impacts and Document Results

Minnkota has evaluated the energy and non-air quality environmental impacts associated with each alternative and determined that these impacts would not prelude the selection of any of the alternatives as BART. The Department agrees with this determination.

Step 5: Evaluate Visibility Results

The different alternatives were not modeled because of the high cost effectiveness. However, the maximum 24-hour average emission rate from the baseline period was modeled. The results are as follows:

Unit 2
Delta Deciview
PM

Year	**Unit**	**90th Percentile**	**98th Percentile**
2000	TRNP-SU	0.0054	0.0151
2001	TRNP-SU	0.0037	0.0068
2002	TRNP-SU	0.0100	0.0090
Average	TRNP-SU	0.0064	0.0103
2000	TRNP-NU	0.0034	0.0024
2001	TRNP-NU	0.0042	0.0093
2002	TRNP-NU	0.0073	0.0106
Average	TRNP-NU	0.0050	0.0074
2000	Elkhorn Ranch	0.0013	0.0046
2001	Elkhorn Ranch	0.0006	0.0054
2002	Elkhorn Ranch	0.0005	0.0082
Average	Elkhorn Ranch	0.0008	0.0061
2000	Lostwood W.A.	0.0009	0.0032
2001	Lostwood W.A.	0.0040	0.0165
2002	Lostwood W.A.	0.0009	0.0123
Average	Lostwood W.A.	0.0019	0.0107
Overall Average		0.0035	0.0086

Step 6: Select BART

The alternative (excluding the baseline alternative) with the least cost for reducing filterable particulate matter emissions is CoHPAC, which has a cost effectiveness of $6,693 per ton. The Department considers this cost to be excessive. There are no energy or non-air quality impacts that would preclude the selection of any of the feasible control options.

The unit is equipped with an electrostatic precipitator that is achieving at least 99.0% control efficiency. The baseline emission rate is 0.06 lb/10^6 Btu; however, the average emission rate for this unit for 2000-2004 was 0.028 lb/10^6 Btu. The plant is expected to have a remaining useful life of at least 20 years.

If all of the particulate matter emitted was eliminated, the most improvement in visibility at any Class I area would be 0.0064 deciviews based on the 90th percentile (0.0103 deciviews based on 98th percentile). The Department considers this amount of improvement to be negligible. Since none of the control alternatives will eliminate all of the particulate matter emissions, the visibility improvement will even be less.

Minnkota is currently under a Consent Decree (CD) which limits particulate emissions to 0.030 lb/10^6 Btu. After considering all of the factors, the Department proposes that BART for filterable particulate matter is no additional controls. Since the CD requires a lower limit, the Department proposes that BART is represented by an emission limit of 0.030 lb/10^6 Btu (average of three test runs).

C. Condensible Particulate Matter (PM_{10})

See the discussion for Unit 1 in Section III.C. Any additional control technology for controlling condensible particulate matter will result in less than a 0.0064 deciview (90th percentile) improvement at any Class I area. The Department considers the use of a wet scrubber and good combustion practices to represent BART for condensible particulate matter from Unit 2. The BART limit for sulfur dioxide (95% reduction) and good combustion practices will act as a surrogate for condensible particulate matter.

D. Nitrogen Oxides

Introduction – See discussion in Appendix B.5 and Section III.D. The rationale will apply to Unit 2 that applies to Unit 1.

Step 1: Identify All Available Technologies

Selective Catalytic Reduction (SCR)
Electro-Catalytic Oxidation (ECO®)
Selective Non-Catalytic Reduction (SNCR)
Hydrocarbon Enhanced -SNCR with or without Advanced Separated Overfire Air (ASOFA)
Rich Reagent Injection (RRI) + SNCR + ASOFA

Rotomix® (ROFA + SNCR)
Conventional Gas Reburn plus SNCR (CGB + SNCR)
Coal Reburn
Coal Reburn + SNCR
Fuel Lean Gas Reburn (FLGR™)
FLGR™ + SOFA
SOFA or Advanced SOFA (ASOFA)
Rotating Overfire Air (ROFA)
Combustion Improvements (Included with ASOFA)
Oxygen Enhanced Combustion (OEC)

Step 2: Eliminate Technically Infeasible Options

Minnkota considers SCR to be technically infeasible at the M.R. Young Station. The Department does not consider high SCR to be technically feasible at this time. However, LDSCR and TESCR are considered technically feasible (see discussion in Appendix B.5 and III.D. of this analysis). Minnkota has determined the following technologies are also technically infeasible:

LDSCR
TESCR
ECO®
HE-SNCR
RRI
Rotomix® (ASOFA + SNCR evaluated)
CGR + SNCR
Coal Reburn + SNCR
FLGR™ + SNCR
OEC®

The Department agrees with Minnkota's determination regarding technical feasibility except for LDSCR and TESCR. ROFA, SOFA, and ASOFA are similar and only ASOFA will be evaluated further.

Step 3: Evaluate Control Effectiveness of Each Remaining Control Technology

Based on the historic baseline emissions, the expected emissions are as follows:

Alternative	**Control Efficiency * (%)**	**Emissions****	
		(tons/yr)	**(lb/10^6 Btu)**
SCR w/reheat + ASOFA	90	1,551	0.079
SNCR + ASOFA	58.0	6,513	0.330
Gas Reburn +	55.4	6,916	0.350

Alternative	Control Efficiency * (%)	Emissions**	
		(tons/yr)	($lb/10^6$ Btu)
ASOFA			
Coal Reburn + ASOFA	54.2	7,102	0.360
FLGR + ASOFA	45.0	8,529	0.432
ASOFA	37.7	9,661	0.489
Baseline	---	15,507	---

*Control efficiency specified by Minnkota in their analysis except for SCR.
**Based on the Department's estimate of baseline emissions. The $lb/10^6$ Btu emission rate is an annual average rate.

The estimated costs for the most efficient alternatives are as follows:

Alternative	Emissions Reduction (tons/yr)	Annualized Cost ($)	Cost Effectiveness ($/ton)	Incremental Cost ($/ton)
Low Dust SCR + ASOFA	13,956	57,351,000/ 89,072,000	4,109/ 6,382	9,260/ 15,652
Tail End SCR + ASOFA*	13,956	66,506,000/ 98,818,000	4,765/7,081	11,105/17,616
SNCR + ASOFA	8,994	11,405,000	1,268	N/A
Gas Reburn + ASOFA**	8,591	63,883,000	7,436	N/A
Coal Reburn + ASOFA**	8,405	19,475,000	2,317	N/A
FLGR + ASOFA	6,978	29,313,000	4,201	N/A
ASOFA	5,846	4,376,000	749	

* Two different estimates of cost are provided for SCR. These represent the range of costs provided by Minnkota based on two catalyst replacement scenarios and two cost bases – stand along SCR systems or shared facilities.
** Inferior options to SNCR + ASOFA

Minnkota has calculated the cost effectiveness and incremental cost effectiveness based on 93.8% removal efficiency and a baseline emission rate that is more reflective of potential emissions instead on historical emissions. This represents the costs under the most optimistic conditions. The Minnkota calculations are:

Alternative	Emissions Reduction (tons/yr)	Annualized Cost ($)*	Cost Effectiveness ($/ton)	Incremental Cost ($/ton)
Low Dust SCR + ASOFA	14,862/14,980	57,351,000/ 89,072,000	3,859/5,946	8,331/13,812
Tail End SCR + ASOFA	14,857/14,980	66,506,000/ 98,818,000	4,477/6,597	10,007/15,550
SNCR + ASOFA	9,372	11,618,000	1,240	2,263
ASOFA	6,172	4,376,000	709	---

** Range of costs using two different catalyst replacement schedules and two different cost bases – standalone SCR systems and shared facilities between Unit 1 and 2.

Step 4: Evaluate Impacts and Document Results

Minnkota has not identified any environmental or energy impact that would preclude of the use of any of the previously evaluated emission control alternatives.

Step 5: Evaluate Visibility Impacts

The following tables show the visibility improvement of SCR + ASFOA versus SNCR + ASOFA.

Unit 2

Overall Average		0.298	0.651	0.353

Because the BART modeling guidance (40 CFR 61, Appendix Y) uses single source modeling, the modeling overpredicts the amount of improvement for North Dakota (see Section 7.4.2 of SIP). The Department has conducted modeling with all sources included in the inventory. The results of this modeling indicates that visibility at TRNP will only improve 0.02 deciviews on average for the 20% worst days when SCR + ASOFA is utilized versus SNCR + ASOFA. At LWA, the visibility will only improve 0.01 deciviews.

Step 6: Select BART

The cost effectiveness of SCR (LDSCR and TESCR) + ASOFA is considered excessive over the entire range of costs. The Department considers the incremental cost over the entire range of costs to be excessive for SCR + ASOFA when compared to SNCR + ASOFA. The BART type modeling predicts an average improvement of 0.058 deciviews based on the 90th percentile (0.353 deciviews based on the 98th percentile); but overpredicts the amount of improvement (see Section 7.4.2 of SIP). The Department's cumulative modeling predicts a 0.02 deciview improvement at TRNP and 0.01 deciview improvement at LWA for the most impaired days when compared to SNCR + ASOFA. There are no environmental or energy impacts that would preclude the selection of any of the control alternatives as BART and the unit is expected to have greater than a 20 year remaining life.

The Department has also considered the cost effectiveness and incremental costs provided by Minnkota. The costs calculated by Minnkota are also considered excessive. The Department also conducted modeling to determine the amount of visibility improvement if SCR did achieve 93.8% NO_x removal. The results indicated a 0.021 deciview improvement for SCR + ASOFA versus SNCR + ASOFA at TRNP and a 0.011 deciview improvement of LWA during the most impaired days.

Because of the excessive cost effectiveness and incremental cost and negligible visibility improvement, SCR + ASOFA is eliminated as a BART alternative. The Department has determined that BART is represented by SNCR + ASOFA. This technology will achieve an annual average emission rate of 0.33 lb/10^6 Btu. Based on a 30-day rolling average basis, an emission rate of 0.35 lb/10^6 Btu is achievable and is proposed as BART for normal operating conditions.

Minnkota has requested an alternative BART limit during startup. Minnkota's justification is found in Section 3.5.2 of their BART analysis. The Department believes an alternative limit is justified (see discussion in Section III.D. Step 6). Therefore, the Department proposes a limit of 3,995.6 lb/hr on a 24-hour rolling average basis during startup.

V. BART Evaluation for Auxiliary Boiler

The auxiliary boiler is a #1 or #2 fuel-oil fired boiler with a nominal rating of 78 x 10^6 Btu/hr. The auxiliary boiler is normally only used when both units at the M.R. Young Station are down. During cold weather, the auxiliary boiler may be used if one unit is off line. During the baseline period (2000-2004), the auxiliary boiler was operated approximately 100 hours per year. Based on the estimated 100 hours per year of operation, the annual emissions from the unit were:

NO_x	0.56 tons
SO_2	1.2 tons
PM	0.06 tons

Based on the small quantity of emissions, it is apparent that no add-on control equipment will be cost effective. Any reduction in emissions will have virtually no effect on visibility impairment. Therefore, the Department proposes that BART is no additional controls. The current permit limits the fuel used in the boiler to #1 or #2 fuel oil. BART is the use of #1 or #2 fuel oil.

VI. BART Evaluation for Emergency Fire Pump and Diesel Generator

The fire pumps and emergency generator are powered by diesel engines and are used for emergency purposes only. Most of the emissions generated are due to testing and maintenance activities. During the baseline period (2000-2004), the fire pumps operated approximately 1.2 hours per year and the emergency generator operated approximately 30 hours per year.

Based on this utilization the estimated annual emissions are as follows:

Pollutant	Unit 1 Fire Pump (tons/yr)	Unit 2 Fire Pump (tons/yr)	Emergency Generator (tons/yr)
NO_x	0.04	0.03	0.17
SO_2	0.003	0.002	0.01
PM	0.003	0.002	0.01

Based on the small quantity of emissions, no add-on control equipment will be cost effective. Any reduction of emissions will not affect visibility impairment. Therefore, the Department proposes that BART is no additional controls.

VII. BART Evaluation for Materials Handling Sources

The materials handling sources at the M.R. Young Station that emit to the atmosphere are as follows:

EUI	**Description**	**Existing Control Equipment**	**Baseline Emissions (tons/yr)**
M1	Unit 1 crusher house and conveyor 1C	Rotoclone	0.4
M2	Unit 1 Coal Silos	Rotoclone	0.5
M3	Unit 2 Crusher House	Rotoclone	0.1
M4	Unit 2 Coal Silos	Rotoclone	2.2
M5	Unit 1 Flyash Silo	ESP	<1
M6	Unit 2 Flyash Silo	ESP	<1
M7	Unit 2 Lime Storage Silo	Bin Vent Filter	<1
M8	Unit 1 Truck Dump	None	10.4
M9	Unit 2 Truck Dump	None	18.8
M12	Lime Storage Silo	Baghouse	<1

Based on the small quantity emissions from the sources, it is apparent that no additional control equipment will be cost effective and will have very little impact on visibility in the Class I areas. Therefore, the Department proposes that BART for the materials handling units is no additional controls and the current emission limits for the units are BART.

VIII. Summary

	Proposed* BART Limit/Work Practice				Emissions Reduction** (tons/yr)		
Source Unit	**PM**	**SO_2**	**NO_x**	**Units**	**PM**	**SO_2**	**NO_x**

M3	---	---	---	lb/hr	0	---	---
M4	---	---	---	lb/hr	0	---	---
M5	---	---	---	lb/hr	0	---	---
M6	---	---	---	lb/hr	0	---	---
M7	---	---	---	lb/hr	0	---	---
M8	---	---	---	lb/hr	0	---	---
M9	---C	---	---	lb/hr	0	---	---
Total						28,805	13,121

* Emission limits for PM are a 3-hour average. The limits for SO_2 and NO_x are on a 30-day rolling average basis.

** Reductions from 2000-2004 average emission rate.

IX. Permit to Construct

The emission limits, monitoring, recordkeeping and reporting requirements will be included in a federally enforceable Air Pollution Control Permit to Construct that will be issued to the owner/operator of the facility. The Permit to Construct is included in Appendix D.

A. Monitoring

1. Monitoring for SO_2 and NO_x will be accomplished using continuous emission monitors which are installed and maintained as required by 40 CFR 75.

Monitoring for particulate matter shall be in accordance with 40 CFR 64, Compliance Assurance Monitoring.

2. For purposes of determining compliance with the SO_2 reduction requirement, the reduction efficiency shall be determined as follows:

$$\% \text{ Reduction} = \frac{\text{Inlet } SO_2 \text{ Rate} - \text{Outlet } SO_2 \text{ Rate}}{\text{Inlet } SO_2 \text{ Rate}} \times 100$$

Where:

Inlet SO_2 Rate is in units of lb/10^6 Btu.

Outlet SO_2 Rate is in the same units as the inlet SO_2 rate.

3. If Minnkota chooses to comply with the 95% reduction requirement at Unit 2, Minnkota may average the % reduction from Unit 1 and Unit 2 provided:

   A) The average reduction is at least 95% as determined in accordance with the following formula:

$$\text{Average ER} = \frac{[(ER_1)(HI_1)+(ER_2)(HI_2)]}{(HI_1 + HI_2)}$$

Where:

AER = Allowable Emission Rate (% reduction)
ER_1 = Actual Emission Rate (% reduction) of Unit 1 based on lb/10^6 Btu
ER_2 = Actual Emissions Rate (% reduction) of Unit 2 based on lb/10^6 Btu
HI_1 = Actual Heat Input (MMBtu) of Unit 1
HI_2 = Actual Heat Input (MMBtu) of Unit 2

Notes:
ER is a 30-day rolling average.
HI is a 30-day rolling average.
30-day rolling average is determined for the 30 successive boiler operating days (must be on a % reduction basis).

   B) The reduction by Unit 1 is at least 95%, and

   C) The reduction by Unit 2 is at least 90%.

B. Recordkeeping and Reporting

The owner/operator will be required to conduct recordkeeping and reporting as required by NDAC 33-15-14-06, Title V Permit to Operate and NDAC 33-15-21, Acid Rain Program (40 CFR 72, 75 and 76).

Attachment I - Best Available Control Technology Determination for Control of Nitrogen Oxides for M.R. Young Station Units 1 and 2

Part I: **High Dust SCR**

A. Technical Review

The SCR process is based on the chemical reduction of the NO_x molecule using a metal based catalyst with activated sites to increase the rate of the reduction reaction. A nitrogen based reducing agent (reagent), such as ammonia or urea, is injected into the post combustion flue gas. The reagent reacts selectively with the flue gas NO_x within a specific temperature range and in the presence of the catalyst and oxygen to reduce the NO_x molecule into molecular nitrogen and water vapor.[2]

The BART Guidelines[1] state that in order for SCR to be technically feasible, it must be both "available" and "applicable". SCR has been applied to the many different types of coal throughout the world. Based on its widespread usage, it would initially appear to be available for use at North Dakota power plants.

The BART Guidelines[1] also state that decisions regarding technical feasibility are made by comparing the physical and chemical characteristics of the exhaust gas stream from the unit under review to those of the unit from which the technology is being transferred. Unless significant differences between the source types exist that are pertinent to the successful operation of the control device, the control option is presumed to be technically feasible. In order to compare the flue gas streams where SCR has been successfully applied to the flue gas from units burning North Dakota (Fort Union) lignite, a comparison of the fuel (coal) characteristics is necessary.

EPA's Air Pollution Control Cost Manual[2] states: "Certain fuel constituents which are released during combustion act as catalyst poisons. Catalyst poisons include calcium oxide and magnesium oxide, potassium, sodium, arsenic, chlorine, fluorine, and lead. These constituents deactivate the catalyst by diffusing into active pore sites and occupying them irreversibly. Catalyst poisoning represents the main cause of catalyst deactivation.

Ammonia-sulfur salts, fly ash, and other particulate matter in the flue gas cause blinding, plugging or fouling of the catalyst. The particulate matter deposits on the surface and in the active pore sites of the catalyst. This results in a decrease of the number of sites available for NO_x reduction and an increase in flue gas pressure loss across the catalyst.

Impingement of particulate matter and high interstitial gas velocities erode the catalyst material. Catalysts with hardened leading edges or increased structural strength are less susceptible to erosion. Increasing catalyst strength through hardening, however, reduces the number of active pore sites."

The most significant problem for the successful operation of SCR catalysts on units that fire North Dakota lignite is the formation of low temperature sodium-potassium-calcium-magnesium sulfates and phosphates. Sodium is a significant contributor to the "stickiness" of the ash produced from firing North Dakota lignite. The sodium content of North Dakota lignite ash ranges from 2-13% with an average of approximately 4% for lignite combusted in North Dakota power plants from 2002-2006. Powder River Basin (PRB) coal from Wyoming typically averages around 1.5% sodium[3].

A review was conducted to compare the constituents of fuels for which SCR has been successfully applied to that of North Dakota lignite. Data was obtained from the U.S. Geological Survey's U.S. Coal Quality Database[3]. The results are shown in Table 1.

In order to properly compare flue gas conditions, an estimate of the total emission rate of the deactivation (fouling and poisoning) constituents can be made. Although the catalyst deactivation rate may not be directly proportional to the emission rates of the various constituents, it does provide a means of comparison of the flue gas characteristics.

AP-42, Compilation of Air Pollutant Emission Factors[4], lists the following particulate matter emission factors as shown in Table 2.

Table 2 AP-42 EMISSION FACTORS		
Combustion Unit Type	**Fuel**	**Emission Factor**
Cyclone	Lignite	6.7A[a]
Cyclone	Bit./Subbit.	2.0A
Wall/Tangential	Bit./Subbit.	10.0A
Wall	Lignite	6.5A
Tangential	Lignite	5.1A

A = Ash content of the coal (%)

To assess whether the flue gas characteristics at the North Dakota electric generating facilities are different from characteristics at other generating stations where SCR has been successfully applied, the emission rate, or loading, of the various deactivation constituents and the chemical form (organic or inorganic) of these constituents must be evaluated. Using the coal characteristics data from Table 1, the emission factors from Table 2, the emission rate of the deactivation constituents were calculated. Emphasis was given to the sodium oxide (Na_2O) emission rate because North Dakota lignite generally contains more Na_2O than bituminous or subbituminous coal. Since cyclone boilers firing North Dakota lignite partition the ash, the sodium is concentrated in the ash leaving the boiler. The results of the following calculation will underestimate the amount of sodium in the flue gas for a cyclone boiler firing North Dakota lignite; however, it does provide a conservative comparison. The results of the calculation are provided in Table 3:

[b] Source: USGS National Coal Database and University of Wyoming.

[c] Source: AP-42, Compilation of Air Pollutant Emission Factors except for cyclone units burning ND lignite; factor is based on stack test data.

[d] Emission factor for wall-fired and tangentially fired units combusting lignite is the average of the AP-42 emissions factors.

The most useful emission rate calculation is that in terms of pounds per wet standard cubic foot (lb/wscf). This estimated emission rate represents the actual concentration of the constituents in the ductwork leaving the boiler at standard temperature and pressure. However, most laboratory and pilot scale testing report the results in lb/dscf or mg/Nm^3. Table 3 shows that the potential for deactivation of the SCR catalyst is much greater for a boiler combusting North Dakota lignite.

The Energy & Environmental Research Center (EERC) at the University of North Dakota is recognized as one of the world's leading coal research facilities. Since 1951, the EERC has focused on research and development, technology demonstration and technology commercialization. As part of the BART assessment for Minnkota Power Cooperative and Basin Electric Power Cooperative, a report by the EERC titled Ash Impacts on SCR Catalyst Performance[5] was included. In that report, it is stated: "The ash deposition behavior of the lignites from North Dakota is the most complex and severe of any coals in the world, and installation of catalysts for NO_x reduction is going to be plagued with problems." The report further states: "Alkali and alkaline earth sulfates are enhanced by cyclone-fired systems. The cyclone firing results in partitioning of the ash between bottom slag and the body of the boiler. The sulfate forming materials are more concentrated in the fly ash as a result of cyclone firing."

In reviewing the flue gas characteristics of plants firing coal types where SCR has been applied with those firing North Dakota lignite, it appears comparison of the characteristics for cyclone fired units combusting North Dakota lignite to cyclone units firing other types of coal alone is more appropriate because of the enhanced sulfates formation in cyclone units. Likewise, it is appropriate to compare pulverized lignite fired units to pulverized units firing different types of coal. The Department's review indicates that the sodium oxide loading in the flue gas for the North Dakota lignite-fired unit would be nearly 24 times (on a lb/wscf basis) that of a cyclone unit burning PRB subbituminous coal. This ratio is actually conservative (expected to higher) because of the partitioning of the ash that occurs in a cyclone boiler firing North Dakota lignite. The estimated combined loading of catalyst deactivation constituents sodium oxide, calcium oxide, magnesium oxide and potassium oxide is more than eleven times that of PRB subbituminous coal-fired cyclone units. For pulverized units, a unit firing North Dakota lignite is expected to emit three times as much sodium oxide as a unit firing PRB subbituminous coal. Although the deactivation of the SCR catalyst may not be directly proportional to the emission rate, it is evident that the concentration of various SCR deactivation chemical constituents in the flue gas of a North Dakota lignite-fired power plant is much different from a unit firing PRB subbituminous coal or other types of coal.

Gutberlet[6] in his technical paper on deactivation of SCR catalyst states: "Alkaline metals chemically attach to active catalyst pore sites and cause blinding. Sodium (Na) and potassium (K) are of prime concern especially in their water soluble forms which are mobile and penetrate into the catalyst pores." Minnkota, in its March 19, 2007 response to questions indicates that most sodium in North Dakota lignite is organically associated. Combustion of the organically associated sodium produces soluble sodium compounds that are readily available for reactions with catalysts and flue gas species. Minnkota also stated that in a conversation with Fleming Hansen of Haldor Topsoe (see Minnkota's November 9, 2007 response to comments[10]), Mr. Hansen indicated that sodium was a major concern and that it causes deactivation, especially in the organically associated form. It is evident to the Department that the form (soluble) of sodium present in the ash from the combustion of North Dakota lignite will deactivate an SCR much more quickly than the other types of coals where SCR has been successful.

The next issue to address is whether the difference in these characteristics would preclude the successful use or reasonable operation of SCR technology on units fired on North Dakota lignite.

The BART Guidelines[1] state: "In Step 2, you evaluate the technical feasibility of the control options you identified in Step 1. You should document a demonstration of technical infeasibility and should explain, based on physical, chemical, or engineering principles, why technical difficulties would preclude the successful use of the control option on the emissions unit under review." "An available technology is applicable if it can reasonably be installed and operated on the source type under consideration." The BART Guideline[1] does not define successful use of the control option or reasonably be installed and operated.

The EERC, several utilities and catalyst vendors conducted pilot scale testing at the Coyote Station, which is a cyclone fired unit that combusts North Dakota lignite. The pilot scale SCR deployed at the Coyote Station was plugged and the catalyst pores deactivated after 2 months (approx. 1430 hours). The Department believes "successful use or reasonably operated" is considerably more than a few thousand hours of operation. For example, the EPA Air Pollution Control Cost Manual[2] states: "For coal-fired boiler applications, SCR catalyst vendors typically guarantee that catalyst for an operating life ranging between 10,000 hours to 30,000 hours." In the technical paper Nitrogen Oxides Emission Control Options for Coal Fired Electric Utility Boilers,[9] it is stated: "On dry-bottom, coal-fired U.S. boilers equipped with full SCR, the planned time between catalyst changes on a typical unit is typically > 24,000 operating hours or ≥ 3 years of operations." The paper also indicated that Merrimack 2, a cyclone boiler with 100% flyash reinjection, the expected time between the replacement of layers is 14,000 operating hours. It appears that 10,000 hours of operation would be a minimum time for successful use or reasonable operation.

Pritchard[7] states in his paper on optimizing SCR catalyst design: "Our experience show that coal-fired SCRs are successful when the system impact and catalyst deterioration factors are understood and specific counter measures are implemented in system and catalyst design." The Coyote pilot test may not have provided much useful data for designing an SCR system for plants firing North Dakota lignite; however, it did indicate a difference between lignite and subbituminous coal. The pilot scale testing protocol was the same for the Coyote Station, Columbia Station and Baldwin Station; however, the test at the Columbia Station used a different catalyst. The Coyote Station combusts lignite while the Columbia Station and Baldwin Station fire subbituminous coal. The EERC has described the blinding and plugging (deactivation) at the Coyote Station as extremely rapid and severe as compared to testing at the Columbia and Baldwin Stations. This indicates to the Department that design of an SCR system for North Dakota lignite would be different from a unit burning subbituminous coal. Because of the lack of deactivation data from the pilot test at the Coyote Station, it would appear to be extremely difficult to design an SCR system that could be successfully used or reasonably operated. Proceeding with installation of such a design without engineering data collected during appropriate pilot testing is subject to an extreme risk. This suggests to the Department that additional research and testing on the effects of the flue gas constituents are required to design a high dust SCR system.

Kling et. al.[11] conducted pilot and bench sale testing of SCR catalysts when subjected to the flue gas from the combustion of biomass. The testing was conducted using three different types of catalyst. Catalyst Type A was typical of that use for coal-fired boilers, Type B was a "bio-optimized" catalyst with an increased vanadium content and Type C has a very high vanadium content. Kling[11] and later Zheng et. al[12] have concluded that it is the alkali aerosols that are less than or equal to 0.1 micrometers that cause most of the catalyst deactivation. In North Dakota lignite, the alkali metals are generally associated with the organic matter of the lignite while in other coals the alkaline constituents are associated with the inorganic portion of the coal (e.g. clays). The combustion of the organically associated alkaline elements causes them to vaporize; when they condense they form submicron aerosols. The combustion of inorganically associated alkalis causes only a small portion to vaporize. Minnkota has supplied information that indicates these condensed alkali aerosols have a mass mean diameter of approximately 0.1 micrometers. Therefore, 50% of the aerosols would be less than 0.1 micrometers in size on a mass basis. The mass of sodium oxide and potassium oxide leaving a pulverized boiler combusting North Dakota lignite would average 1.55×10^{-5} lb/dscf (266 mg/Nm^3) and 2.11×10^{-6} lb/dscf (36 mg/Nm^3), respectively. This value would be higher for cyclone boilers (431 and 59 mg/Nm^3 respectively).

Crespi[13] has provided data that suggests potassium oxide is approximately twice as potent catalyst deactivation chemical on a molar basis (1.3 times on a mass basis) than sodium oxide. The equivalent potassium oxide emission rate for a pulverized boiler based on this data would be 241 mg/Nm^3. The aerosols are most likely in the sulfate form. This would lead to an equivalent potassium sulfate emission rate of 446 mg/Nm^3.

Kling[11] found a deactivation rate of 21-52% over 1500 hours for fuel made up of tree bark and 30% demolition wood waste. This fuel had a potassium chloride loading of 16.7 mg/Nm^3 and a sodium chloride loading of 5.8 mg/Nm^3. The Kling results were for aerosols with an aerodynamic diameter of less than 0.1 micrometers. If all of the sodium and potassium in lignite vaporizes, 50% of the total loading would be less than or equal to 0.1 micrometers or 223 mg/Nm^3 for a pulverized unit. Zheng[12] has suggested that potassium chloride is two and one half times more potent catalyst poison than potassium sulfate (0.4% per day versus 1% per day). An equivalent loading of sodium and potassium for North Dakota lignite as potassium chloride would be 89 mg/Nm^3. This loading is more than four times that of the Kling[11] testing. For a cyclone boiler it would be approximately seven times as much loading. The Kling[11] results suggest 2,885-7,140 hours until 100% deactivation. The higher loading at the North Dakota facilities suggests a much shorter catalyst life.

Zheng et. al.[11] found a catalyst deactivation rate of 0.4% per day for a potassium sulfate. The testing was conducted using a concentration of 20-30 mg/Nm^3 of potassium sulfate with a mass mean diameter of 0.55 micrometers. Although data is not available to determine the loading of aerosols with a diameter less than 0.55 micrometers for all boilers burning North Dakota lignite, a comparison to the fraction less than 0.1 micrometers indicates a concentration is 7-11 times larger than the concentration in Zheng's tests. The 0.4% deactivation rate per day is equivalent to 6000 hours at 100% deactivation. Flue gas from the combustion of North Dakota lignite in a pulverized boiler would likely produce a much higher deactivation rate. A cyclone boiler would probably deactivate an SCR catalyst even faster.

The recent testing by Kling[11] and Zheng[12] indicate that it is unlikely to achieve 10,000 hours of catalyst life when combusting North Dakota lignite. In fact, the catalyst life could be only a few thousand hours as suggested by the pilot scale testing at the Coyote Station.

Besides catalyst deactivation, a high-dust SCR would experience plugging problems due to ash deposition and the carryover of "popcorn ash" from the boiler. Ash deposition is a problem for all units firing North Dakota lignite. Sodium is a significant contributor to the "stickiness" of the ash. Since the ash of North Dakota lignite contains much more sodium than other types of coal where SCR has been applied, deposition problems will be greatly increased. Since this sticky ash is not easily removed, the catalyst life could be severely reduced.

The flue gas temperature variation at the location a high dust SCR would be placed is also a concern for cyclone units. Minnkota indicates that the temperature generally ranges from approximately 430°F to 960°F for Unit 1 depending on the unit's load. For Unit 2, it could vary from 430-880°F. However, temperatures as high as 1050°F at Unit 1 and 990°F at Unit 2 have been measured. Basin Electric has indicated that the Unit 2 temperature can be significantly higher than 750°F.

The <u>EPA Air Pollution Control Cost Manual</u>[2] states:
"The NO_x reduction reaction is effective only within a given temperature range. The use of a catalyst in the SCR process lowers the temperature range required to maximize the NO_x reduction reaction. At temperatures below the specified range, the reaction kinetics decrease and ammonia passes through the boiler (ammonia slip). At temperatures above the specified range, nitrous oxide (N_2O) forms and catalyst sintering and deactivation occurs.

In an SCR system, the optimum temperature depends on both the type of catalyst utilized in the process and the flue gas composition. For the majority of commercial catalysts (metal oxides), the optimum temperatures for the SCR process range from 480°F to 800°F (250°C to 427°C). The figure shows that the rate of the NO_x removal increases with temperatures up to a maximum between 700°F to 750°F (370°C to 400°C)" (figure omitted here).

The Control Cost Manual[2] goes on to state: "The relationships between flue gas temperature, catalyst volume, and NO_x removal are complicated functions of the catalyst formulation and configuration. The physical and chemical properties of each catalyst are optimized for different operating conditions. For a given catalyst formulation, the required catalyst volume and/or temperature range can even change from one manufacturer of the catalyst to another. The selection of catalyst, therefore, is critical to the operation and performance of the SCR system."

This complicated relationship suggests that additional research, design and testing may be required before the temperature problem could be overcome for cyclone units.

The final reason for technical infeasibility is erosion of the catalyst. Because of the high ash content and frequent cleaning cycles due to the deposition characteristics of North Dakota lignite ash, erosion may be more of a concern than with a bituminous or subbituminous coal-fired unit.

The BART assessments for Minnkota and Basin Electric were prepared by Burns and McDonnell, which has considerable experience with SCR systems, and the EERC, which has extensive experience with North Dakota lignite. Sargent and Lundy, LLC (S&L), another consulting firm acting on behalf of Basin Electric Power Cooperative, also made two presentations to the Department on the application of SCR technology to North Dakota lignite. S&L indicated it had designed 46% of the SCR systems in the United States. Of the SCR systems, 39 were for coal-fired units with 10 designed for Powder River Basin subbituminous coal. S&L listed[8] their "Keys to Achieving Success" as:

- Understand deactivation mechanisms
- Understand ash behavior
- The "Understanding" establishes:
  - Catalyst formulation
  - Catalyst pitch
  - Reactor velocity
  - Catalyst surface and volume
- Results in reactor size and shape to match catalyst management plan
- Physical model for:
  - NH_3 and NO_x mixing
  - Gas distribution and velocity profile
- CFD modeling:
  - Identify and mitigate areas of potential ash deposits
  - Mixing gases of different temperatures

S&L also provided possible solutions for deactivation of the catalyst. However, they indicated there was no known solution for deactivation due to soluble alkalis such as the soluble sodium compounds generated by the combustion of North Dakota lignite. S&L speculated that more catalyst and a larger reactor may be possible solutions; however, how much more catalyst or how much larger the reactor would have to be to solve the problem was unknown. S&L also pointed out that some design issues for North Dakota have not been addressed by Powder River Basin experience. Some of these issues include:

- The high level of soluble alkali in North Dakota lignite
- The particle size and sticky nature of high alkaline North Dakota lignite
- Potential abrasive qualities of North Dakota lignite ash

S&L concluded their presentation with the following statement about North Dakota lignite: "There are attributes of this fuel in an SCR environment that are not well understood today and need more investigation to predict its performance." S&L recommendations included a parametric pilot test program to:

Answer questions on:

- soluble alkalis
- ash characteristics
- size
- stickiness
- abrasive qualities
- Compare findings with PRB experience.

The BART Guidelines[1] describe the process commonly used for bringing a control technology concept to reality as a commercial product as follows:

- concept stage
- research and patenting
- bench scale or laboratory testing
- pilot scale testing
- licensing and commercial demonstration
- commercial sales

The BART Guidelines[1] go on to state "A control technique is considered available within the context presented above, if it has reached the stage of licensing and commercial availability. Similarly, we do not expect a source owner to conduct extended trials to learn how to apply a technology on a totally new and dissimilar source type. Consequently, you would not consider technologies in the pilot scale testing stages of development as "available" for purposes of BART review."

"Commercial availability by itself, however is not necessarily a sufficient basis for concluding a technology to be applicable and therefore technically feasible. Technical feasibility, as determined in Step 2, also means a control option may reasonably be deployed on or "applicable" to the source type under consideration."

B. Summary:

The characteristics of the exhaust, or flue gas stream, after combustion of fuel by a boiler are governed by the design and operating characteristics of the boiler and the characteristics of the fuel. In this scenario, the fuel is North Dakota (Fort Union) lignite. The BART applicants concluded in their BART analyses that available SCR catalysts are not applicable for their unit(s).

One foremost issue in the NO_x BART analyses is whether any unique characteristics due to lignite fired by the boilers are cause for doubt that known SCR technology is not applicable and technically infeasible. We note that plugging of a catalyst on its face due to deposition of particles larger than the pitch of a catalyst (a.k.a. catalyst channel blockage) and plugging of pores on surfaces of a catalyst are generally different physical interactions. Our review of the supplemental information (see Minnkota BACT analysis[10]) concludes that the following facts are not disputed by EPA.

1) In cyclone firing of Fort Union lignite, about 45 - 50% of the ash forming components of the coal end up as flue-gas ash. For wall-fired and tangentially fired units, 25 - 35% of the ash ends up in the flue gas. Unburned or partially burned organic fraction of the Fort Union lignite, which contains more sodium than other coals, reacts with silicate particles causing a "stickiness" quality of flue gas ash, which results in ash deposits on heat transfer surfaces. And larger particles fracture from heat-transfer surfaces (a.k.a. popcorn ash) and enter the flue gas stream. Consequently, deposition on surfaces of catalytic reactors occurs and rates of deposition are higher.

2) Fort Union lignite has a higher moisture content and is oxygen rich compared to other coal types. This lignite also has a higher sulfur content compared to PRB coal. Consequently, the flue gas stream is rich in sulfur dioxide (SO_2) and sulfate (SO_4) compared to other coal types.

3) Fort Union lignite has a higher organic matter content. This lignite contains a higher proportion of alkali metal constituents, especially sodium (Na). Cyclone combustion of the coal produces ash, which is partitioned as slag on high temperature boiler surfaces and as flue gas vapor and fine particles (less than 15 micrometers (microns)). About 75% of total sodium in the lignite is associated with the organic fraction of the lignite; so very little of the sodium is associated with the mineral fraction of the lignite such as clays. During combustion, organic and water-soluble sodium vaporizes. Consequently, combustion of the coal leads to higher flue-gas concentrations of alkali metals in vapor form.

4) Alkali vapors condense (homogeneous nucleation) due to flue-gas cooling or react (heterogeneous nucleation) with other flue gas constituents, e.g., mineral silicates and sulfate. The size distribution of flue gas particles is bi-modal, relating to organically associated inorganics in coal and coalesced minerals and inorganics in flue gas; the size distribution varies by coal type and combustion method.

5) NO_x reduction occurs on the flat surfaces of a catalyst and in pores within the flat surfaces. The pores are open to the flue gas passing through the catalyst reactor. Condensed vapors, alkali sulfates and alkaline-earth oxides and silicates are minute particles (less than 1 microns), which enter pores of the catalyst (a.k.a. plugging) and prevent catalytic reaction with NO_x. Residual alkali vapors, Na, potassium (K) and calcium (Ca) displace hydrogen (H) on fresh catalyst, which prevents catalytic reaction with NO_x (a.k.a poisoning) and reacts with sulfate to cause blinding of catalyst surfaces. Pore condensation of sodium also causes catalyst deactivation, which is a major deactivation mechanism. The rate of catalyst deactivation depends on the concentration and form of alkali in the flue gas; higher Na and K accelerate catalyst poisoning, blinding and plugging, which requires more frequent catalyst maintenance.

6) There are no SCR systems planned, constructed or operating in the flue gas stream of boilers fired with Fort Union lignite. Fort Union lignite has some coal characteristics that are uniquely different than Gulf Coast lignites, such as the larger proportion of organic matter and association of alkali, sodium specifically, with that organic matter.

7) Slipstream SCR reactors of the same design were installed at three power plants to test SCR for NO_x emissions control. One of the plants was cyclone fired with Fort Union lignite and the others with subbituminous coal. Deposition on the reactor surface after two months using the lignite was significantly greater; the deposits were rich in sodium, calcium and sulfur. The tests confirmed catalyst blinding and plugging, but did not provide rates for catalyst deactivation. Tests also indicated that the deposits causing blinding and plugging of pores contained more sodium compared to PRB coal.

8) There may be an engineering solution to reduce deposition on the surface of catalytic reactors. But there is no known in-reactor engineering solution to:

(a) reduce deactivation rates caused by heterogeneous reactions that form the particles that cause pore blinding and plugging, or

(b) to restore the catalytic reactions by removing particles from catalyst pores.

9) There are no usable data for rates of deactivation of SCR catalyst in the flue gas from combustion of Fort Union lignite. Catalyst pitch is the only apparent catalyst geometric affecting ash deposition; but pitch also affects flue gas velocity through the reactor and, thus, times of exposure of NO_x for reduction to nitrogen (N_2) and water (H_20).

10) The BART Guidelines[1] do not provide specific numeric performance measures that an SCR NO_x control technology must achieve to satisfy the guideline's applicable (technically feasible) criteria.

11) The State of Louisiana recently determined that high dust SCR was not technically feasible for an activated carbon plant which utilizes lignite in the process because of the flue gas characteristics (high alkaline compounds) that will deactivate the catalyst.

Companion issues including ammonia slip and pyrosulfates emitted from a high-dust SCR will exaggerate flue-gas particulate (ash) deposits on low-temperature convective pass surfaces in the economizer and the primary air pre-heaters.

C. Conclusions:

The Department has completed an extensive review of all aspects of the application of SCR technology to the North Dakota power plants. Whether the problems associated with adapting SCR technology to a unit firing North Dakota lignite can be overcome is highly speculative.

The Department makes the following conclusions:

1) North Dakota lignite is extremely variable in heat content, ash content, and in the constituents that make up the ash. This variability will affect the design and operation of an SCR system.

2) The only pilot scale testing that has ever been conducted on a unit firing North Dakota lignite was at the Coyote Station. The pilot scale SCR plugged after only 2 months and little useful data was obtained. However, the testing used the same protocol as testing at the Columbia and Baldwin Station which had fewer problems. The Columbia and Baldwin Stations burn subbituminous coal. The Coyote testing demonstrates to the Department that North Dakota lignite firing will have more severe effects (plugging and catalyst deactivation) than units firing subbituminous coal when the same design is employed. Operation of an SCR

system for only 2 months between catalyst change out is much less time than is normally expected (at least 10,000 hours or 13.7 months) for power plants. Operation of an SCR system for only 2 months between catalyst replacement is not considered successful use or reasonable operation of SCR technology.

3) North Dakota lignite contains primarily organic sodium compounds. The combustion of the lignite produces soluble sodium compounds which causes more severe catalyst deactivation problems than insoluble sodium compounds.

4) The flue gas constituents that cause SCR catalyst deactivation at North Dakota power plants are significantly different from Texas lignite, Wyoming PRB subbituminous coal, and Pennsylvania bituminous coal. When cyclone boilers combusting North Dakota lignite are compared to any other type of combustion unit burning the other types of coal, the concentration of sodium compounds in the flue gas is at nearly five times greater (based on average coal and lb/wscf basis) than the other types of fuel and the total primary alkali constituents (CaO, Na_2O, MgO and K_2O) are approximately double. When pulverized units firing North Dakota lignite are compared to pulverized units firing other coals, the sodium ratio is approximately three times and the total primary alkali constituents ratio is approximately 1.4. The flue gas generated at North Dakota power plants is different from the flue gas at any plant where SCR technology has been applied, primarily due to the high concentration of soluble sodium compounds and the total flue gas loading of catalyst deactivation chemicals. Recent testing by Kling[11] and Zheng[12] suggest that it may not be possible to obtain 10,000 hours of catalyst life and probably much less than 10,000 hours. This difference in flue gas characteristics will preclude the successful use or reasonable operation of existing SCR technology at these units. Additional pilot scale testing is necessary to learn if the technology can be adapted.

5) Both Burns and McDonnell and Sargent and Lundy have extensive experience with the design and operation of SCR systems. Burns and McDonnell has expressed concerns whether an SCR system can be successfully designed and operated at a boiler combusting North Dakota lignite. S&L has indicated that certain design issues have not been addressed by PRB (subbituminous coal) experience. They have also indicated that some important unanswered questions pose significant risks for an SCR design engineer and recommended pilot scale testing before design takes place. The questions left unanswered include:

- High level of soluble alkali in North Dakota lignite
- Particle size and sticky nature of high alkaline North Dakota lignite ash
- Potential abrasive qualities of North Dakota lignite ash

6) The BART Guidelines[1] list the stages in the development of a commercial control system from concept stage to commercial sales. Experimentation with the SCR system takes place during the bench scale/laboratory testing or pilot scale testing stages. Although adjustments of full scale (commercial product) units is often necessary, the source operator should not be required at this stage to conduct

experimentation in order to make the equipment work. This could cause extended time delays and resource penalties for the source operator. To design and install an SCR system for a unit firing North Dakota lignite without obtaining additional data from bench scale or pilot scale testing would be experimentation.

7) The temperature variation of the flue gas at cyclone units entering the SCR will adversely affect performance and must be resolved for successful application of this technology. Engineering studies will be required to determine if this problem can be resolved. Minnkota and Basin Electric are not required to experience extended time delays or resource penalties to allow research to be conducted. Neither are they required to experience extended trials to learn how to apply a technology. The temperature problems for the SCR will require extensive, and correspondingly expensive, engineering studies to determine if this problem can be resolved.

8) There are unresolved issues regarding catalyst erosion from the ash. Recent pilot scale testing will have to be evaluated to determine if the erosion problems are resolvable.

9) Poisoning, blinding and plugging of a catalyst are affected by the geometries and properties of the catalyst. Firing of Fort Union lignite results in a flue gas stream that highly accelerates poisoning, blinding and plugging (of pores) due to the rich sodium and potassium vapors, particles and ammonium sulfates (due to ammonia injection) in lignite-fired flue gas. The engineering solutions of a larger SCR reactor, more catalyst and larger pitch do not resolve the rapid plugging of catalyst pores, at least with some certainty to assure a predictable useful life of catalyst before change out. There is no catalyst vendor solution to reduce or eliminate catalyst pore plugging. The chemical and physical process of pore plugging cannot be reversed, which dictates catalyst change out.

10) Without pilot scale testing, the long term NO_x reduction efficiency, the volume of the reactor, the catalyst pitch, life of the catalyst, or even the type of catalyst to be used cannot be predicted with a high degree of confidence. Sargent and Lundy has pointed out that to design an SCR system for a plant burning North Dakota lignite without pilot scale testing would present significant risks for the SCR design engineer. Without these design factors determined, any cost estimate would be conjecture and any evaluation of cost effectiveness or incremental cost in Step 4 of the BART analysis would be meaningless. The BART sources are not required to conduct pilot testing to obtain this data.

Therefore, the Department has determined, based on guidance in 40 CFR 51, Appendix Y[1], that high dust SCR technology is not available and thus not technically feasible at this time for units combusting North Dakota lignite.

Part II. **Low Dust and Tail Gas SCR**

A. Introduction

Selective catalytic reduction (SCR) systems that are placed downstream of the particulate matter (PM) and sulfur dioxide (SO_2) central systems are generally referred to as tail end SCR. Tail end SCR systems have been used on coal-fired and biomass fired boilers in the United States as well as other countries. However, no SCR system including a tail end SCR, has ever been operated on a boiler firing North Dakota lignite. The flue gas produced by the combustion of North Dakota lignite contains high concentrations of alkali aerosols (primarily sodium and potassium). Cyclone boilers, such as the two units at the M.R. Young Station, produce higher concentrations of submicron aerosols than conventional pulverized or fluidized bed boilers. The higher temperature in the cyclone boilers vaporizes the organically associated sodium and potassium in North Dakota lignite. When these elements condense, they form submicron aerosols. Minnkota[14] (page 12) has indicated that the condensed vapors have a mean diameter of approximately 0.1 micrometers. Papers by Kling[11] and Zheng[12] have indicated that the aerosols with a diameter less than or equal to 0.1 micrometers cause the greatest catalyst deactivation.

The NSR Manual[1] states that decisions regarding technically feasibility are made by comparing the physical and chemical characteristics of the exhaust gas stream from the unit under review to those of the unit from which the technology is being transferred. Unless significant differences between the source types exist that are pertinent to the successful operation of the control device, the control option is presumed to be technically feasible unless the source can present information to the contrary.

Since no low dust or tail end SCR system has even been applied to a boiler that combusts North Dakota lignite, an evaluation of the flue gas characteristics was made to determine if they were substantially different from facilities that have successfully applied SCR technology or to determine if empirical data would indicate whether LDSCR or TESCR can be successfully applied.

B. Flue Gas Characteristics

The Minnkota lignite represents the worst-cast for the evaluation of low dust or tail SCR application to a unit combusting North Dakota lignite. At the M.R. Young Station, both units use an electrostatic precipitator (ESP) to control PM emissions. Unit 2 is equipped with a wet scrubber to control SO_2 emissions while a wet scrubber will be constructed for Unit 1. Minnkota[15] (p. 20) as part of their BACT analysis has provided an analysis of the particulate matter emitted from Unit 2. The analysis indicated the PM was 6.56% sodium (Na), 2.26% potassium (K), 5.71% sulfur (S), 57.52% oxygen (O) and the remaining other elements.

The form of the sodium and potassium is most likely in sulfate form[16] (p. 32). If all of the sodium and potassium are in the sulfate form, sodium sulfate and potassium sulfate would compromise approximately 25% of the total particulate matter emitted from Unit 2. Minnkota has indicated that the sample of the particulate matter that was analyzed was obtained while some flue gas was bypassing the SO_2 scrubber. The amount of sodium, potassium and/or sulfur in the sample could be biased high when compared to a sample when all flue gas passes through the wet scrubber.

A review of the latest PM stack tests at M.R. Young Unit 2 (8/07 and 5/08) indicated an average PM emission rate of 10.61 milligrams per normal cubic meter (mg/Nm^3). Based on 25% of the PM being sodium and potassium sulfate, the combined emission rate of these two compounds is approximately 2.7 mg/Nm^3. This indicates a sodium and potassium removal efficiency of greater than 99% by the ESP and wet scrubber.

Minnkota has submitted data from a study by Markowski[16] (p. 31) which indicated that approximately 81% of the sulfate emitted is less than 1.1 micrometers in size and approximately 36% is less than 0.26 micrometers in size. Based on the latest stack tests and the Markowski data, the submicron sodium sulfate plus potassium sulfate emission rate would be less than 2.2 mg/Nm^3 and the emission rate of sodium and potassium sulfate less than 0.26 micrometers in size would be approximately 1.0 mg/Nm^3. These values are similar to those Markowski reported which were 1.335 mg/m^3 and 0.602 mg/m^3 respectively.

C. Catalyst Deactivation

The two primary flue gas constituents that will cause SCR catalyst deactivation in a tail end configuration are sodium and potassium, most likely in sulfate form[16] (p.32-35). Crespi[17] (et.al.), in their paper regarding the Amager Station, presented a graph which shows the effect of various poisons on the activity of vanadia – titania catalysts. Minnkota[14] (page 21) provided similar information that indicates that potassium oxide is a more potent catalyst poison on a molar basis than sodium oxide. Although no actual data is supplied, analysis of the graph indicates that potassium oxide is 1.7[17] – 2.0[18] times more potent catalyst poison than sodium oxide (on a molar basis) up to a vanadium/titanium to poison ratio of 0.6. Because potassium oxide has a larger molecular weight than sodium oxide, the poisoning ratio is 1.1 – 1.3 on a mass basis.

As indicated earlier, Kling[11] and Zheng[12] have indicated that the aerosols less than or equal to 0.1 micrometers cause the catalyst deactivation. Data are not available to calculate the portions of the PM emissions from Unit 2 that would be less than or equal to 0.1 micrometers. A conservative assumption is that all of the sodium and potassium sulfate less than 0.26 micrometers is less than or equal to 0.1 micrometers. The total emission rate for sodium and potassium sulfate combined is estimated at less than 1.0 mg/Nm^3 of which 0.78 mg/Nm^3 is sodium sulfate and 0.20 mg/Nm^3 is potassium sulfate based on the filter analysis submitted by Minnkota[15].

Kling[11] has provided catalyst deactivation rates for varies biomass fuels which produce a flue gas that contains sodium and potassium aerosols. The testing was conducted using different types of honeycomb W_2O_5/TiO_2 SCR catalyst. Type A catalyst was catalyst typically applied at coal-fired power plants, Type B was a "bio-optimized" catalyst with increased vanadium content, and Type C had an even higher vanadium content.

For a mixture of peat and 15% wood, the flue gas contained 4.4 mg/Nm^3 of potassium chloride and 0.8 mg/Nm^3 of sodium chloride aerosols with an aerodynamic particle diameter less than 0.1 micrometers.

	Peat + 15% Wood*	Center Lignite**
Potassium (mg/Nm^3)	4.4	0.20
Sodium (mg/Nm^3)	0.8	0.78

*As chloride
**As sulfate

The maximum deactivation rate was 12% in 768 hours using Type A catalyst. Another result indicated 15% deactivation in 1488 hours using Type B catalyst. The shorter test on peat plus 15% wood indicates 6400 hours to 100% deactivation while the longer test indicates 9920 hours to 100% deactivation. Regarding the deactivation rates, Kling[11] et.al stated "Exposure of this kind of short samples gives a larger deactivation compared to a full-length catalyst [1,4] that is mainly a consequence of turbulence of the inlet of the catalyst, before laminar flow is attained."

The flue gas concentration of sodium from Center lignite is similar to that of the peat plus 15% wood; however, the potassium content is approximately 17 times lower. Zheng[12] has reported that potassium chloride has an SCR catalyst deactivation rate of 1% per day versus 0.4% per day for potassium sulfate, or 2½ times more. It appears the catalyst life for an SCR at M.R. Young Station would be substantially longer than that estimated for peat plus 15% wood.

Zheng et.al.[12] found a deactivation rate of 0.4% per day for potassium sulfate or 6,000 hours to 100% deactivation. The testing was conducted at a loading of 20-30 mg/Nm^3. The aerosols varied in size from 0.07 micrometers to 1.05 micrometers with a mass mean diameter of 0.55 micrometers. The Markowski data indicates that approximately 53% of outlet sulfate was less than or equal to 0.52 micrometers. Based on the latest stack tests at M.R. Young Unit 2, this equates to an emission rate of approximately 1.4 mg/Nm^3 for those sodium and potassium sulfate aerosols less than 0.52 micrometers. The Minnkota emission rate is substantially less (14-21 times) than the Zheng testing. Again, this does not consider the fact that potassium sulfate is a more potent catalyst poison than sodium sulfate. This suggests that a much longer catalyst life is possible for North Dakota lignite.

For a LDSCR application, the only air pollution control device prior to SCR will be a dry electrostatic precipitator (ESP). Stack test results from the FINE Particles – Technology, Environmental and Health Technology Programme[20] suggests that an ESP on a biomass boiler will have a control efficiency of greater than 90% for submicron particles and can achieve greater than 96% for particles less than 0.1 micrometers in size. This is consistent with AP-42[4] data for Kraft recovery boilers which indicates an ESP can remove more than 98% of the submicron particulate matter in the flue gas which is primarily sodium sulfate[21]. Similar results are reported for coal-fired/biomass boilers by Mohr[22], Lind[23] and the Power Station Emissions Hanbook[24]. This indicates that most of the submicron sodium and potassium aerosols, including those aerosols less than 0.1 micrometers in size, will be removed by electrostatic precipitators.

Minnkota has submitted data on the ash composition that accumulate on the electrodes of the Power Span ECO electrodes during a pilot test[14] (p. 26). The data suggests that the sodium and potassium concentration in the particulate matter downstream of the Unit I ESP is higher than the concentration in the particulate matter downstream of the Unit II wet scrubber. However, the concentration is less than a factor of two higher. The total loading of sodium and potassium, as indicated by the data submitted by Minnkota, would still be considerably less than the loadings in the Kling[11] and Zheng[12] tests. This suggests that the catalyze deactivation rate of LDSCR and MRYS should be lower than in the referenced tests.

D. Vendor Information

The U.S. Department of Justice, through their contractor Mr. Hans Hartenstein, has provided emails from various catalyst and SCR system providers[19] as part of Minnkota BACT process. Each of the responses from the vendors indicated that tail end SCR is technically feasible for the Milton R. Young Station.

The Department contacted three of the vendors, Ceram Environmental, Haldor Topsoe and Babcock Power. The companies generally confirmed the information in the emails to Mr. Hartenstein. Babcock Power indicated they had no worries about getting 10,000 hours of catalyst life at the M.R. Young Station. However, they recommended “coupon” testing prior to design of the SCR. Ceram was convinced it was technically feasible; however, their representative did acknowledge that if the sodium and potassium aerosols are making it through the ESP and wet scrubber, catalyst deactivation could be a problem. Haldor Topsoe indicated that the catalyst deactivation at M.R. Young would be manageable if the catalyst is kept dry during outages. Although no written guarantees have been provided by the vendors, it appears that vendors are willing to provide them for a tail end SCR at the M.R. Young Station.

E. Similar Facilities using SCR

There are no boilers that combust North Dakota lignite and are equipped with SCR technology. In general, other U.S. coals are much lower in the organically associated alkalis that cause SCR catalyst deactivation. Biomass fired boilers would have flue gas characteristics that more closely approximate those from North Dakota lignite. At least four biomass boilers that are equipped with tail end or low dust SCR are currently in operation.

These include:

- Whitefield Power & Light, New Hampshire – Boiler uses whole tree chips and has operated since October 2004.

- Bridgewater Power, New Hampshire – Boiler uses whole tree chips and has operated since October 2007.

- Pine Tree Power, New Hampshire.
- Boralex Stratton, Main – Boiler was whole tree chips, waste wood, and construction and demolition waste. The boiler has operated since December 2004.

The Department is also aware of proposed installation at the Burlington Electric Plant in Vermont, Synterprise Global Solutions in Tennessee and the Amager Heat and Power Plant near Copenhagen, Denmark. The Amager Station is also allowed to burn coal and may not be required to operate the SCR when combusting biomass.

Although there are boilers that combust 100% biomass and utilize SCR for NO_x control, there is very little information about the actual loading of potassium and sodium aerosols at the inlet to the SCR. The New Hampshire Department of Environmental Services (NHDES) was contacted regarding the biomass boilers that use low dust/tail end SCR. The Whitefield Power Plant is a 16 MWe spreader stoker that is equipped with a multiclone and electrostatic precipitator for particulate matter control. The NHDES confirmed the boiler had been operating for approximately four years. NHDES was not aware of any catalyst deactivation problems at this facility. The plant has a NO_x emission limit of 0.075 lb/10^6 Btu. The other facilities in New Hampshire are similar; however, they are not operated as long. No data was available regarding the loading of potassium and sodium at the inlet of the SCR.

F. Conclusions

The Department has concluded that an SCR system must have a catalyst life of at least 10,000 before SCR technology could be deemed successfully applied to the source. No data has been found from an actual operating facility which has similar flue gas characteristics to M.R. Young Station for applying high dust, low dust or tail end SCR. However, experimental and pilot scale testing by Kling[11] provides a good comparison for a low dust or tail end SCR. The total sodium and potassium loading of aerosols less than 0.1 micrometers expected at the inlet of a tail end SCR at M.R. Young Station is expected to be at least 5 times less than found is Kling tests on peat plus 15% wood. Kling's data indicated up to 9920 hours of catalyst life for catalyst type B. Zheng's[12] data suggested 6,000 hours of catalyst life when exposed to potassium sulfate at a concentration (0.55 micrometer aerosols) which is 14-21 times higher than the concentration of sodium and potassium sulfate aerosols of this size expected after a wet scrubber at M.R. Young Station. Kling[11] also pointed out that the testing probably over estimates the deactivation rate because of turbulence in the pilot scale inlet of the catalyst which would be more laminar in a full scale SCR.

Existing biomass boilers are using tail end SCR successfully. Although the boilers are not cyclone fired units, the new Hampshire units use similar PM control devices as M.R. Young Station (i.e. ESP). The Whitefield Plant has operated for more than four years without deactivation problems. Kling[11] has referred to "bio-optimized" catalyst and higher vanadium catalysts that appear to have a longer life than the typical coal-fired boiler SCR catalyst for a given concentration of sodium and potassium aerosols. A "bio-optimized" catalyst will be installed at the Amager Station[13]. Vendors believe that tail end SCR is technically feasible and can be successfully applied at M.R. Young Station.

The Minnkota situation represents the worst-case scenario for boilers burning North Dakota lignite that are subject to BART. Based on the experimental data available, the use of tail end SCR on biomass fired boilers, and vendor information that tail end SCR is feasible at the M.R. Young Station, the Department concludes that tail end and low dust SCR are technically feasible for boilers combusting North Dakota lignite that are subject to BART requirements.

Selective Catalytic Reduction (SCR)
Technical Feasibility
For
M.R. Young Station

I. Introduction

On July 27, 2006 a Consent Decree was entered by the United States District Court for the District of North Dakota for Civil Action No. 1:06-CV-034, United States of America and the State of North Dakota versus Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative. The Consent Decree resolved alleged violations of the Federal Clean Air Act and the North Dakota Air Pollution Control Rules (NDAC 33-15) including the Prevention of Significant Deterioration Rules (NDAC 33-15-15). Section V, Paragraph 65, of the Consent Decree required Minnkota Power Cooperative and Square Butte Power Cooperative (hereafter Minnkota) to submit to the Department for review and approval, a nitrogen oxides (NO_x) top-down Best Available Control Technology (BACT) analysis for the two existing units at the M.R. Young Station. The Consent Decree required Minnkota to evaluate various technologies including selective catalytic reduction (SCR), selective noncatalytic reduction (SNCR), over-fire air (OFA) and rich reagent injection (RRI). Minnkota must also submit any additional information requested by the Department or the U.S. Environmental Protection Agency (hereafter EPA) which is pertinent to the BACT determination. On October 9, 2006, the Department received the required BACT analyses.

Under Section III, paragraphs 23 and 24 of the Consent Decree, the BACT analysis must be made in accordance with the provisions of Chapter B of EPA's New Source Review Workshop Manual[9] (hereafter NSR Manual). As discussed in the NSR Manual, the steps for conducting a BACT analysis using the "top down" approach are as follows:

Step 1: Identify All Control Technologies.

- List is comprehensive.

Potentially applicable control alternatives can be categorized in three ways.

- Inherently Lower-Emitting Processes/Practices, including the use of materials and production processes and work practices that prevent emissions and result in lower "production-specific" emissions; and
- Add-on Controls, such as scrubbers, fabric filters, thermal oxidizers and other devices that control and reduce emissions after they are produced.
- Combinations of Inherently Lower Emitting Processes and Add-on Controls. For example, the application of combustion and post-combustion controls to reduce NO_x emissions at a gas-fired turbine.

The top-down BACT analysis should consider potentially applicable control techniques from all three categories. Lower-polluting processes should be considered based on demonstrations made on the basis of manufacturing identical or similar products from identical or similar raw materials or fuels. Add-on controls, on the other hand, should be considered based on the physical and chemical characteristics of the pollutant-bearing emission stream. Thus, candidate add-on controls may have been applied to a broad range of emission unit types that are similar, insofar as emissions characteristics, to the emissions unit undergoing BACT review.

Step 2: Eliminate Technically Infeasible Options.

- A demonstration of technical infeasibility should be clearly documented and should show, based on physical, chemical, and engineering principles, that technical difficulties would preclude the successful use of the control option on the emissions unit under review.

The NSR Manual[9] provides guidance for determining whether a control option is technically infeasible. Two concepts are important in making this determination, "availability" and "applicability". A technology is considered "available" if it can be obtained through commercial channels or is otherwise available within the common sense meaning of the word. An available technology is "applicable" if it can reasonably be installed and operated on the source type under consideration. A technology that is available and applicable is considered technically feasible.

Regarding "availability" the NSR Manual[9] states:

> "A control technique is considered available, within the context presented above, if it has reached the licensing and commercial sales stage of development. A source would not be required to experience extended time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required to experience extended trials to learn how to apply a technology on a totally new and dissimilar source type. Consequently, technologies in a pilot scale testing stages of development would not be considered available for BACT review."

With respect to "applicability" the NSR Manual[9] states:

> "Technical judgment on the part of the applicant and the review authority is to be exercised in determining whether a control alternative is applicable to the source type under consideration. In general, a commercially available control option will be presumed applicable if it has been or is soon to be deployed (e.g., is specified in a permit) on the same or a similar source type. Absent a showing of this type, technical feasibility would be based on examination of the physical and chemical characteristics of the pollutant-bearing gas stream and comparison to the gas stream characteristics of the source types to which the technology had been applied previously. Deployment of the control technology on an existing source with similar gas stream characteristics is generally sufficient basis for concluding technical feasibility barring a demonstration to the contrary.

For process-type control alternatives the decision of whether or not it is applicable to the source in question would have to be based on an assessment of the similarities and differences between the proposed source and other sources to which the process technique had been applied previously. Absent an explanation of unusual circumstances by the applicant showing why a particular process cannot be used on the proposed source the review authority may presume it is technically feasible.

In practice, decisions about technical feasibility are within the purview of the review authority. Further, a presumption of technical feasibility may be made by the review authority based solely on technology transfer. For example, in the case of add-on controls, decisions of this type would be made by comparing the physical and chemical characteristics of the exhaust gas stream from the unit under review to those of the unit from which the technology is to be transferred. Unless significant differences between source types exist that are pertinent to the successful operation of the control device, the control option is presumed to be technically feasible unless the source can present information to the contrary."

Step 3: Rank Remaining Control Technologies By Control Effectiveness

This includes:

- control effectiveness (percent pollutant removed);
- expected emission rate (tons per year);

- expected emission reduction (tons per year);
- energy impacts (Btu, KW-hr);
- environmental impacts (other media and the emissions of toxic and hazardous air emissions); and
- economic impacts (total cost effectiveness and incremental cost effectiveness).

Step 4: Evaluate Most Effective Controls and Document Results

- Case-by-case consideration of energy, environmental, and economic impacts.
- If the most effective option is not selected as BACT, evaluate next most effective control option.

Step 5: Select BACT

- Most effective option not rejected is BACT and establish emission limit or work practice standard.

The Department solicited public comments on its preliminary BACT determination for nitrogen oxides (NO_x) controls at the M.R. Young Station (MRYS). Comments from the Environmental Protection Agency and several environmental groups disagreed with the conclusion that high dust SCR (HDSCR), low dust SCR (LDSCR) and tail end SCR (TESCR) were technically infeasible. Comments from other parties agreed with the Department's preliminary determination. The Department has evaluated the comments and has reaffirmed its preliminary determination that HDSCR is technically infeasible. However, the Department now believes LDSCR and TESCR are technically feasible.

This document explains the Department's current views on technical feasibility. This document does not represent a final Department action. The Department will make its final BACT determination after the remaining steps for conducting a BACT analysis have been completed. Minnkota will be required to submit additional information necessary for the Department to make its final BACT determination including an evaluation of the cost of LDSCR and TESCR.

II. High Dust Selective Catalytic Reduction (HDSCR)

HDSCR, or conventional SCR, refers to an SCR system that is installed prior to any air pollution control equipment and usually between the economizer outlet and air heater inlet. HDSCR has been installed on many pulverized coal and cyclone boilers firing bituminous and subbitiminous coal in the United States.

A. Public Comments

1. NDDH's Technical Feasibility Analysis of High Dust SCR is Incorrect and Based Upon Flawed Data

The NSR Manual states "A demonstration of technical infeasibility is based on a technical assessment considering physical, chemical and engineering principles, and/or empirical data showing that the technology would not work on the emissions unit under review, or that unresolvable technical difficulties would preclude the successful deployment of the technique."

The Department asked EPA's consultant, Mr. Roger Christmann, if he was aware of any installation in the world where HDSCR had been applied to a facility with as high of sodium loading as at MRYS. Mr. Christmann indicated no. This indicates that there has never been a design established for a flue gas with the chemical characteristics found at MRYS. Simple mathematics prepared by the Department shows that the flue gas at MRYS is much higher in sodium and other catalyst deactivation chemicals than other power plant flue gases. EPA seems to ignore the fact that the sodium at MRYS is the soluble form (organically associated) which is a more potent catalyst deactivation chemical than the insoluble (inorganically associated) form found in other coals. EPA tries to dismiss this showing by ratioing the loading of Powder River Basin (PRB) subbituminous coal to bituminous coal without indicating the actual loading. The Department showed the actual loading (lb/dscf and lb/wscf) as well as the ratio to other facilities. When you start out with a very small loading, as is the case with bituminous coal, a large ratio for subbituminous coal also gives you small loading. As EPA's own consultant points out, SCR has never been applied to sodium loading as high as at MRYS.

Minnkota and its consultants have documented very well the effect of soluble sodium on an SCR catalyst. Although the Coyote testing did not provide any deactivation rate data for high soluble sodium North Dakota lignite, it did show that an HDSCR design for subbituminous coal will probably not work successfully with North Dakota lignite. As Sargent and Lundy pointed out, there is no known solution for the soluble alkalis such as the soluble sodium and potassium found in North Dakota lignite. EPA ignores the chemical differences between Texas lignite and North Dakota lignite.

With respect to the catalyst vendor "guarantees", all of the vendors that Minnkota contacted indicated that pilot scale testing was either required or should be done prior to applying high dust SCR technology to a North Dakota lignite-fired boiler. Minnkota has provided information that indicates the potential for greatly reduced catalyst life due to the chemical characteristics of the flue gas. Although two vendors indicated a catalyst life which the Department would consider as a "successful application" of HDSCR technology at MRYS, others did not give such an indication. All vendors indicated the flue gas temperature problems (too hot or too cold) must be resolved for the application of HDSCR to be successful. No solution to this problem has been found at this time. EPA has indicated that some of the vendors may have been prompted by Minnkota, or its consultants, to indicate that pilot testing should be done. Even if some vendors may have been "prompted" to make these statements, it is irrelevant since the vendors could have chosen not to make the statement.

Although the Texas CEQ has determined that HDSCR is technically feasible for Texas lignite, the chemical constituents of North Dakota lignite that affect the feasibility of HDSCR are quite different. The State of Louisiana recently determined that HDSCR was not technically feasible for an activated carbon plant because of the flue gas characteristics of the lignite used in the process.

The NSR Manual[9] indicates that an add-on control technology is only technically feasible if it can lead to "successful operation" or "successful deployment." The Department has indicated that anything less than 10,000 hours of catalyst life would not be successful operation of the SCR system and thus technically infeasible. Kling et. al.[2] conducted pilot and bench sale testing of SCR catalysts when subjected to flue gas from the combustion of biomass. The testing was conducted using three different types of catalyst. Catalyst Type A was typical of that used for coal-fired boilers, Type B was a "bio-optimized" catalyst with an increased vanadium content and Type C had a very high vanadium content. Kling[2], and later Zheng et. al[3], have concluded that it is the alkali aerosols that are less than or equal to 0.1 micrometers that cause most of the catalyst deactivation. In North Dakota lignite, the alkali metals are generally associated with the organic matter of the lignite while in other coals the alkaline constituents are associated with the inorganic portion of the coal (e.g. clays). The combustion of the organically associated alkaline elements causes them to vaporize; when they condense, they form submicron aerosols. The combustion of inorganically associated alkalis causes only a small portion to vaporize. Minnkota has supplied information that indicates these condensed alkali aerosols have a mass mean diameter of approximately 0.1 micrometers. Therefore, 50% of the aerosols would be less than 0.1 micrometers in size on a mass basis. The average mass of sodium oxide and potassium oxide emitted from the MRYS boilers was calculated at 3.05 x 10^{-5} lb/dscf (524 mg/Nm^3) and 9.01 x 10^{-6} lb/dscf (155 mg/Nm^3), respectively.

Crespi[6] has provided data that suggests potassium oxide is approximately twice as potent a catalyst deactivation chemical on a molar basis (1.3 times on a mass basis) than sodium oxide. The equivalent potassium oxide emission rate for MRYS based on this data would be 558 mg/Nm^3. The aerosols are most likely in the sulfate form.[5] This would lead to an equivalent potassium sulfate emission rate of 1034 mg/Nm^3.

Kling[2] found a deactivation rate of 21-52% over 1500 hours for fuel made up of tree bark and 30% demolition wood waste. This fuel has a potassium chloride loading of 16.7 mg/Nm^3 and a sodium chloride loading of 5.8 mg/Nm^3. The Kling[2] results were for aerosols with an aerodynamic diameter of less than 0.1 micrometers. If all of the sodium and potassium in lignite vaporizes, 50% of the total loading would be less than or equal to 0.1 micrometers or 517 mg/Nm^3 of equivalent potassium sulfate. Zheng[3] has suggested that potassium chloride is two and one half times more potent catalyst poison than potassium sulfate (0.4%

per day versus 1% per day). An equivalent loading of sodium and potassium for a HDSCR at MRYS as potassium chloride would be 207 mg/Nm^3. This loading is nearly 10 times that of the Kling[2] testing. The Kling[2] results suggest 2,885-7,140 hours until 100% deactivation. The higher loading at the North Dakota facilities suggests a much higher deactivation rate and a shorter catalyst life.

Zheng et. al.[3] found a catalyst deactivation rate of 0.4% per day for a potassium sulfate. The testing was conducted using a concentration of 20-30 mg/Nm^3 of potassium sulfate with a mass mean diameter of 0.55 micrometers. Although data is not available to determine the loading of aerosols with a diameter less than 0.55 micrometers, a comparison to the fraction less than 0.1 micrometers indicates a concentration 17-26 times larger than the concentration in Zheng's tests. The 0.4% deactivation rate per day is equivalent to 6000 hours at 100% deactivation. For a HDSCR, the flue gas from the MRYS would likely produce a higher deactivation rate.

The recent testing by Kling[2] and Zheng[3] indicate that it is unlikely that a HDSCR will achieve 10,000 hours of catalyst life when combusting Center lignite at MRYS. In fact, the catalyst life could be only a few thousand hours as suggested by the pilot scale testing at the Coyote Station.

2. MRYS Temperature Variation Issue Related to HDSCR

EPA has indicated the temperature problems with HDSCR can be resolved.

Mr. Steve Moorman of Babcock and Wilcox in a July 18, 2007 email stated the resolution of the temperature problem would require a technical feasibility analysis of a "very complex nature" to determine if boiler modifications could bring furnace exit gas temperatures into the range needed for compatibility with operation of HDSCR. Modifications outside of the boiler may solve the temperature problem; however, a study would be required. EPA's statement that the technical issues with the temperature issue can be resolved appears to be premature.

The email also states "Our budget estimate to complete this study is $275,000 to $400,000 including the performance test, project management costs and travel expenses. We project the study will require 20 to 24 weeks to complete including the time to run the performance tests." The NSR Manual[9] states: "A control technique is considered available, within the context presented above, if it has reached the licensing and commercial sales stage of development. A source would not be required to experience extended time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required to experience extended trials to learn how to apply a technology on a totally new and dissimilar source type. Consequently, technologies in the pilot scale testing stages of development would not be considered available for BACT review." The Department considers the time and money necessary to determine if the temperature problems can be overcome to be excessive.

3. EPA's Conclusion on HDSCR

When considering application of HDSCR to a cyclone boiler burning North Dakota lignite, the MRYS is considered a new source type. In the past, EPA has recognized cyclone boilers, and more generally slag tap furnaces, that burn lignite from North Dakota, South Dakota and Montana as a separate source category for NO_x emissions in the New Source Performance Standards, Subparts D and Da. This separate category was established primarily based on the use of high sodium lignite. Not until EPA developed a fuel and furnace neutral standard was this category replaced. The replacement of this category was apparently done without an evaluation of the flue gas characteristics of North Dakota lignite. The NSR Manual[9] states "Add-on controls, on the other hand, should be considered based on the physical and chemical characteristics of the pollutant-bearing emission stream. Thus, candidate add-on controls may have been applied to a broad range of emission unit types that are similar, insofar as emissions characteristics, to the emission unit undergoing BACT review." (NSR Manual, Chapter B, Section IV.A).

Minnkota has demonstrated that the flue gas characteristics at MRYS are different from other coal-fired boilers where HDSCR has been applied. The NSR Manual states "A source would not be required to experience time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required to experience extended trials to learn how to apply a technology on a totally new and dissimilar source type." (Chapter B, Section IV.B). Minnkota is not required to conduct extensive and expensive feasibility analyses for modifying the boiler to correct temperature problems that make HDSCR infeasible.

EPA has indicated that catalyst regeneration is a viable option (that is currently used in practice) for restoring catalyst life either in-situ, on-site, or off-site water washing. EPA cites a PowerPoint presentation at the 2007 NO_x Round Table and Expo by Reinhold Environmental Limited as evidence that this technique is available. DOJ's consultant, Mr. Hans Hartenstein, also made a presentation at the referenced Expo. In Mr. Hartenstein's presentation the following statement is made "Regeneration = Removal of catalyst poisons plus restoration of catalytically active ingredients - can typically not be done in-situ or on-site, but should be done off-site to ensure required close process control." EPA may be referring to "rejuvenation" of a catalyst for which Mr. Hartenstein states "Removal of catalyst poisons without the need for replenishing catalytically active compounds - can **sometimes** [emphasis added] be done in-situ, but is most commonly done either on-site or off-site." These statements were also made by

Ehrnschwender and Holsccher at the February 2008 Expo (Considerations for Catalyst Deactivation and Regeneration When Firing Biomass). Minnkota and its consultants have addressed this issue by stating "Regarding the contention of Hartenstein, there is extremely limited experience with in-situ catalyst cleaning on coal-fired units. ENBW in Germany developed this technique, but it has never had a commercial success. It has also never been used for blinded or chemically poisoned catalyst, but only for mechanically plugged catalyst." There is no evidence regarding the effectiveness of washing to rejuvenate an SCR catalyst on the MRYS. Pilot scale testing would be necessary to determine the feasibility of this catalyst maintenance technique.

4. The NDDH BACT Determination Incorrectly Applies the Concept of Pilot Testing in EPA's NSR Manual to Conclude that SCR is not Technically Feasible

EPA states that "For determining whether a control option is available, EPA's NSR Manual does not describe the comparison of gas stream characteristics between the source under review and other sources."

There has never been SCR technology applied to a boiler that combusts North Dakota lignite. EPA has recognized in the past, that cyclone boilers, such as those at Minnkota, that burn lignite from North Dakota is a separate source category for NO_x emission limits under the New Source Performance Standards, Subpart D and Da. Chapter B, Section IV.A, Identify Alternative Emission

Control Techniques **(Step 1)** [emphasis added] states "The top-down BACT analysis should consider potentially applicable control techniques from all three categories. Lower polluting processes should be considered based on demonstrations made on the basis of manufacturing identical or similar products from identical or similar raw materials or fuels. **Add-on controls, on the other hand, should be considered based on the physical and chemical characteristics of the pollutant-bearing emission stream. Thus, candidate add-on controls may have been applied to a broad range of emission unit types that are similar, insofar as emissions characteristics, to the emissions unit undergoing BACT review.**" [emphasis added] Clearly, identification of control options under Step 1 must take into account the flue gas characteristics. If the flue gas characteristics can be shown to prevent successful application of the technology to the source under view, the technology is not identified as "potentially applicable" to the source in Step 1 and is therefore not commercially available under Step 2. Minnkota has shown that the flue gas characteristics for a HDSCR at MRYS are different from that at any other coal-fired power plant where SCR has been installed. Mr. Roger Christmann, EPA consultant, stated that he was not aware of any power plant where HDSCR had been applied with as high of sodium loading as MRYS.

HDSCR technology designed for other coal-fired power plants is not applicable to a North Dakota lignite-fired unit and there is no commercially available design. Pilot scale testing would be necessary to show whether HDSCR can work successfully. As Sargent and Lundy (S&L) pointed out, there are no known solutions for the catalyst surface masking and catalyst deactivation caused by the soluble alkalis (Na_2O and K_2O) found in North Dakota lignite. S&L indicated that some thresholds or limits are yet to be defined for HDSCR involving ash with greater than 2% Na_2O and greater than 1% K_2O. Ash from MRYS contains an average 4.4% Na_2O and 1.3% K_2O. The Na_2O can be as high as 13% and K_2O as high as 7%. Any pilot scale testing would be used to obtain data on the soluble alkalis and ash characteristics and compare the findings with experience on Powder River Basin Coal.

The pilot scale testing for a HDSCR would not be for optimizing an existing applicable control technology. It would be for researching solutions for the high soluble alkalis and possibly designing a new SCR system for a new and dissimilar source category.

5. <u>The NDDH BACT Determination Frustrates the Technology Forcing Function of the BACT that was Intended by Congress.</u>

MRYS is a different source category based on its flue gas characteristics at a HDSCR location. The Department has taken the position that the flue gas characteristics at the MRYS would preclude the successful application of existing HDSCR technology. Decisions regarding technical feasibility are based on the flue gas characteristics, not whether it has been applied to a coal-fired boiler or some other general source category. We believe Congress never intended forcing a technology on a source when there is a low probability of successful deployment of that technology.

B. Conclusions

Recent testing by Kling[2] and Zheng[3] suggest a low probability of achieving successful application of HDSCR technology by MRYS. The high concentration of sodium and potassium in the flue gas will rapidly deactivate the catalyst. The results suggest much less than 10,000 hours of catalyst life which the Department believes is necessary for successful application of HDSCR.

Minnkota has supplied data indicating temperature problems (both too high and too low) at the location of HDSCR which will affect the catalyst life. Babcock and Wilcox has estimated that a study of the temperature problems could take up to 24 weeks and cost up to $400,000. The NSR manual indicates that a company is not expected to experience extended trials to learn how to apply a technology.

Based on the flue gas characteristics at the location of the high dust SCR and the temperature problems (both too high and too low), the Department does not consider HDSCR to be technically feasible for MRYS.

III. Tail End SCR and Low Dust SCR

A. Introduction

SCR systems placed between the particulate control device and sulfur dioxide control equipment are called low dust SCR (LDSCR). Systems that are placed downstream of the particulate matter (PM) and sulfur dioxide (SO_2) control systems are generally referred to as tail end SCR (TESCR). This is in contrast to a HDSCR location where none of the particulate matter and sulfur dioxide has been removed from the flue gas. LDSCR and TESCR systems have been used on coal-fired and biomass fired boilers in the United States as well as other countries. However, no SCR system including a low dust or tail end SCR has ever been operated on a boiler firing North Dakota lignite. The flue gas produced by the combustion of North Dakota lignite contains high concentrations of alkali aerosols (primarily sodium and potassium). Cyclone boilers, such as the two units at the M.R. Young Station, produce higher concentrations of submicron aerosols than conventional pulverized or fluidized bed boilers. The higher temperature in the cyclone boilers vaporizes the organically associated sodium and potassium in North Dakota lignite. When these elements condense, they form submicron aerosols. Minnkota[1] (p. 12) has indicated that the condensed vapors have a mean diameter of approximately 0.1 micrometers. Papers by Kling[2] and Zheng[3] have indicated that the aerosols with a diameter less than or equal to 0.1 micrometers cause the greatest catalyst deactivation.

The NSR Manual[9] states that decisions regarding technically feasibility are made by comparing the physical and chemical characteristics of the exhaust gas stream from the unit under review to those of the unit from which the technology is being transferred. Unless significant differences between the source types exist that are pertinent to the successful operation of the control device, the control option is presumed to be technically feasible unless the source can present information to the contrary.

Since no LDSCR or TESCR system has ever been applied to a boiler that combusts North Dakota lignite, an evaluation of the flue gas characteristics was made to determine if they were substantially different from facilities that have successfully applied SCR technology or to determine if empirical data would indicate whether low dust or tail end SCR can be successfully applied.

B. Flue Gas Characteristics

At the MRYS, both units use an electrostatic precipitator (ESP) to control PM emissions. Unit 2 is equipped with a wet scrubber to control SO_2 emissions while a wet scrubber will be constructed for Unit 1. Minnkota[4] (p.20) has provided an analysis of the particulate matter emitted from Unit 2 which can be used for evaluation of TESCR. The analysis indicated the PM was 6.56% sodium (Na), 2.26% potassium (K), 5.71% sulfur (S), 57.52% oxygen (O) and the remaining other elements.

The sodium and potassium after the ESP and wet scrubber is most likely in sulfate form[5] (p.32). If all of the sodium and potassium is in the sulfate form, sodium sulfate and potassium sulfate would comprise approximately 25% of the total particulate matter emitted from Unit 2 (see Appendix A). Minnkota has indicated that the sample of the particulate matter that was analyzed was obtained while some flue gas was bypassing the SO_2 scrubber. The amount of sodium, potassium and/or sulfur in the sample could be biased high when compared to a sample when all flue gas passes through the wet scrubber.

A review of the latest PM stack tests at M.R. Young Unit 2 (8/07 and 5/08) indicated an average PM emission rate of 10.61 milligrams per normal cubic meter (mg/Nm^3 at 6% O_2 – see Appendix B). Based on 25% of the PM being sodium and potassium sulfate, the combined emission rate of these two compounds is approximately 2.7 mg/Nm^3. This indicates a sodium and potassium removal efficiency of greater than 99% by the ESP and wet scrubber.

Minnkota has submitted data from a study by Markowski[5] (p.31) which indicated that approximately 81% of the sulfate emitted after the Unit 2 wet scrubber is less than 1.1 micrometers in size and approximately 36% is less than 0.26 micrometers in size. Based on the latest stack tests and the Markowski data, the submicron sodium sulfate plus potassium sulfate emission rate would be less than 2.2 mg/Nm^3 and the emission rate of sodium and potassium sulfate less than 0.26 micrometers in size would be approximately

1.0 mg/Nm^3. These values are similar to those Markowski reported which were 1.335 mg/m^3 and 0.602 mg/m^3 respectively.

C. Catalyst Deactivation

The two primary flue gas constituents that will cause SCR catalyst deactivation in a low dust or tail end configuration are sodium and potassium, most likely in sulfate form[5] (p.32-35). Crespi et.al.[6], in their paper regarding the Amager Station, presented a graph which shows the effect of various poisons on the activity of vanadia – titania catalysts. Minnkota[1] (page 21) provided similar information that indicates that potassium oxide is a more potent catalyst poison on a molar basis than sodium oxide. Although no actual data is supplied, analysis of the graph indicates that potassium oxide is 1.7[7] – 2.0[8] times more potent catalyst poison than sodium oxide (on a molar basis) up to a poison to vanadium/titanium ratio of 0.5 (see Appendix C). Because potassium oxide has a larger molecular weight than sodium oxide, the poisoning ratio is 1.1 – 1.3 on a mass basis.

As indicated earlier, Kling[2] and Zheng[3] have indicated that the aerosols less than or equal to 0.1 micrometers cause the catalyst deactivation. Data are not available to calculate the portions of the PM emissions from Unit 2 that would be less than or equal to 0.1 micrometers. A conservative assumption is that all of the sodium and potassium sulfate less than 0.26 micrometers is less than or equal to 0.1 micrometers. Based on this assumption and the PM analysis data, the total emission rate for sodium and potassium sulfate combined that is less than or equal to 0.1 micrometers is size is estimated at 0.98 mg/Nm^3 of which 0.78 mg/Nm^3 is sodium sulfate.

Kling[2] has provided catalyst deactivation rates for various biomass fuels which produce a flue gas that contains sodium and potassium aerosols. The testing was conducted using different types of honeycomb W_2O_5/TiO_2 SCR catalyst. Type A catalyst was catalyst typically applied at coal-fired power plants, Type B was a "bio-optimized" catalyst with increased vanadium content, and Type C had an even higher vanadium content.

For a mixture of peat and 15% wood, the flue gas contained 4.4 mg/Nm^3 of potassium and 0.8 mg/Nm^3 of sodium aerosols with an aerodynamic particle diameter less than 0.1 micrometers.

	Peat + 15% Wood[a]	Center Lignite[b]
Potassium (mg/Nm^3)	4.4	0.20
Sodium (mg/Nm^3)	0.8	0.78

[a] As chloride

[b] As sulfate

The maximum deactivation rate was 12% in 768 hours using Type A catalyst. Another result indicated 15% deactivation in 1488 hours using Type B catalyst. The shorter test result on peat plus 15% wood indicates 6400 hours to 100% deactivation while the longer test result indicates 9920 hours to 100% deactivation. Regarding the deactivation rates, Kling et.al[2] stated "Exposure of this kind of short samples gives a larger deactivation compared to a full-length catalyst [1, 4] that is mainly a consequence of turbulence of the inlet of the catalyst, before laminar flow is attained."

The sodium concentration in the flue gas after the wet scrubber from Center lignite is similar to that of the peat plus 15% wood; however, the potassium content is approximately 17 times lower. It appears the catalyst life for an SCR at M.R. Young Station should be substantially longer than that estimated for peat plus 15% wood.

Zheng et.al.[3] found a deactivation rate of 0.4% per day for potassium sulfate or 6000 hours to 100% deactivation. The testing was conducted at a loading of 20-30 mg/Nm^3. The aerosols varied in size from 0.07 micrometers to 1.05 micrometers with a mass mean diameter of 0.55 micrometers. The Markowski data indicates that approximately 53% of outlet sulfate was less than or equal to 0.52 micrometers. Based on the latest stack tests at M.R. Young Unit 2, this equates to a total emission rate of approximately 1.4 mg/Nm^3 for those sodium and potassium sulfate aerosols less than 0.52 micrometers. The Minnkota emission rate is substantially less (14-21 times) than the Zheng testing.

The above results do not consider the fact that potassium is a more potent catalyst poison than sodium and chlorides are more potent than sulfates. These facts make it even more likely that the catalyst life will be longer than the testing indicated by Kling[2] and Zheng[3] since Center lignite combustion at MRYS produces primarily sodium sulfate aerosols while biomass combustion produces primarily potassium chloride aerosols.

For a LDSCR application, the only air pollution control device prior to SCR will be a dry electrostatic precipitator (ESP). Stack test results from the FINE Particles – Technology, Environmental and Health Technology Programme[13] suggests that an ESP on a biomass boiler will have a control efficiency of greater than 90% for submicron particles and can achieve greater than 96% for particles less than 0.1 micrometers in size. This is consistent with AP-42[12] data for Kraft recovery boilers which indicates an ESP can remove more than 98% of the submicron particulate matter in the flue gas which is primarily sodium sulfate[14]. Similar results are reported for coal-fired/biomass boilers by Mohr[15], Lind[16] and the Power Station Emissions Handbook[17]. This indicates that most of the submicron sodium and potassium aerosols, including those aerosols less than 0.1 micrometers in size, will be removed by the electrostatic precipitators at MRYS.

Minnkota has submitted data on the ash composition that accumulated on the electrodes of the Power Span ECO electrodes during a pilot test[11] (p. 26). The data suggests that the sodium and potassium concentration in the particulate matter downstream of the Unit I ESP is higher than the concentration in the particulate matter downstream of the Unit II wet scrubber. However, the concentration is less than a factor of two higher. The total loading of sodium and potassium, as indicated by the data submitted by Minnkota, would still be considerably less than the loadings in the Kling[2] and Zheng[3] tests. This suggests that the catalyst deactivation rate of a LDSCR at MRYS should be lower than in the referenced tests.

D. Vendor Information

The U.S. Department of Justice, through their contractor Mr. Hans Hartenstein, has provided emails from various catalyst and SCR system providers[10] (Appendix D). Each of the responses from the vendors indicated that tail end SCR is technically feasible for the Milton R. Young Station.

The Department contacted three of the vendors, Ceram Environmental, Haldor Topsoe and Babcock Power. The companies generally confirmed the information in the emails to Mr. Hartenstein. Babcock Power indicated they had no worries about getting 10,000 hours of catalyst life at the M.R. Young Station. However, they recommended "coupon" testing prior to design of the SCR. Ceram was convinced it was technically feasible; however, their representative did acknowledge that if the sodium and potassium aerosols are making it through the ESP and wet scrubber, catalyst deactivation could be a problem. Haldor Topsoe indicated that the catalyst deactivation at M.R. Young would be manageable if the catalyst is kept dry during outages. Although no written guarantees have been provided by the vendors, it appears that vendors are willing to provide them for a tail end SCR at the M.R. Young Station.

E. Biomass Facilities using LDSCR/TESCR

There are no boilers that combust North Dakota lignite and are equipped with SCR technology. LDSCR and TESCR has been applied to coal-fired boilers in Europe, Asia and the United States. However, in general, other U.S. coals are much lower in the organically associated alkalis that cause SCR catalyst deactivation. Biomass fired boilers have flue gas characteristics that more closely approximate those from North Dakota lignite. At least four biomass boilers that are equipped with tail end or low dust SCR are currently in operation in the United States. The boilers are spreader stoker design and use an electrostatic precipitator as the primary particulate matter control device. These include:

- Whitefield Power & Light, New Hampshire – Boiler uses whole tree chips and has operated since October 2004.
- Bridgewater Power, New Hampshire – Boiler uses whole tree chips and has operated since October 2007.
- Pine Tree Power, New Hampshire – Biomass combustion.
- Boralex Stratton, Maine – Boiler uses whole tree chips, waste wood, and construction and demolition waste. The boiler has operated since December 2004.

The Department is also aware of proposed TESCR or LDSCR installations at the Burlington Electric Plant in Vermont, Synterprise Global Solutions in Tennessee and the Amager Heat and Power Plant near Copenhagen, Denmark. The Amager Station is also allowed to burn coal and may not be required to operate the TESCR when combusting biomass.

Although there are boilers that combust 100% biomass and utilize LDSCR for NO_x control, there is no information about the actual loading of potassium and sodium aerosols at the inlet to the SCR. The New Hampshire Department of Environmental Services (NHDES) was contacted regarding the biomass boilers that use LDSCR. The Whitefield Power Plant is a 16 MWe spreader stoker that is equipped with a multiclone and electrostatic precipitator for particulate matter control. The NHDES confirmed the boiler had been operating for approximately four years. NHDES was not aware of any catalyst deactivation problems at this facility. The plant has a NO_x emission limit of 0.075 $lb/10^6$ Btu. The other facilities in New Hampshire are similar; however, they have not operated as long. No data was available regarding the loading of potassium and sodium at the inlet of the SCR.

F. Conclusions

In the June 2008 Preliminary Best Available Control Technology Determination for Control of Nitrogen Oxides for M.R. Young Station Units 1 and 2, the Department concluded that an SCR system must have a catalyst life of at least 10,000 hours before SCR technology could be deemed successfully applied to the source. The life of the catalyst will depend on many factors including the reduction efficiency required, the allowable ammonia slip, the volume of catalyst used, the plant load variability, the coal flue gas characteristics, the makeup of the catalyst (e.g. high vanadium catalyst will last longer than a catalyst with a lower vanadium content), the design of the reactor system, the number of catalyst layers, the catalyst management plan, and other factors. The catalyst could be replaced when deactivation has reached 50% or less or it could be replaced at a higher deactivation point depending on the system's ability to meet the regulatory requirements for the NO_x emission rate and/or ammonia slip rate.

No data has been found from an actual operating facility which has similar flue gas characteristics to M.R. Young Station that use high dust, low dust or tail end SCR. However, experimental and pilot scale testing by Kling[2] and Zheng[3] provides empirical data for comparison. The total sodium and potassium loading of aerosols less than 0.1 micrometers expected at the inlet of a TESCR at M.R. Young Station is expected to be at least 5 times less than found in the Kling tests on peat plus 15% wood. Kling's data indicated up to 9920 hours before 100% deactivation for catalyst type B. Zheng's[3] data suggested 6,000 hours before 100% deactivation when exposed to potassium sulfate aerosols with an mean diameter of 0.55 micrometers at a concentration which is 14-21 times higher than the concentration of sodium and potassium aerosols of this size expected after a wet scrubber at M.R. Young Station. The loading at a low dust location would also be substantially less than the loading in the Kling or Zheng tests. Kling[2] also pointed out that the testing probably over estimates the deactivation rate because of turbulence in the pilot scale inlet of the catalyst which would be more laminar in a full scale SCR.

Existing biomass boilers are using LDSCR successfully. Although the boilers are not cyclone fired units, the New Hampshire units use similar PM control devices as M.R. Young Station (i.e. ESP). The potassium chloride emitted from the biomass boilers is a much more potent catalyst poison than the sodium sulfate emitted at the MRYS. The Whitefield Plant has operated for more than four years without deactivation problems. Kling[2] has referred to "bio-optimized" catalyst and higher vanadium catalysts that appears to have a longer life than the typical coal-fired boiler SCR catalyst for a given concentration of sodium and potassium aerosols. A bio-optimized catalyst (high vanadium content) will be installed at the Amager Station[6] (p. 13). Vendors believe that TESCR is technically feasible and can be successfully applied at M.R. Young Station.

Based on the empirical data available at that time, vendor information that TESCR is feasible at the M.R. Young Station and the use of low dust SCR on biomass fired boilers, the Department concludes that tail end and low dust SCR appear to be technically feasible at M.R. Young Station.

Tail End SCR

Appendix B: SCR Vendor Query Correspondence

1. Vendor Correspondence with SCR system suppliers

1.1 E-Mail correspondence with Clay Erickson, Babcock Power (SCR System Vendor – extensive tail-end SCR experience)

From: cerickson@babcockpower.com [mailto:cerickson@babcockpower.com]
Sent: Thursday, June 19, 2008 15:59
To: Hans Hartenstein
Cc: jlangone@babcockpower.com; tlicata@babcockpower.com
Subject: Re: Tail-end SCR

Hans,

Babcock Power has reviewed the Milton Young plant in the past, based on these reviews Babcock Power finds

- A tail-end SCR is technically and commercial feasible
- Babcock Power does not recommend or require additional pilot testing only proper flue gas characterization as with any SCR system per performed
- Will provide commercial guarantees for the SCR and catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime

Babcock Power has the largest SCR experience list in the world; from this experience we are completely confident in the application of a tail end system at Milton Young. If you have further questions please let me know.

With best regards,
Clay

Subject: Tail-end SCR

Clay,

As discussed during our phone conversation today, during which you stated that Babcock Power considers a high-dust SCR principally, technically feasible even though not without technically resolvable challenges for Minnkota's Milton R. Young Station, I would also be interested in Babcock Power's position on the technical feasibility of a tail-end SCR (downstream of a wet scrubber including flue gas reheat) Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Babcock Power:

- Consider a tail-end SCR technically feasible?
- Recommend or require additional pilot testing?
- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

Given the fact that tail-end SCRs in Germany including the ones built by your licensor Fisia Babcock (most of which are on wet bottom boilers) went into operation in the late 1980s and most of them still operate on the initial fill of catalyst after almost 20 years and up to 130,000 operating hours, I would assume that Babcock Power / Fisia Babcock has sufficient confidence in your tail-end SCR experience to competently respond to these questions. Please let me know if you have any additional questions. Thanks.

Best regards,
Hans Hartenstein

Subject: Tail-end SCR

Don,

As discussed during our phone conversation today, during which you stated that Babcock & Wilcox considers a tail-end SCR (downstream of a wet scrubber including flue gas reheat) principally technically feasible for Minnkota's Milton R. Young Station, I would be interested in Babcock & Wilcox's position on the following questions. Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Babcock & Wilcox:

- Consider a tail-end SCR technically feasible? Yes
- Recommend or require additional pilot testing? Requires further discussion with catalyst suppliers.

- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be? While B&W has considered tail-end SCR systems on other projects we have not had these commercial guarantee discussions with the catalyst suppliers for the North Dakota lignite application. Before consideration of providing these guarantees a comfort level would be required after obtaining guarantees from catalyst suppliers.

Given the fact that tail-end SCRs in Germany went into operation in the late 1980s and most of them still operate on the initial fill of catalyst after almost 20 years and up to 130,000 operating hours, I would assume that Babcock & Wilcox has sufficient confidence in tail-end SCR systems to competently respond to these questions. Please let me know if you have any additional questions. Thanks.

Best regards,
Hans Hartenstein

To: Hans Hartenstein
Cc: Khalaf Cindy R
Subject: Argillon Tail-end SCR
Importance: High

On behalf of Cindy Khalaf -

Hans,

Further to our phone call, as far as I know, Argillon has more tail end experience than any other SCR catalyst manufacturer and, as you noted, we also have experience with high dust, German lignite SCRs. Argillon also won the first US lignite SCR catalyst project (Luminant Oak Grove 1 & 2) and provided commercial guarantees. These units are not in service yet. So, yes, we consider ourselves able to answer these questions competently.

Consider a tail-end SCR technically feasible?

Yes, we consider this configuration to be technically feasible. As you know, tail end SCRs are often used when there are significant catalyst poisons in a flue gas stream. A wet scrubber can remove most of these poisons, resulting in very low catalyst deactivation.

Recommend or require additional pilot testing?

For a high dust configuration, we would say definitely. For a tail-end configuration, we would say no. We would only like to see a flue gas analysis for conditions at the inlet to the SCR in order to predict deactivation rate.

Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

Generally speaking, yes, we would provide guarantees for DeNOx & slip as specified (not to exceed 90% or 2 ppm), 24k hours life, SO_2 conversion rate - low but value TBD, pressure drop - value TBD. Of course we would have to see the technical specifications before being more specific. In addition, tail-end SCRs perform much longer, so depending on the application specifics, customer, etc., we may decide to extend the operating life guarantees. This is a commercial decision and will be reviewed on a case-by case basis.

If you have any more questions, please let me know.

Regards,
Cindy

To: Khalaf Cindy R
Subject: Tail-end SCR

Cindy,

As discussed during our phone conversation today, during which you stated that Argillon considers a high-dust SCR principally technically, feasible based on your high-dust SCR experience with lignite fired units in Europe even though not without technically resolvable challenges for Minnkota's Milton R. Young Station, I would also be interested in Argillon's position on the technical feasibility of a tail-end SCR (downstream of a wet scrubber including flue gas reheat). Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Argillon:

- Consider a tail-end SCR technically feasible?
- Recommend or require additional pilot testing?
- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

Given the fact that tail-end SCRs in Germany including the ones equipped with Argillon catalyst went into operation in the late 1980s and most of them still operate on the initial fill of catalyst after almost 20 years and up to 130,000 operating hours, I would assume that Argillon has sufficient confidence in your tail-end SCR experience to competently respond to these questions. Please let me know if you have any additional questions. Thanks.

Best regards,
Hans Hartenstein

2.2 E-Mail Correspondence with John Cochran, CERAM Environmental (Catalyst Manufacturer – extensive tail-end SCR experience)

From: John Cochran [mailto:John.Cochran@ceram-usa.com]
Sent: Wednesday, June 25, 2008 15:14
To: Hans Hartenstein
Cc: Greg Holscher; Noel Rosha; Orehovsky Kurt
Subject: RE: Request for Information

Hans,

CERAM certainly considers the use of a tail-end SCR on applications such as the Milton R. Young Station as technically feasible provided a proper design approach is used. CERAM has the experience from more than 100 tail-end and low dust applications dating from 1988 that would substantiate our opinion. For a tail-end approach we see no need for additional pilot testing. As such, we can provide full commercial guarantees for catalyst performance (activity or lifetime, conversion rate, pressure drop, etc.).

The choice between high dust and tail-end processes certainly should consider capital costs, operating costs and process risk. Based on our experience certainly process risk would favor a tail-end approach, but albeit for most circumstances at a higher "all-in" cost. Should very high retrofit factors be present for a high dust arrangement then the relative economic factors may even favor a tail-end approach.

I hope this information is useful to your evaluation. Please advise should you have any further questions or information needs. Thanks.

Best Regards,
John Cochran

Hans Hartenstein

2.3 E-Mail Correspondence with Scot Pritchard, Cormetech (Catalyst Manufacturer – no tail-end SCR experience)

From: Pritchard, Scot G. [mailto:PritchardSG@Cormetech.com]
Sent: Thursday, June 19, 2008 17:41
To: Hans Hartenstein
Subject: RE: Tail-end SCR

Hans,

I was thinking of if you put a coupon in the tailend location and it showed something weird then you would have to do something more elaborate i.e. A slipstream with longer hours, etc. We do not anticipate this - in fact you could probably do without the coupon test as well since I don't see any reason why this system would be any different the primary tail end experience i.e. Unlikely any nasties make it through the lower temperature environment and scrubber process. The coupon is OK but I really don't expect to see much. Finally, we have not done any specific coupon tests (because slipstream has been the primary way to evaluate) so we would need to think through the best way to do it - i.e. holder, mounting arrangement, test method, hours of exposure, etc. If you already have something in mind please let us know.
Hope that helps with the clarification.

Scot

From: "Hans Hartenstein" <Hans.Hartenstein@Evonik-EnergyServices.us>
Sent: Thursday, 6/19/08 4:26 pm
To: "Pritchard, Scot G." <PritchardSG@Cormetech.com>
Subject: RE: Tail-end SCR

Scot,

Thanks for the input from Cormetech, which is greatly valued. One question for clarification purposes only, though. Coupon tests and/or flue gas analysis would only be performed in order to characterize the flue gas going into the tail-end SCR as is needed for the design of any APC equipment. Obviously, nobody could offer any performance guarantees concerning what's coming out of a tail-end SCR without knowing what's going into it. You state that in case coupon tests would show a significant accumulation of catalyst poisons, a subsequent slip stream test, which is unquestionably more accurate and representative of a full scale - in this case tail-end - SCR, would be recommended. Stating this, do I understand you right that you would recommend this slip stream testing mainly for the purpose of properly characterizing the flue gas composition at the inlet to the tail-end SCR in order to provide a reliable basis for correct catalyst design? Do I assume correctly, that you would not require extensive and long-term (12 - 24 months) pilot testing with a slip stream reactor because you have serious doubts about the principal technical feasibility of a tail-end SCR for this application? Please clarify. Thanks.

Best regards,
Hans Hartenstein

Subject: RE: Tail-end SCR

Hans,

Please see my input below.

As discussed during our phone conversation today, during which you stated that Cormetech considers a high-dust SCR principally technically, feasible even though not without technically resolvable challenges for Minnkota's Milton R. Young Station, I would also be interested in Cormetech's position on the technical feasibility of a tail-end SCR (downstream of a wet scrubber including flue gas reheat) Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Cormetech:

- Consider a tail-end SCR technically feasible? - yes

- Recommend or require additional pilot testing? - We generally do not consider coupon testing an accurate representation of an SCR, however in order to minimize cost and provide basic screening information we would suggest the potential use of a coupon sample test. If the coupon shows significant accumulation of catalyst poisons, a subsequent slipstream type test which is more representative of a full scale SCR i.e match velocity, AVs, etc. would be recommended.
- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be? Presuming the coupon test does not show anything unusual (which we do not expect to see anything unusual) we would be willing to provide commercial guarantees for a low dust application. Basic guarantees would be associated with life (this would not include specific Ko and K/Ko as guarantees - the guarantee would be an efficiency and slip guarantee at a certain number of operating hours), SO2 conversion, pressure loss.

As discussed, the high dust application needs additional due diligence testing (slipstream, ash testing, etc.) as well as the practicality of the applicable operating temperature to establish the commercial stance for a high dust application on North Dakota Lignite. We have done such work for Texas lignite as well as other coal sources and other fuels/applications in the past and would expect to be able to achieve the same for this application. The economics for any given application would be considered on a case by case basis.
Let me know if you have any questions. Also I would appreciate anything of the final document that you can share.

Thank you and regards,

Scot Pritchard

Flemming,

Thanks for your note. Just to make sure that I understand you correctly. Is it correct to state that Haldor Topsoe feels fully confident that a tail-end SCR is technically feasible and would not experience any accelerated catalyst deactivation? Therefore, you would be willing to guarantee catalyst performance (NOx removal efficiency, pressure drop, SO_2/SO_3 conversion rate and catalyst lifetime) without any need for further pilot testing. Please confirm. Thanks.

Best regards,
Hans Hartenstein

To: Hans Hartenstein

Subject: Re: Tail-end SCR

Hans,

Like you describe we have had very good operating experience with SCR in the clean environment after a scrubber or bag filter. There appears to be practically no catalyst deactivation and with the low amount of particulate the catalyst pitch can be small, which both leads to a compact SCR as compared to a high dust SCR.

Based on the clean flue gas after the FGD we would not require any further testing in order to guarantee a catalyst performance.

The actual guarantees would be as normally applied in a high dust installation and depend on the catalyst volume and operating conditions. At the low operating temperature expected at the tail-end position the SO_2 oxidation will be negligible.

I hope this confirmation will have your approval.

EXECUTIVE SUMMARY

On July 6, 2005, the U.S. EPA finalized the Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations. The final regulations require eligible sources to be analyzed to determine a BART emission limit for nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM). The North Dakota Department of Health (NDDH) reviewed the operational history of North Dakota sources and determined which sources were BART eligible and provided a state specific modeling protocol for use in the analysis. Basin Electric Power Cooperative's (BEPC's) Units 1 and 2 at the Leland Olds Station (LOS) were determined to be BART eligible by the NDDH. As discussed in the analysis, small emission units at LOS produce emissions in levels anticipated to be too small to affect visibility in Class 1 areas and were excluded from further consideration in the study. This BART determination was conducted in accordance with the eligibility conclusion made by NDDH and follows the steps outlined in the guidelines and the NDDH protocol.

The BART determination process has five predefined steps. Steps 1 through 3 include identifying and evaluating feasible control technologies. Steps 4 and 5 involve a technical evaluation of the impacts related to each control technology. The evaluation reviews multiple impacts including economics and visibility impairment in Class 1 areas. The result of conducting this five step analysis is a list of control technologies for regulated pollutants that provides a cost effective system of emission reduction and visibility impact reduction. This technology list, including control efficiencies, is then translated into an emission rate constituting BART that must be achieved by the eligible source. Although the impacts requiring analysis are explicitly stated within the guideline, no methodology is provided for using the impacts to select a control technology. Thus, every BART analysis will have a certain level of subjectivity based upon source characteristics, reviewed technologies, and background information used to perform the evaluation.

This analysis used several reference works, including the RACT/BACT/LAER Clearinghouse (RBLC), to identify which control technologies to evaluate. The technologies were then reviewed for feasibility and systematically eliminated by analyzing the impacts provided in the guidelines. Specifically, the control technologies were ranked by control efficiency and removed from the list based upon the cost per ton of removal and the reduction in visibility impairment impact. Based upon that evaluation, the BART recommendations are made for each pollutant and are summarized in the tables below.

Leland Olds Station Unit 1 Recommended BART

Pollutant	Percent Removal %	Emission Rate lb/MMBtu
SO_2	90	0.34
NO_X	-	0.29
PM(1)	NA	0.10

(1) - Filterable PM only.

Leland Olds Station Unit 2 Recommended BART

Pollutant	Percent Removal %	Emission Rate lb/MMBtu
SO_2	95	0.17
NO_X	54.5	0.304
PM(1)	NA	0.10

(1) - Filterable PM only.

The rates provided in these tables are based upon the control efficiency of a recommended BART control technology applied to each unit at the Maximum Continuous Rating (MCR) burning 100% lignite fuel. However, because the accuracy of the cost estimate is ± 30% and in some cases is greater than the differences between the estimated costs of feasible control alternatives, the technology used to meet the BART recommendation may change. These rates are not provided as recommended permit conditions. The guidelines suggest that emission limits be developed on a 30-day rolling average for Electric Generating Units (EGUs). Unfortunately, the guidelines do not provide a methodology to calculate the limit for permitting purposes and only state that an enforceable limit that reflects BART requirements must be established.

To develop recommended permit conditions for each pollutant, emissions calculations were performed using an increased Boiler Heat Input and coal sulfur content. Historical variability in plant operations show that the boiler design capacity Heat Input rate was exceeded 10.6% and 7.6% of the operating time for Unit 1 and Unit 2 respectively. Normal plant operation includes exceeding the original boiler design capacity Heat Input rate, which has an impact on hourly emissions variability. Short-term increases of heat input can raise hourly emissions, which can have a significant impact on short-term emission averages. To take into account the influence that an average heat input rate higher-than-nameplate boiler design heat input capacity rating would have on baseline emissions over a 30-day averaging period, a 5% increase in heat input was used for developing a recommended 30-day emission limit for each pollutant for permitting purposes.

Sulfur content of the coal was the primary constituent of concern because SO_2 emissions are directly related to the amount of sulfur in the coal and are not as related to equipment design. A forty year mining plan was analyzed to determine the future maximum annual sulfur content to be used in the BART analysis. The results indicated that future delivered coal will have a maximum annual average sulfur content of approximately 1.13% with a standard deviation of 0.12%. A 30-day rolling average SO_2 emission rate was calculated using the maximum sulfur content plus 1 standard deviation (i.e., 1.25% S).

As previously stated, selection of BART for control of the major pollutants of interest needs to be translated into an emission rate limit, which is not a fixed percent reduction from baseline. The post-control emission rate is influenced by the unit pre-control baseline emission rate and the effectiveness of BART selected for the particular pollutant. Boiler Heat Input is the single most important variable affecting the NO_X emissions rate. The pre-control baseline NO_X emission rate is influenced by the variability of the hourly boiler heat input rate over the duration of the averaging period selected. For LOS Unit 1, the recommended BART 30-day rolling average unit NO_X emission rate is 0.29 lb/mmBtu (presumptive level). A recommended BART 30-day rolling average unit NO_X emission rate of 0.35 lb/mmBtu for LOS Unit 2 results from applying a 54.5 percent reduction to the unit NO_X pre-control baseline emission rate of 0.77 lb/mmBtu that reflects the higher Boiler Heat Input rate. A provisional operating period of one year of operational experience is recommended in conjunction with the recommended BART 30-day rolling average NO_X permit emission rate to allow BEPC to demonstrate the actual control system capabilities of Unit 2's boiler. At the end of that period, it is recommended that the NO_X BART permit limits be reviewed considering the demonstrated operating history.

To account for the higher heat input and higher future sulfur content, a representative SO_2 emission rate was calculated based upon a 5% higher heat input and the maximum annual average sulfur content plus 1 standard deviation (i.e., 1.25% S). The resulting recommended 30-day rolling average SO_2 permit limit for LOS Unit 1 is 0.39 lb SO_2/mmBtu. Similarly, the resulting SO_2 permit limit for LOS Unit 2 is 0.19 lb SO_2/mmBtu.

Emission evaluated rates for particulate matter are based upon the design of the existing electrostatic precipitator and the heat input. The resulting recommended 30-day rolling average PM permit limits for both Unit 1 and 2 are 0.10 lb PM/mmBtu. Using the methodologies discussed for each pollutant, recommended emission limits for each pollutant are tabulated below.

Recommended 30-Day Rolling Average BART Emission Limits for LOS Unit 1

Pollutant	Emission Rate(1) lb/MMBtu
SO_2	0.39
NO_X	0.29
PM	0.10

(1) - 30-day rolling average, based upon an average boiler heat input rate of 2,622 * 1.05 = 2,753 mmBtu/hr and percent removal compared to pre-control baseline emission levels. NO_X pre-control baseline emission rate for this recommended limit is 0.29 lb/mmBtu. Note that the recommended PM emissions are not a 30-day rolling average.

Recommended 30-Day Rolling Average BART Emission Limits for LOS Unit 2

Pollutant	Emission Rate(1) lb/MMBtu
SO_2	0.19
NO_X	0.35
PM	0.10

(1) - 30-day rolling average, based upon an average boiler heat input rate of 5,130 * 1.05 = 5,387 mmBtu/hr and percent removal compared to pre-control baseline emission levels. NO_X pre-control baseline emission rate for this recommended limit is 0.77 lb/mmBtu. Note that the recommended PM emissions are not a 30-day rolling average.

Although the emission limits presented above for each unit are recommended for permitting purposes, this analysis also recommends discussing an alternative compliance method as suggested in the BART Guidelines. The guidelines provide that states, "should consider allowing sources to ''average'' emissions across any set of BART-eligible emission units within a fenceline, so long as the emission reductions from each pollutant being controlled for BART would be equal to those reductions that would be obtained by simply controlling each of the BART-eligible units that constitute a BART-eligible source." (70 FR 39172) During the process of developing enforceable permit conditions, the opportunity to apply a plant-wide limit using an "averaging" or "bubbling" strategy should be considered.

1.0 INTRODUCTION

The U.S. EPA finalized the Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations[1] in the Federal Register on July 6, 2005 (70 FR 39104). BART is defined as "an emission limitation based on the degree of reduction achievable through the application of the best system of continuous emission reduction for each pollutant which is emitted by a BART-eligible source. The emission limitation must be established, on a case-by-case basis, taking into consideration the technology available, the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology" (70 FR 39163). This document presents the BART analysis for each of three major pollutants (nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM)) for Basin Electric Power Cooperative's (BEPC's) Leland Olds Station (LOS) Units 1 and 2 located in Stanton, North Dakota.

A BART eligible source is one that meets three criteria identified by EPA in the guidelines for the determination of BART. A source is BART eligible if operations fall within one of 26 specifically listed source categories (70 FR 39158), the source entered into service between August 7, 1962 and August 7, 1977, and the source has the potential to emit 250 tons per year or more of a visibility-impairing air pollutant (SO_2, NO_X or PM). The North Dakota Department of Health (NDDH) reviewed the operational history of sources within North Dakota and independently determined which sources are BART eligible. The NDDH classified the electric generating units (EGUs) at Leland Olds Station as BART eligible. For the purposes of this report, the NDDH's determination will be used and Units 1 and 2 at LOS are assumed to be subject to a BART analysis.

Where a particular source is determined to be eligible, the general steps for determining BART for each pollutant are as follows (70 FR 39164):

STEP 1 - Identify all available retrofit control technologies (within the BART Guidelines).
STEP 2 - Eliminate technically infeasible options.
STEP 3 - Evaluate control effectiveness of remaining control technologies.

---

[1] "Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations"; Environmental Protection Agency; Federal Register, Volume 70, No. 128; July 6, 2005.

STEP 4 - Evaluate the following impacts for each feasible control technology and document results: (70 FR 39166).

- The cost of compliance.
- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

STEP 5 – Evaluate the visibility impacts.

Basin Electric Power Cooperative retained Burns & McDonnell to assist in the completion of the Best Available Retrofit Technology analysis for Leland Olds Station. Burns & McDonnell is a full service engineering, architectural, construction and environmental firm. The company plans, designs and constructs electric generating facilities and has been providing environmental services to the power industry since the 1970s. As a result of their long history providing these services, Burns & McDonnell has extensive experience in permitting, Best Available Control Technology (BACT) studies and control technology analysis.

This report includes steps 1 through 5 of the BART Determination for emissions from Units 1 and 2 at LOS. Section 1 of the report quickly summarizes the plant conditions, provides the parameters used in the analysis and discusses the approach to the BART Determination. The true BART analysis begins with Sections 2 through 5. Each section contains the analysis for each major pollutant (NO_X, SO_2 and PM). Within the section for each pollutant, the results of each step of the BART analysis are summarized for each unit. Separate summaries for each unit are provided at the end of the report to communicate the results of each step in the analyses, combine results obtained for each pollutant and develop permit limit recommendations based upon a 30 day rolling average.

1.1 BACKGROUND

Basin Electric Power Cooperative operates the Leland Olds Station in Stanton, North Dakota. Leland Olds Station is a steam electric generating plant with two units. Unit No. 1 is a Babcock & Wilcox (B&W) wall-fired, dry-bottom, pulverized coal-fired boiler serving a turbine generator with a nameplate rating of 220 MW. Particulate control is provided by a Research Cottrell electrostatic precipitator (ESP) rated at 99.5% control. Unit 1 has no sulfur dioxide (SO_2) control system and exhausts to a 350 foot tall, concrete stack with a brick liner. Unit No. 2 is a B&W cyclone-fired unit burning crushed coal, with a turbine-generator name plate rating of 440 MW. Particulate control for

Unit 2 is provided by two parallel Joy Manufacturing precipitators rated at 99.1% control. Unit 2 does not have a flue gas desulfurization system and exhausts to a 500 foot tall, concrete stack with a brick liner. Unit 1 began commercial operation in 1966 and Unit 2 in 1976. Due to their designation by the NDDH, both units are subject to the requirements for BART analysis under the Regional Haze Rule.

1.2 BART ANALYSIS PARAMETERS

Table 1.2-1 contains the design parameters for LOS Unit 1 and Unit 2 used in the analysis. Typical coal parameters used in the BART analysis are provided in Table 1.2-2. The economic factors were specified by BEPC for this study and are presented in Table 1.2-3.

Table 1.2-1 – Unit Design and Operating Parameters

Design Unit Operating Characteristics[(1)]	**Unit 1 Design**	**Unit 2 Design**
Boiler Type	Wall-Fired	Cyclone
Boiler Manufacturer	B&W	B&W
Boiler Design Heat Input Capacity (nameplate), mmBtu/hr	2,622	5,130
Unit Nameplate Generator Output Capacity, MW_g (gross)	216	440

Total	96.78	92.80		92.80

(1) - Typical blend of 93% North Dakota lignite and 7% Powder River Basin (PRB) subbituminous coal on an annual basis.

(2) - A forty year mining plan was analyzed to determine the future maximum annual sulfur content to be used in the BART analysis. The mining plan data used in the analysis is presented in Appendix B2.

Table 1.2-3 – Economic Factors[(1), (2)]

Total Possible Operating Hours per Year	8,760
Amortization Life, Years	20
Cost of Money	6%
Property Taxes, Insurance, %	NA
Conversion Tax (in lieu of property tax)	(see footnote 3)
Amortization Rate for APC Capital Costs	6%
Interest During Construction (IDC)	6%
Discount Rate	6%
Construction Cost Escalation	3%
Non-Fuel O&M Escalation	2%
Fuel (coal and natural gas) Escalation	2%
Auxiliary Electric Power Cost, $/MW-hr	$38.00
Fly Ash Disposal Cost ($/ton)	$5.51
Bottom Ash Disposal ($/ton)	$2.10
Operating Labor Rate (fully burdened), $/hr	$40.60
Administrative or Supervisory Overheads	30%
Lime Cost ($/ton delivered) (4)	$60.50
Limestone Cost ($/ton delivered) (4)	$25.00
Urea Cost, ($/ton delivered)	$380.00
Ammonia Cost ($/ton delivered)	$304.45
Natural Gas ($/mmBtu)	$7.98

(1) - All costs in the table were provided by BEPC.
(2) - All costs are in 2005 dollars unless noted otherwise.
(3) - Conversion tax is provided in the economics for each pollutant control technology.
(4) - Lime and limestone costs are in 2006 dollars.

1.3 APPROACH

The purpose of the Regional Haze Rule is to address visibility impairment in mandatory Class 1 areas that results from the emission of SO_2, NO_X, PM, Volatile Organic Compounds (VOCs) and ammonia from certain major sources. The visibility impact of VOCs and ammonia are considered negligible for a BART analysis, according to the NDDH's November 2005 modeling protocol[2], and are not addressed further in this report. Before the actual BART analysis can begin, a basis must be defined for establishing emission rates to be used by eligible sources. The NDDH requested companies use the same basis that is used for the Prevention of Significant Deterioration (PSD) program which is to determine the hourly averages from the highest 24-month rolling summation emissions within the

---

[2] "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota"; North Dakota Department of Health, Division of Air Quality; November, 2005.

previous 5-year operating period. BEPC reviewed its operating data for 2000 through 2004 to obtain historical emission rates presented in Table 1.3-1.

Table 1.3-1 – Leland Olds Station Historical Emissions for BART Analysis

Pollutant	Unit 1		Unit 2	
	lb/h(1)	tpy(2)	lb/h(1)	tpy(2)
SO_2	4,280	18,749	7,899	34,596
NO_X	697	2,967	2,987	12,023
PM (3)	68.68	263.9	153.32	577.2

(1) - Pounds per hour (lb/h) for SO_2 and NO_X for these historic pre-control baseline emission rates determined as actual 24-month highest rolling summation tons x 2000 lb/ton divided by actual 24-month operating hours for the same time period.

(2) - Tons per year (tpy) for SO_2 and NO_X calculated as the 24 month highest rolling summation tons divided by 2.

(3) - PM emissions calculated from actual 24-month highest rolling summation heat input (mmBtu) divided by actual 24-month operating hours for the same time period multiplied by the average PM total lb/mmBtu from particulate matter tests performed annually.

The historical emission rates are averages based upon operating at partial capacity and burning specific types of coal. Due to the narrow operational characteristics that are a result of past coal quality from which these emission rates were obtained, they are considered not representative for performing a BART analysis at LOS that accurately reflects future coal quality. BEPC discussed an alternative method to obtain acceptable emission rates with the NDDH and obtained approval to use different rates in the LOS BART analysis. The alternative rates are based upon each unit operating at 100% capacity and burning lignite with higher sulfur content. A forty year mining plan was analyzed to determine the future annual average lignite sulfur content used in the BART analysis. The alternative baseline emission rates for the future coal case scenario are labeled “PTE Emissions” and are presented in Table 1.3-2.

Table 1.3-2 – Leland Olds Station Future PTE Emissions for BART Analysis

Pollutant	Unit 1		Unit 2	
	lb/h(1)	tpy(2)	lb/h(1)	tpy(2)
SO_2	9,001	39,424	17,610	77,132
NO_X	760	3,330	3,422	14,989
PM	73	320	169	740

(1) - Pounds per hour (lb/h) for these future PTE pre-control baseline emission rates determined from assumed unit emission rates (lb/mmBtu) multiplied by boiler design capacity heat input rating (mmBtu/hr) provided in Table 1.2-1.

(2) - Tons per year (tpy) calculated from the average hourly unit emission rates multiplied by 8,760 hours per year of possible operation.

In Part IV of the Guidelines for BART Determination, and discussed in Section 1.0 of this report, the EPA provides five basic steps for a case-by-case BART analysis. The format of this report follows these basic steps. The approach used to complete each step is summarized below.

1.3.1 IDENTIFICATION OF RETROFIT CONTROL TECHNOLOGIES

The initial step in the BART determination is the identification of retrofit control technologies. In order to identify the applicable control technologies, several reference works are consulted. A preliminary list of control technologies and their estimated capabilities is developed.

1.3.2 FEASIBILITY ANALYSIS

The second step of the BART process is to evaluate the control processes that have been identified and determine if any of the processes are technically infeasible. The BART guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the "availability" and "applicability" of each control technology.

A control technology is considered available, "if the source owner may obtain it through commercial channels, or it is otherwise available in the common sense meaning of the term" or "if it has reached the stage of licensing and commercial availability." On the contrary, a control technology is not considered available, "in the pilot scale testing stages of development." (70 FR 39165) When considering a source's applicability, technical judgment must be exercised to determine "if it can reasonably be installed and operated on the source type." The EPA also does not "expect a source owner to conduct extended trials to learn how to apply a technology on a totally new and dissimilar source type." (70 FR 39165) "A technology that is available and applicable is technically feasible." (70 FR 39165)

1.3.3 EVALUATE TECHNICALLY FEASIBLE CONTROL OPTIONS BY EFFECTIVENESS

The third step in the BART analysis is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the BART analysis, the control efficiency is reviewed and presented with the description of each technology. The evaluation of the technically feasible BART alternatives concludes with the alternatives ranked in descending order of control effectiveness.

1.3.4 IMPACT ANALYSIS

Step four in the BART analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) lists four factors to be considered in the impact analysis. The BART Determination will consider the following four factors in the impact analysis:

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

The first three of the four factors considered in the impact analysis are discussed in the associated pollutant section. The remaining useful life of the source is included as part of the cost of compliance. Due to the complexity involved with estimating costs, additional discussion is provided below.

1.3.5 METHODOLOGY FOR ESTIMATED COSTS

The economic evaluations of each control alternative are presented together for each pollutant in the respective sections of the report. Capital and O&M cost estimates for each control alternative are presented. The Levelized Total Annual Cost (LTAC) and Unit Control Costs for the control alternatives are calculated and presented. The Levelized Total Annual Cost (LTAC) represents the levelized annual cost of procurement, construction and operation over a 20 year design life, again in current (2005) dollars. As a minimum, the design life for any alternative was taken to be that recommended by “The EPA Air Pollution Control Cost Manual”, Sixth Edition, January 2002, EPA/452/B-02-001.

The LTAC is also used to calculate the average annual and incremental cost effectiveness of each alternative. The LTAC represents an annual payment in current day dollars sufficient to finance the project over its entire life.

In determining the LTAC a Capital Recovery Factor and an O&M Levelization Factor were calculated from the project economic conditions and then applied separately to the estimated capital and O&M costs. The equation used is shown below.

$$LACC/NPV = \left(\frac{i(1+i)^n}{(1+i)^n - 1} \right) = CRF$$

Where,
LACC = Levelized Annual Capital Cost
NPV = Net Present Value of the capital investments required.
i = discount rate
n = design life in years
CRF = Capital Recovery Factor

Therefore:

LACC = CRF x NPV

For the economic conditions described in Table 1.2-3 the Capital Recovery Factor was calculated to be 0.08718.

In determining the levelized annual O&M cost the estimated annual O&M cost, the inflation rate, the discount rate, and the equipment life are taken into account. The O&M Levelization Factor (OMLF) was calculated as follows.

$$LAOMC/A_1 = \left(\frac{1+i_d}{1+i_i} - 1 \right) \left(\frac{i_d (1+i_d)^n}{(1+i_d)^n - 1} \right) = OMLF$$

Where,
A = Levelized Annual O&M Cost (LAOMC)
A_1 = Total annual O&M cost in current dollars
i_d = discount rate
i_i = inflation rate
n = design life in years

Therefore:

LAOMC = OMLF x A_1

For the economic conditions described in Table 1.2-3 the Operating and Maintenance Levelization Factor was calculated to be 1.19314.

The Levelized Total Annual Cost, or LTAC is the sum of the levelized capital cost and the levelized O&M cost. Therefore:

$$\text{LTAC} = \text{LACC} + \text{LAOMC} = (\text{CRF x NPV}) + (\text{OMLF x } A_1) = 0.08718 \text{ x P} + 1.19314 \text{ x } A_1$$

The differences between alternatives are also presented graphically in the form of a plot of the LTAC versus the annual emissions reduction (tpy) for each alternative. This form of plot graphically depicts the cost effectiveness (in $/ton of pollutant reduction) of each alternative relative to all of the others. The cost effectiveness is also referred to as the Unit Control Cost and defined as the LTAC divided by the annual emissions reduction (ton/yr). The area on the plot indicated by the various data points represents the cost effectiveness envelope for the alternatives under consideration. A smooth line is drawn on this plot connecting the rightmost points (those with the lowest cost for a given level of emissions reduction). This line is referred to as the Dominant Control Curve (DCC). The DCC defines the right hand boundary of the envelope encompassing all of the alternatives considered. The DCC is used as a screening tool between considered alternatives. Those alternatives whose plotted position is above and/or to the left of the DCC are not as cost effective as those forming the line and thus can be eliminated from further analysis if desired.

In order to compare various pollutant control alternatives, the Unit Control Cost and the incremental Unit Control Cost of each alternative were also calculated and tabulated for comparison purposes. The Unit Control Cost compares control technologies on a basis of dollars expended per ton of pollutant reduced ($/ton). This relationship is graphically depicted in the DCC chart.

To more accurately compare between alternatives with different costs and control efficiencies, the incremental cost effectiveness is also determined for those alternatives on the DCC. The incremental cost effectiveness is defined as the LTAC of a given control option minus the LTAC of an alternative, divided by the difference between the annual emissions reduction (tpy) of the given control option and the alternative being evaluated. The combination of these two economic analyses can be used as an argument for the elimination of control technologies with significantly greater marginal control costs than the given case. The equation used for the incremental cost effectiveness is shown below.

$$ICF = \frac{(LTAC_1 - LTAC_2)}{(AE_1 - AE_2)}$$

Where,

ICF = Incremental cost effectiveness ($/incremental ton removed)
$LTAC_1$ = Levelized Total Annual Cost of control alternative No. 1 ($/yr)
$LTAC_2$ = Levelized Total Annual Cost of control alternative No. 2 ($/yr)
AE_1 = Control option No. 1 Annual Emissions Reduction (ton/yr)
AE_2 = Control option No. 2 Annual Emissions Reduction (ton/yr)
(The higher cost, more effective control option is subscript 1 in this equation.)

The economic analyses presented in this report not only include the estimated capital and O&M costs for each alternative, but also the LTAC for economic comparison of the various alternatives. In addition, the Unit Control Cost or cost effectiveness is presented for each alternative. Finally, a comparison between alternatives, in the form of the incremental cost effectiveness, is presented in both numerical and graphical form. Thus a comprehensive comparison of the economic impacts of each alternative, as well as the differences in economic impact between alternatives is clearly presented.

1.3.6 METHODOLOGY FOR VISIBILITY IMPACTS DETERMINATION

In the BART Determination Guidelines, and discussed in Section 1.0 of this report, the EPA provides five basic steps for a case-by-case BART analysis. The fifth step involves evaluating visibility impacts utilizing dispersion modeling. Visibility impairment impacts for modeled pre-control and post-control emission levels and visibility improvements are to be assessed in deciViews (dV). The BART guidelines describe the thresholds for visibility impairment as:

> "A single source that is responsible for a 1.0 dV change or more should be considered to "cause" visibility impairment; a source that causes less than a 1.0 dV change may still contribute to visibility impairment..... any threshold that you (the States) use for determining whether a source "contributes" to visibility impairment should not be higher than 0.5 dV." (70 FR 39161)

The NDDH BART protocol does not distinguish between a source that "causes" or "contributes" to visibility impairment but follows the EPA's Regional Haze Rule threshold recommendations. Thus, 0.5 dV is the deminimis threshold level of visibility impairment impact for an otherwise BART-eligible source under the NDDH BART protocol. In other words, a BART-eligible source for which modeling predicts a visibility impairment impact of greater than 0.5 dV is deemed to have a visibility impairment impact and thus is subject to a BART analysis under this the NDDH BART protocol. A BART-eligible source for which the modeling predicts less than a 0.5 dV impact would be deemed to not have a visibility impairment impact, and thus could be exempted from BART on that basis. Most noticeably, the EPA refrains from addressing the question of whether or not a difference in visibility impairment impact improvement of less than 0.5 dV between two BART alternatives would constitute equivalency under the visibility analysis, or if any difference in the model results, no matter how slight, should be interpreted as ranking one solution over the other.

The approach taken in the BART analysis for LOS incorporates the visibility analysis results as part of the decision making process. Thus, when ranking a particular BART alternative during the selection process, the visibility improvement associated with the implementation of that particular alternative is included in the ranking. If two alternatives have an identical potential for visibility improvement, the remaining criteria identified for consideration as part of the impact analysis are then used to differentiate between the two alternatives. Where similar visibility improvement potentials are identified for two or more alternatives, the incremental cost to achieve the slightly greater visibility improvement is determined and evaluated against incremental costs for the next most stringent alternative. This approach identifies the more effective BART alternative in terms of regional haze considerations, not in terms of the most stringent control alternative, as would happen if a strictly top-down approach had been implemented.

1.3.7 ADDITIONAL APPROACH METHODS

In addition to the steps discussed above, there are two subjects within the guidelines which warrant mention due to their effects on the contents of the report. The first subject deals with the presumptive limits and their application to power plants smaller than 750 MW in size. The Guidelines for BART Determination include the following statement with regard to presumptive BART for SO_2 (70 FR 39171):

> "You (meaning States) must require 750 MW power plants to meet specific control levels for SO_2 of either 95 percent control or 0.15 lbs/MMBtu, for each EGU greater than 200 MW that is currently uncontrolled unless you determine that an alternative control level is justified based on a careful consideration of the statutory factors. For a currently uncontrolled EGU

> greater than 200 MW in size, but located at a power plant smaller than 750 MW in size, such controls are generally cost effective and could be used in your BART determination….."

Similarly for NO_X, the EPA states (70 FR 39171):

> "For coal-fired EGUs greater than 200 MW located at greater than 750 MW power plants and operating without post-combustion controls, we have provided presumptive NO_X limits differentiated by boiler design and type of coal burned. You may determine that an alternative control level is appropriate based on a careful consideration of the statutory factors. For coal-fired EGUs greater than 200 MW located at power plants 750 MW or less in size and operating without post-combustion controls, you should likewise presume that these same levels are cost-effective."

For power plants greater than 750 MW in size, the EPA requires state agencies to apply the presumptive limits for BART as a floor for NO_X control. However, for power plants smaller than 750 MW in size, the presumptive limits are described as being "cost-effective" but not set as a minimum performance requirement. Thus, BART for EGUs at power plants smaller than 750 MW in size, like LOS, is not required to meet the presumptive limits. This BART analysis for LOS will evaluate potential control options that can attain presumptive limits on typical EGUs. Consequently, based upon the feasibility analysis, the recommended control options may not achieve the EPA's presumptive BART limits for specific pollutants from certain units.

The second part of the guideline that should be addressed relates to which emission units are subject to BART for a particular pollutant. The guideline states that:

> "Once you determine that a source is subject to BART for a particular pollutant, you must establish BART for that pollutant. The BART determination must address air pollution control measures for each emissions unit or pollutant emitting activity subject to review." (70 FR 39163)

According to this statement, the BART determination must consider any emission unit that emits the pollutant of concern (i.e., NO_x, SO_2, PM) regardless of size. The BART analysis for LOS will review control options for the main boilers for Unit 1 and Unit 2. However, smaller emissions sources at the facility are anticipated to provide negligible contribution to visibility impacts from LOS in Class 1 areas. Smaller sources at LOS are discussed in Section 1.3.8 through 1.3.10.

1.3.8 SMALL SOURCE EMISSION UNITS

The BART determination must consider any emission unit that emits the pollutant of concern (i.e., NO_x, SO_2, PM) regardless of size. However, smaller emissions sources at the facility are anticipated to provide negligible contributions to visibility impairment in Class 1 areas. The nearest Class 1 area is Theodore Roosevelt National Park located approximately 145 km to the west. Although technically eligible, smaller source emissions units were not reviewed because they have limited hours of operation and consequentially their emissions are too small to affect visibility in Class 1 areas. Table 1.3-3 lists emission units at Leland Olds Station that have very low operating hours due to the function of the equipment.

Table 1.3-3 – Leland Olds Station Limited Operation Emissions Units(1)

Emission Unit	Fuel	Rating	Operating Hours	NO_X (tons/yr)	SO_2 (tons/yr)	PM (tons/yr)
Auxiliary Boiler	Fuel Oil	51.6 mmBtu/hr	3.6	0.0128	0.0257	0.0013
Emergency Fire Pump	Fuel Oil	255 hp	4.3	0.00015	0.00030	0.00001

(1) - Emissions are based upon amount of fuel used, sulfur content of the fuel oil, AP-42 emission factors and actual average plant operations for the period of 2000 – 2004.

1.3.9 MATERIAL HANDLING EMISSIONS

Table 1.3-4 lists the emission rates for the material handling units at Leland Olds Station. The majority of the material handling units are associated with the totally enclosed coal delivery system. Since the system is totally enclosed, there would normally be no emissions associated with the equipment. However, the original equipment included air handling systems to reduce fire and explosions hazards caused by build-up of coal dust. The air handling systems used either rotoclones or baghouses for particulate control.

Table 1.3-4 – Leland Olds Station Material Handling Emissions Units

Emission Unit	Unit ID	PM Emissions (tons/yr) (1)
Rotoclone Transfer Tower G	M1	0(2)
Rotoclone Reclaim Tunnel	M2	0(2)
Rotoclone Crusher House (E)	M3	0(2)
Rotoclone Crusher House (W)	M4	0(2)
Rotoclone Transfer Tower	M5	0(2)
Rotoclone Unit 1 Bunker House	M6	0(2)
Rotoclone Unit 2 E. Bunker	M7	4.38
Rotoclone Unit 2 W. Bunker	M8	4.38
Rotoclone Unit 2 W. Trans. Conveyor	M9	4.38
Rotoclone E. Trans. Conveyor	M10	4.38
Baghouse Fabric Filter Main Fly Ash Silo	M11	0.95
Baghouse Fabric Filter 100 Ton Fly Ash Silo	M12	0.01
Baghouse Fabric Filter Coal Unloading	M13	12.39
Baghouse Fabric Filter Agglomerator	M14	0.04
Rotoclone Unit 1 Coal Bunker	M15	0(2)
Baghouse Fabric Filter Coal Unloading Silo	M16	0.19

(1) - Emissions are based upon manufacturers design emission rate and Units 1 and 2 operating at 100% capacity for 8760 hours. Hours of operation were maximized to account for variations in service and resulting annual emissions variation.

(2) - A fogging system was installed in 2003 to replace rotoclones used for fire suppression. The system uses totally enclosed transfer points and does not have any emissions.

In 2003, a water based fogging system was installed in the coal delivery system to provide a higher level of coal dust suppression inside the enclosed system. The existing air handling equipment with the rotoclones were placed in a stand-by mode thereby eliminating associated emissions. As shown in Table 1.3-4, the emission points currently using the fogging system do not have emissions. A search of the RACT/BACT/LAER database for coal handling sources showed that baghouses are currently recognized as the most effective control available for material handling sources emitting PM. No further BART analysis was conducted for baghouse controlled sources listed in Table 1.3-4 because the most effective control technology is already in use on these sources. Materials handling units at LOS using controls produce emissions in levels anticipated to be too small to affect visibility in the nearest Class 1 area located approximately 145 km away and were excluded from further consideration in the study.

1.3.10 FUGITIVE DUST

The primary source of fugitive dust is from the outside coal storage area and other plant activities normally found at a coal-fired electrical generating facility. The coal stockpile, access roads and plant activities are performed and maintained with good operating practices. On the coal stockpile and on other applicable fugitive sources, dust suppression is achieved through the use of water sprays or surfactants.

The level of fugitive PM emissions are not expected to affect the visibility in Class 1 areas based upon the approximate 145 km distance to the nearest Class 1 area, the large particle size and relatively small emission rates. As such, fugitive sources were not evaluated in this BART analysis for LOS.

1.4 THE ROLE OF MODELING AND CALPUFF IN A BART ANALYSIS

The proposed BART guidelines list visibility impact at a Class I area as one of the factors in a BART determination. The EPA interpreted the statutory provision of Section 169A of the Clean Air Act to require that a BART-eligible source is one that is “reasonably anticipated to cause or contribute” to regional haze if it can be shown that the source emits pollutants within a geographic area from which pollutants can be emitted and transported downwind to a Class I area (70 FR 39161). A Class I area, as listed by the EPA, is an area of the country with pristine air quality that is sensitive to changes in visibility. For Class I areas more than 50 km from a source, the EPA has identified CALPUFF as a guideline model for long-range transport that is suitable for predicting potential changes in visibility. CALPUFF is a non-steady-state meteorological and air quality dispersion modeling system used to access long-range transport of pollutants. Two Class 1 areas have been identified for inclusion in the visibility analysis for LOS. These are the Theodore Roosevelt National Park (TRNP), and the Lostwood National Wildlife Refuge (Lostwood NWR), which are approximately 145 and 160 km (90 and 100 miles), from Leland Olds Station, respectively.

The NDDH modeling protocol confirmed that the two Class I areas to be considered for visibility impairment analysis are the TRNP and Lostwood NWR. However, the three units or areas of the TRNP are to be treated as separate Class I areas for the analysis.

1.4.1 CALPUFF MODELING METHODOLOGY

Visibility impairment is caused by a combination of particles and gases in the atmosphere. Some particles and gases scatter light, others absorb light. The combined effect of scattering and absorption is called “light extinction” which is most commonly seen as haze. This haziness is measured in deciView (dV) units, and is related to light extinction coefficient by the following equation:

$$dV = 10 \ln(b_{ext}/10)$$

Where b_{ext} is light extinction coefficient in inverse megameters.

Visibility impairment is a function of light extinction. Light extinction occurs when light energy is either scattered or absorbed by particles in the air. The amount of moisture in the air also plays a role in light extinction. Certain gases combine with moisture in the air to form small light scattering particles. These gases, most notably SO_2 and NO_X, are significant components of coal-fired power plant emissions. Particulate Matter (PM) also contributes to light extinction. In the BART Determination Guidelines, the EPA states that "You may use PM_{10} as an indicator for particulate matter. We do not recommend the use of Total Suspended Particulates (TSP). As emissions of PM_{10} include the components of $PM_{2.5}$ as a subset, there is no need to have separate 250 ton thresholds for PM_{10} and $PM_{2.5}$; 250 tons of PM_{10} represents at most 250 tons of $PM_{2.5}$, and at most 250 tons of any individual particulate species such as elemental carbon, crustal material, etc." (70 FR 39160). The NDDH modeling protocol states that particulate matter emissions should be specified as either course (PM_{10} minus $PM_{2.5}$) or fine ($PM_{2.5}$). The distinction between course and fine particulate occurs in the modeling.

The NDDH modeling protocol recommends a specific version of the CALPUFF modeling system as modified by the NDDH to specifically address terrain, climate, and emission characteristics of LOS. (CALMET and CALPUFF were recompiled by the NDDH while the CALPOST executable used for this visibility analysis was the EPA guideline executable). Along with the CALPUFF modeling system, the NDDH also provided the RUC2-MM5 gridded wind field data (2000-2002), surface, upper air, and precipitation files, and CALMET and CALPUFF input files. The input files contained the specific coordinate grid points, wind field options, terrain, dispersion options, receptor coordinates and plume characteristics and other model parameters that the NDDH has determined best represents the region. The NDDH version of CALPUFF was used for modeling.

In order to predict the change in light extinction at TRNP and Lostwood NWR areas, SO_2, NO_X, and PM were modeled with CALPUFF using pre-control and post-control emission scenarios. A variety of post-control scenarios were used to determine the reduction in visibility impact for each control technology. The NDDH identified 104 receptors allocated over both TRNP and Lostwood NWR. These receptors are location points for which CALPUFF was used to perform a visibility calculation.

The BART guideline states that a visibility improvement is based upon the modeled change in visibility impacts, measured in deciViews, for the pre-control and post-control emission scenarios.

The comparison should be made for the 98th percent days (70 FR 39170). The NDDH modeling protocol provides additional clarification about BART applicability by stating, "…the context of the 98th percentile 24-hour delta-deciView prediction is with respect to days of the year, and is not receptor specific. A 24-hour prediction greater than 0.5 delta-deciView at any receptor in a Class I area would constitute a day of exceedance, and up to 7 days of exceedance would be allowed per year per Class I area (i.e., the 98th percentile is approximated by the eighth-highest daily prediction)." In other words, visibility impacts should be compared on an annual basis using the eighth highest day for comparison (365 * (1-.98) ~ 7 days of acceptable exceedance). However, NDDH subsequently advised that the delta-deciView comparison should be made at the 90th percentile to be consistent with the Western Regional Air Partnership (WRAP) protocol. Therefore, the visibility impairment impact reduction presented for each control scenario in this section is based on the 90th percentile value.

1.4.2 MODELING SCENARIOS

Since a BART analysis is based on the degree of reduction achieved by the application of control technologies, the CALPUFF analysis examined multiple operating scenarios based upon the feasible control technologies identified for each pollutant. These scenarios represent the emissions of SO_2, NO_X, and PM under the following conditions:

- Pre-Control NDDH BART Modeling Protocol historical emissions
- Post-Control emissions based upon future coal data, PTE conditions and control technologies

The removal efficiencies modeled in each scenario are presented in Table 1.4-1.

Table 1.4-1 – Leland Olds Station Emissions Modeling Scenarios

Scenario	**Unit 1**		**Unit 2**	
	NO_X	**SO_2**	**NO_X**	**SO_2**
Screening	Uncontrolled	Uncontrolled	Uncontrolled	Uncontrolled
1(1)	Presumptive(2)	90.0%	60.3%	95.0%(3)
2(1)	Presumptive(2)	93.0%	54.5%	95.0%(3)
3(1)	Presumptive(2)	95.0%(3)	28.0%	95.0%(3)
4(1)	20.7%	90.0%		
5(1)	20.7%	93.0%		
6(1)	20.7%	95.0%(3)		

(1) - Percentages for emission reductions for future PTE post-control (future coal scenario) cases were applied to future PTE baseline average hourly unit emission rates and correspond to control options evaluated in this analysis.

(2) - Presumptive BART NO_X emissions for dry-bottom, wall-fired boilers burning lignite for LOS Unit 1.

(3) - Presumptive BART SO_2 emissions.

These scenarios represent the range of emissions evaluated to date for consideration in making a BART analysis. The removal efficiencies presented in Table 1.4-1 correspond to control options evaluated in this analysis. The pre-control scenario from the NDDH BART modeling protocol is based on the historical, maximum 24-hour emission rates for LOS between 2000 and 2002. These rates were supplied to the NDDH by BEPC, but were based upon emissions from burning specific types of coal. Due to analyses performed on future coal reserves, BEPC has determined that these historic rates are not representative of future maximum 24-hour emissions and has requested NDDH to allow the use of an alternative baseline. NDDH agreed to the alternative baseline. The alternative baseline and post-control scenarios are based upon various control technology emission reductions being applied to emissions from burning future coal at a heat input equal to the 100% of the boiler design capacity rating. Due to the number of variations involved for each pollutant, the scenarios are discussed in the section related to the controlled pollutant.

*****

2.0 NO_X BART EVALUATION

A summary of the BART analysis, steps 1 through 5, for NO_X emissions from Leland Olds Station Unit 1 and Unit 2 are described in this section. A review and discussion of the EPA's presumptive BART NO_X emission limits for dry bottom, wall-fired boilers and cyclone-fired boilers burning lignite is presented. Technical descriptions of LOS Unit 1 and Unit 2 boilers and existing air pollution control equipment are provided. NO_X control technologies are identified, evaluated for feasibility and control capability, then ranked according to effectiveness. The impacts analysis for cost of compliance are summarized, with the estimated capital costs, and operating and maintenance (O&M) costs, for remaining feasible NO_X control alternatives. Remaining useful life impact analysis is included in the calculations for estimated annual costs of the feasible alternatives. Following the cost estimates, the cost effectiveness for selected feasible NO_X control technologies are plotted, and those that comprise the Dominant Control Curve are identified. The energy, non-air quality environmental, and visibility impacts are developed and summarized.

The NO_X BART evaluations for LOS Units 1 and 2 were combined for this part of the BART analysis due to similar control technologies (e.g., both EGUs include coal-fired boilers burning North Dakota lignite), with unit-specific cost-effectiveness and impacts analysis developed for each boiler.

Leland Olds Unit 1 is a Babcock and Wilcox pulverized coal-fired steam generator installed in 1966 (RB-412). The unit includes a pulverized coal-fired subcritical steam-generating boiler using balanced-draft and natural circulation. Original unit design steam generating capacity is 1.570 million lbs/hr at 2,475 psi. The boiler is fired by 20 second-generation low-NO_x burners, consisting of two rows of four burners each arranged within compartmented windboxes across the back wall, and opposed by three rows of four burners across the front wall of the furnace. Four close-coupled, windbox/register-style overfire air ports are arranged across each of the front and rear walls of the furnace just above the top rows of burners. The unit has a tubular air heater installed between the boiler and the ductwork leading to the electrostatic precipitator (ESP) for preheating primary air to promote coal drying and conveying through the ten pulverizers to the burners. Compartmented windboxes are supplied with main combustion air (secondary air) preheated by two rotary regenerative (Ljungstrom) air heaters arranged in parallel. These secondary combustion air heaters (SCAHs) cool the flue gases prior to admission to the ESP. Exhaust gases leave the air heaters and pass through an ESP for particulate collection and removal prior to the two induced draft (ID) fans (installed in parallel) which discharge to the stack. Design nameplate output rating is 216 MW.

LOS Unit 1 does not currently employ post-combustion NO_X emission reduction technology. A summary of the identified NO_X emission control technologies is summarized in Section 2.1.

Leland Olds Station Unit 2 is a Babcock and Wilcox cyclone-fired steam generator first placed into commercial operation in 1975 (RB-489). The unit includes a subcritical steam-generating boiler using balanced-draft and assisted natural circulation. Original unit design steam generating capacity is 3.075 million lbs/hr at 2,620 psi. The boiler is fired by twelve 10-foot diameter cyclone burners, arranged "3 over 3" on front and rear walls of the lower furnace. The unit has a tubular air heater, installed for preheating primary air for coal drying and conveying, and secondary combustion air. The air preheater is located between the boiler and the flue gas ductwork leading to the pair of electrostatic precipitators (ESPs) installed in parallel. Exhaust gases leave the air heater and pass through the two parallel ESPs for particulate collection and removal prior to the two induced draft fans (installed in parallel) which discharge to the stack. Design nameplate output rating is 440 MW.

LOS Unit 2 does not currently employ post-combustion NO_X emission reduction technology. A summary of the identified NO_X emission control technologies is discussed in Section 2.1.

2.0.1 DISCUSSION OF BART GUIDELINES FOR NO_X BART CONTROL ALTERNATIVES AT LELAND OLDS STATION

EPA's final Guidelines for BART Determinations (BART Guidelines), and the Preamble to the final rule, established presumptive emission limits for nitrogen oxides for coal-fired electric generating units (EGUs), including wall-fired dry bottom, pulverized coal boilers burning lignite[1] [70 FR 39172, 39135]. According to the final BART Guidelines, "States, as a general matter, must require owners and operators of greater than 750 MW power plants to meet these BART emission limits" [70 FR 39131]. However, the EPA also recognized that:

> "A State may establish different requirements if the State can demonstrate that an alternative determination is justified based on a consideration of the five statutory factors. In addition, while States are not required to follow these guidelines for EGUs located at power plants with a generating capacity less than 750 MW, based on our analysis…the States will find these same presumptive controls to be highly cost-effective, and to result in a significant degree of visibility improvement, for most EGUs greater than 200 MW, regardless of the size of the plant at which they are located. A State is free to reach a different conclusion if the State

> believes that an alternative determination is justified based on a consideration of the five statutory factors" [70 FR 39131].

The EPA further states in the BART Guidelines that:

> "For sources without post-combustion controls (i.e. SCRs and SNCRs), we [the EPA] are establishing a presumption as to the appropriate BART limits for coal-fired units based on boiler design and coal type. These presumptions apply to EGUs greater than 200 MW at power plants with the generating capacity greater than 750 MW and are based on control strategies that are generally cost-effective for all such units" [70 FR 39134].

Also in the BART Guidelines is the statement:

> "both cost effectiveness and post-control rates for NO_X do depend largely on boiler design and type of coal burned. Based on these analyses, we [the EPA] believe that States should carefully consider the specific NO_X rate limits for different categories of coal-fired utility units, differentiated by boiler design and type of coal burned, set forth below as likely BART limits" [70 FR 39134].

2.0.1.1 PRESUMPTIVE BART NO_X LIMITS FOR PULVERIZED COAL-FIRED BOILERS

According to the BART Guidelines, there are a total of 491 BART-eligible coal-fired EGUs. Of those EGUs, 121 are dry-bottom, wall-fired units greater than 200 MW output. There are 44 dry-bottom, wall-fired units greater than 200 MW output located at power plants with less than 750 MW total output capacity [70 FR 39134, Table 1]. Unit 1 at Leland Olds Station satisfies this criterion.

According to the EPA, for "all types of boilers other than cyclone units, the limits … are based on the use of current combustion control technology. Current combustion control technology is generally, but not always, more cost-effective than post-combustion controls such as SCRs" [70 FR 39134]. Also, "the types of current combustion control technology options assumed [in the EPA's analysis] include low NO_X burners, over-fire air, and coal reburning" [70 FR 39134]. Furthermore, the EPA "assumed that coal-fired EGUs would have the space available to install separated over-fire air" [70 FR 39134].

In the BART Guidelines, the EPA lists the presumptive NO_X emission limits for BART-eligible coal-fired units, distinguished by unit type, and coal type. For dry-bottom, wall-fired EGUs burning lignite coal, the NO_X presumptive limit is 0.29 lb/mmBtu [70 FR 39135, Table 2]. The analysis performed by the EPA for establishing the presumptive limits for NO_X emissions from pulverized coal-fired EGUs assumed only the application of low-NOx burners and overfire air combustion controls.

The actual highest 24-month rolling NO_X summation total from 2000-2004 divided by the actual 24-month rolling summation unit heat input for the same time period for Unit 1 at Leland Olds Station meets the presumptive BART NO_X emission limits stated above. The future PTE case also meets presumptive BART NO_X emission limits. The requirements of performing a NO_X BART analysis on a BART-eligible coal-fired unit with a nameplate capacity greater than 200 MW at a powerplant less than 750 MW that has a unit NO_X emission rate that meets the EPA's presumptive BART NO_X emission limit is not apparent in the BART Guidelines. However, this BART analysis presents a NO_X control technology feasibility evaluation, with impact analysis for NO_X control alternatives. This includes the four prescribed impact criteria plus the impact assessment for visibility impairment improvement for a separated overfire air alternative following the general procedures of the BART Guideline.

2.0.1.2 PRESUMPTIVE BART NO_X LIMITS FOR CYCLONE-FIRED BOILERS

EPA's presumptive limit for emissions of nitrogen oxides from cyclone-fired boilers was established in the final BART Guidelines and the Preamble to the final rule [70 FR 39172]. In discussing NO_X controls for EGUs, there are two somewhat distinct approaches to reducing NO_X at existing sources. One approach is to use combustion controls. The other approach is removal technology applied to the flue gas stream (such as SCRs and SNCRs).

For NO_X emissions control, the EPA analyzed:

> "the installation of SCRs at BART-eligible EGUs, applying SCR to each unit and fuel type. The cost-effectiveness was generally higher than for current combustion control technology except for one unit type, cyclone units. Because of the relatively high NO_X emission rates of cyclone units, SCR is more cost-effective than the use of current combustion control technology for these units. The use of SCRs at cyclone units burning bituminous coal, sub-bituminous coal, and lignite should enable the units to cost-effectively meet NO_X rates of 0.10 lbs/mmBtu. As a result, [the EPA] are establishing a presumptive NO_x limit of 0.10 lbs/mmBtu based on the use of SCR for coal-fired cyclone units greater than 200 MW located at 750 MW power plants. As with other presumptive limits established in this guideline, [the

> States] may determine that an alternative level of control is appropriate based on [the States'] consideration of the relevant statutory factors. For other cyclone units, [the States] should review the use of SCR and consider whether these post-combustion controls should be required as BART"[1] [70 FR 39172].

Also, for cyclone boilers,

> "SCRs were found to be more cost-effective than current combustion control technology [which the EPA established in their analysis as coal reburning]; thus the NO_X limits for cyclone units are set based on using SCRs" [70 FR 39134].

The EPA identified a population of 56 BART-eligible coal-fired cyclone boilers used in their cost-effectiveness analysis for applying SCRs for NO_X control [70 FR 39134 Table 1]. Of the 56 cyclones, 35 are units larger than 200 MW, and 19 are units larger than 200 MW located at 750 MW plants [70 FR 39134]. Conversely, there are 16 cyclone-fired units greater than 200 MW output located at power plants with less than 750 MW total output capacity. Unit 2 at Leland Olds Station fits this criterion.

The EPA's Technical Support Document[2] published in the Edocket (EPA's internet website) for the BART Guidelines describes the cost-effectiveness analysis that resulted in the establishment of SCR as the presumptive NO_X control technology for BART-eligible cyclone-fired coal EGUs. For such cyclone EGUs, the analysis assumed that the unit capacity capital cost factor was $100/kW and 90 percent of the boiler outlet NO_X concentration was removed by SCR technology. The EPA's cost-effectiveness analysis assumed presumptive BART emission rates for the cyclone-fired EGU at Leland Olds Station as 0.07 lb/mmBtu, based on a pre-control emission rate of 0.7 lb/mmBtu. This is approximately 60 percent lower than the lowest BART NO_X presumptive limit (0.17 lb/mmBtu) for dry-bottom, tangentially-fired boilers that burn pulverized lignite coal.

In the EPA's setting of presumptive NO_X limits for coal-fired EGUs larger than 200 MW at power plants greater than 750 MW total gross output rating, the EPA also recognizes that:

> "because of differences in individual boilers, however, there may be situations where the use of such controls would not be technically feasible and/or cost-effective…As noted, the NO_X limits set forth here today are presumptions only; in making a BART determination, States have the ability to consider specific characteristics of the source at issue and to find that the presumptive limits would not be appropriate for that source" [70 FR 39134].

This BART analysis presents a NO_X control technology feasibility evaluation of pre-combustion, combustion, and post-combustion controls, including SCR, separated overfire air, SNCR, and coal reburn for Leland Olds Station Unit 2. This includes the four prescribed impact criteria plus the impact assessment for visibility impairment improvement following the general procedures of the BART Guideline.

2.0.1.3 TECHNOLOGY AVAILABILITY AND APPLICABILITY FOR EMISSION CONTROLS

The second step of the BART process is to evaluate the control processes that have been identified and determine if any of the processes are technically infeasible. The final BART Guidelines states that "two key concepts [are] important in determining whether a technology could be applied: "availability" and "applicability" [70 FR 39165].

As explained in more detail in the final BART Guidelines:

> "a technology is considered "available" if the source owner may obtain it through commercial channels, or it is otherwise available in the common sense meaning of the term" [70 FR 39165].

For the purposes of this analysis, the term "commercial" is further defined to mean "capable of establishing a full contractual agreement with commercial and performance guarantees supported by appropriate financial backing" for the implementation of full-scale, full-time systems of the technique or technology application.

Also per the BART Guidelines:

> "An available technology is "applicable" if it can be reasonably be installed and operated on the source type under consideration. A technology that is available and applicable is technically feasible" [70 FR 39165].

A control technique is considered available "if it has reached the stage of licensing and commercial availability" [70 FR 39165]. "Commercial availability by itself, however, is not necessarily a sufficient basis for concluding a technology to be applicable and therefore technically feasible" [70 FR 39165]. Also, "vendor guarantees may provide an indication of commercial availability and technical feasibility of a control technique and contribute to a determination of technical feasibility or technical infeasibility, depending on circumstances" [70 FR 39165]. Furthermore, the EPA does "not consider a vendor guarantee alone as sufficient justification that a control option will work.

Conversely, lack of a vendor guarantee by itself does not present sufficient justification that a control option is technically infeasible" [70 FR 39165]. [A State agency] "should make decisions about technical feasibility based on chemical, and engineering analyses, as discussed above, in conjunction with information about vendor guarantees" [70 FR 39165]. The EPA also does not "expect a source owner to conduct extended trials to learn how to apply a technology on a totally new and dissimilar source type. Consequently [a State agency] would not consider technologies in the pilot scale stages of development as "available" for the purposes of a BART review" [70 FR 39165]. This would appear to apply to many emerging technologies in the bench, pilot-scale, or "proof-of-concept" testing phases of development, so these were eliminated from the list of potential controls included in subsequent sections of this analysis.

Also in the EPA's final BART Rule is a qualification of "applicability" for technical feasibility, as described by the statement:

> "[a State agency] need[s] to exercise technical judgment in determining whether a control alternative is applicable to the source type under consideration. Where [a State agency] conclude[s] that a control option identified in Step 1 is technically infeasible, [the State agency] should demonstrate that the option is either commercially unavailable, or that specific circumstances preclude its application to a particular emission unit. Generally, such a demonstration involves an evaluation of the characteristics of the pollutant-bearing gas stream and the capabilities of the technology. Alternatively, a demonstration of technical infeasibility may involve a showing that there are unresolvable technical difficulties with applying the control to the source (e.g. size of the unit, location of the proposed site, operating problems related to specific circumstances of the source, space constraints, reliability, and adverse side effects on the rest of the facility)" [70 FR 39165].

2.0.1.4 TECHNOLOGY EVALUATION FOR CONTROL EFFECTIVENESS

The third step in a BART evaluation is to evaluate the remaining control technologies for control effectiveness. The purpose is to establish a level of control effectiveness of the remaining feasible control technologies compared to baseline emission levels so that a suitable basis for estimating cost effectiveness can be determined. In order to determine control and cost effectiveness, "the degree of control using a metric [units] that ensures an "apples to apples" comparison of emissions performance levels among options" [70 FR 39166] is one of the two key issues that must be addressed in a BART analysis. For fossil fuel-fired boilers associated with steam-electric generating units, pounds of nitrogen oxides per unit of fuel heat input (i.e. lb/mmBtu), is a common means of comparing and calculating NO_X emissions.

The second key issue in the evaluation of technically feasible control alternatives is giving appropriate treatment and consideration of control techniques that can operate over a wide range of emission performance levels. Many control techniques, including both add-on controls and inherently lower polluting processes, can perform over a wide range of levels. To clarify this concept:

> "It is not the [EPA's] intention to require analysis of each possible level of efficiency for a control technique, as such an analysis would result in a large number of options. It is important, however, that in analyzing a technology [the States] take into account the most stringent emission control level that the technology is capable of achieving. [The States] should consider recent regulatory decisions and performance data (e.g. manufacturer's data, engineering estimates, and the experience of other sources) when identifying emissions performance level or levels to evaluate" [70 FR 39166].

2.0.1.5 IMPACT EVALUATION FOR FEASIBLE CONTROLS

The fourth step in a BART evaluation is to evaluate BART-specific impacts of remaining feasible control technologies. This consists of four parts:

- Impact analysis part 1: Costs of compliance.
- Impact analysis part 2: Energy impacts.
- Impact analysis part 3: Non-air quality environmental impacts.
- Impact analysis part 4: Remaining useful life of the source.

The purpose of the impacts evaluation is to determine if the remaining useful life of the source or any energy, economic, and non-air quality environmental reasons would eliminate the remaining control technologies from consideration.

Section 1.2 includes information pertinent to the cost analysis for part 1 of the impacts, involving several basic subtasks as prescribed by the BART Guidelines:

1. Identify the emissions units being controlled;
2. Identify design parameters for emissions controls; and
3. Develop cost estimates based upon those design parameters.

According to the BART Guidelines:

> "The part of the plant being evaluated for control costs must be clearly identified and well defined. The analysis should provide a clear summary list of equipment and the associated control costs. Specifying the control system design parameters, and the values selected for those parameters, should ensure that the control option will achieve the level of emission control being evaluated. Once the control technology alternatives and achievable emissions performance levels have been identified, estimated capital and annual costs are developed. The basis for equipment cost estimates also should be documented, either with data supplied by an equipment vendor or by a referenced source (such as the OAQPS Control Cost Manual, latest edition), with the latter preferred where possible. The cost analysis should also take into account any site-specific design or other conditions identified above that affect the cost of a particular BART technology option" [70 FR 39166].

2.0.1.6 VISIBILITY IMPACT EVALUATION FOR FEASIBLE CONTROLS

The fifth step in a BART analysis is to conduct a visibility improvement determination for the source. In order to predict the change in light extinction at the nearest Class 1 areas (TRNP and LNWR), hourly average SO_2, NO_X, and particulate matter emission rates were modeled with CALPUFF using pre-control baselines and different emission control scenarios. Other pollutants are emitted during coal combustion, but the BART guidelines focus on these three. The BART visibility impairment impact analysis was based on:

- NDDH BART protocol screening analysis emission rates (historic highest 24-hour pre-control average)[3]; and
- Potential-To-Emit (PTE) emission rates for the future PTE case (post-control).

A BART visibility impact analysis calculates the change in modeled visibility impairment predicted for the pre-control emissions rates (baseline) compared to the visibility impairment predicted from modeled post-control emissions rates over the days with the highest 90% and 98% visibility impacts above natural background levels at each receptor. Since visibility is a 24-hour averaged analysis, each receptor was tabulated for each day and the visibility impairment impact predicted for the worst 7 days (98th percentile) or worst 36 days (90th percentile). Results from the three-year modeling period included the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area (100th percentile). The visibility impairment impact (dVs) predicted for the 98th percentile and 90th percentile levels were also included with model results. This data is shown in Section 2.4 for LOS Unit 1, and Section 2.5 for LOS Unit 2, with additional details in Appendix D1.

The modeled visibility impact scenarios represent the range of emissions evaluated for consideration in making a BART analysis. The LOS boilers' heat inputs for the future PTE case are from the current NDDH Title V operating permit for LOS dated 7/27/98. The BART guidelines specify "presumptive BART" as 95% SO_2 control and NO_X levels of 0.29 lb/mmBtu for dry-bottom, wall-fired boilers burning pulverized lignite. These conditions were applied to the emissions for one run of visibility modeling of the post-control future PTE case for LOS Unit 1. Additional modeling runs for LOS Unit 1 were performed for various high levels of SO_2 control with a NO_X emission level expected to result from the next highest cost NO_X control alternative, i.e. achieving below the presumptive BART NO_X level using separated overfire air. The emissions for the post-control future PTE case for LOS Unit 2 include a presumptive BART level of 95% SO_2 control along with various alternative levels of NO_X control presented in Table 1.4-1.

2.0.1.7 BASIS FOR NO_X BART ANALYSIS AT LOS - UNIT 1

For LOS Unit 1, control and cost-effectiveness were evaluated at the historic highest 24-consecutive month average NO_X emission rate during the calendar years 2000-2004. This pre-control NO_X emission rate averaged 247 tons per month for the period ending on the last day of August 2004. This is equivalent to 2,967 tons of NO_X per year, and corresponds to an average hourly NO_X emission rate of 697 lbs per hour of actual operation. The historic 24-month average hourly NO_X emission rate for LOS Unit 1 is based upon an annual average unit operation of 8,510 hrs/yr corresponding to the same time period. This annual unit operation is equivalent to a 97.2% plant availability factor relative to 8,760 hrs/yr. An equivalent 24-month average NO_X emission rate of 0.285 lb/mmBtu was derived for this period of operation. An average gross unit output of 217.8 MW and average gross fuel heat input rate of 2,443 mmBtu/hr correspond to this same historic 24-month operating period. Compared to an average gross fuel heat input rate of 2,468 mmBtu/hr corresponding to a nominal 220 MW gross unit output, this historic highest 24-month operation resulted in an average running plant capacity factor (RPCF) of 99.0 percent during this same time period. The availability factor of 97.2% and the running plant capacity factor were used to calculate an overall capacity factor of 96.2 percent. LOS Unit 1's nameplate capacity of 216 MW (gross) output was used for the basis of controls design for BART determination purposes according to the EPA's Technical Support Document – Methodology for Developing BART NO_X Presumptive Limits[2]. This nameplate capacity also served as the assumed number for calculating capital costs based on $/kW unit capacity capital cost factors.

For LOS Unit 1, control and cost-effectiveness were also evaluated at the post-control basis for the maximum future PTE case. This analysis assumed an hourly average gross fuel heat input rate equal to the boiler design capacity rating of 2,622 mmBtu/hr for 8,760 hours per year of operation for LOS Unit 1's boiler.

The BART Guidelines specify presumptive BART levels for NO_X emissions from a dry bottom, wall-fired EGU burning pulverized lignite as 0.29 lb NO_X/mmBtu. The equivalent 24-month highest historic average NO_X emission rate was 0.285 lb /mmBtu during the calendar years 2000-2004. If the EPA's presumptive BART level were applied to LOS Unit 1's NO_X emissions, this would indicate that LOS Unit 1 already complies on a historic long-term average basis. Maintaining an average NO_X emission rate of 0.29 lb /mmBtu for the future PTE case for LOS Unit 1 also complies with the EPA's presumptive BART NO_X emission level for dry-bottom wall-fired boilers burning pulverized lignite in power plants greater than 750 MW.

2.0.1.8 BASIS FOR NO_X BART ANALYSIS AT LOS - UNIT 2

For LOS Unit 2, the highest 24-consecutive month average NO_X emission rate during the calendar years 2000-2004 averaged 1,002 tons per month, for the period ending on the last day of February 2003. This pre-control NO_X emission rate is equivalent to 12,023 tons/yr, and corresponds with an average NO_X emission rate of 2,987 lbs per hour of actual operation. The historic 24-month average hourly NO_X emission rate for LOS Unit 2 is based upon an annual average unit operation of 8,050 hrs/yr corresponding to the same time period. This annual unit operation is equivalent to a 91.9% plant availability factor relative to 8,760 hrs/yr. An equivalent 24-month average NO_X emission rate of 0.667 lb /mmBtu was derived for this period of operation. An average gross unit output of 406.5 MW and average gross fuel heat input rate of 4,478 mmBtu/hr correspond to this same historic 24-month operating period. Compared to an average gross fuel heat input rate of 4,846 mmBtu/hr corresponding to a nominal 440 MW gross unit output, this historic highest 24-month operation resulted in an average running plant capacity factor (RPCF) of 92.4% during this same time period. LOS Unit 2's nameplate capacity of 440 MW (gross) output was used for the basis of controls design for BART determination purposes according to the EPA's Technical Support Document –

Methodology for Developing BART NO_X Presumptive Limits[2]. This nameplate capacity also served as the assumed number for calculating capital costs based on $/kW unit capacity capital cost factors.

For LOS Unit 2, control and cost-effectiveness were also evaluated at the post-control basis for the future PTE case. This analysis assumed an hourly average gross fuel heat input rate equal to the boiler design capacity rating of 5,130 mmBtu/hr for 8,760 hours per year of operation for LOS Unit 2's boiler.

2.1 IDENTIFICATION OF RETROFIT NO_X CONTROL TECHNOLOGIES

The first step in the BART evaluation for nitrogen oxides emissions following determination of BART eligibility is to identify potentially applicable retrofit control alternatives. A comprehensive literature search was performed, with sources including technical papers and presentations made by parties involved with design, construction, and testing of NO_X control techniques at conferences sponsored by nationally-recognized technical organizations, plus hardware supplier experience lists.

Uncontrolled NO_X emissions from a coal-fired electric generating unit are highly dependent on type of firing method, amount of solid fuel fired per unit time and furnace volume, and the fuel's basic combustion properties and elemental composition. The methods for reduction of such emissions:

- either prevent pollution, i.e. use inherently lower-emitting processes/practices which produce fewer NO_X emissions during the power generation process; or
- involve improvements to, or provide new add-on controls that, reduce emissions after they are produced before they are emitted from the facility; or
- are combinations of inherently lower-emitting processes and add-on controls.

There are three basic categories of NO_X emission control alternatives:

- Pre-combustion controls;
- Combustion controls; and
- Post-Combustion controls.

A significant number of the identified control options have been commercially-available, installed, and operating in many full-scale, permanent installations i the United States for five years or more.

A summary of the potentially available alternatives identified for NO_X emissions control on coal-fired steam-electric generating units is shown in Table 2.1-1.

TABLE 2.1-1 – Potentially Available NO_X Control Alternatives Identified for BART Analysis

Control Technology
Pre-Combustion Controls
Fuel Blending/Switching/Cleaning
Combustion Controls
Basic Combustion Control Improvements
Low NO_X Burners (LNB)
Separated Overfire Air (SOFA) / Boosted SOFA
Flue Gas Recirculation
Fuel Reburn
Oxygen-enhanced Combustion (OEC)
Water/steam Injection (Combustion Tempering)
Post-Combustion Controls
Selective Non-Catalytic Reduction (SNCR)(1)
Selective Catalytic Reduction (SCR)
Electro-Catalytic Oxidation (ECO®)(2)

Notes: these are basic forms of the identified techniques.
Not all variations or combinations are included.
(1) – SNCR technologies include Rich Reagent Injection, and Hydrocarbon-enhanced SNCR, commercially available as "NO_XStar™".
(2) – Multi-pollutant control technology currently under commercial development by Powerspan Corp.

Pre-combustion controls, such as fuel switching, fuel blending, and fuel cleaning, have been practiced and performed at numerous utility power plants, typically for sulfur dioxide and nitrogen oxide emissions control reasons.

Combustion controls, such as low-NO_X burners (LNBs) and overfire air systems, are very commonly applied to pulverized coal and gaseous or liquid fuel-fired boilers. Flue gas recirculation (FGR) has been applied and practiced at numerous natural gas and fuel oil-fired utility and industrial power plants for NO_X emissions control. FGR has been applied to large coal-fired utility boilers, primarily for steam temperature control purposes, not for emissions control. Conventional Gas Reburn (CGR) with overfire air has been placed in commercial operation on several cyclone-fired boilers, primarily in the eastern region of the United States. Coal Reburn (CR) with overfire air has been successfully demonstrated on two cyclone-fired boilers and commercially installed on three pulverized coal-fired boilers in the United States.

Selective Catalytic Reduction (SCR) and Selective Non-Catalytic Reduction (SNCR) are post-combustion technologies that have been applied mostly on eastern or midwestern bituminous coal-fired boilers. Others, mostly comprised of a combination of available control technologies, are often referred to as "hybrid" or "layered" control technologies. Variations of SNCR, such as recently developed "Rich Reagent Injection" (RRI) technology with and without SNCR, have only been demonstrated on a limited number of cyclone-fired boilers. Other layered NO_X emission control technologies, such as Fuel Lean Gas Reburn with SNCR, hydrocarbon-enhanced SNCR (commercially available as NO_XStar™), and oxygen-enhanced combustion have only been demonstrated and/or installed on a limited number of pulverized coal-fired power plants.

Emerging post-combustion multi-pollutant control technologies, such as Powerspan's Electro-Catalytic Oxidation (ECO®), which include NO_X control, were also identified. These are typically in the pilot-scale commercial development phase, and have not been successfully demonstrated on a full scale basis on any pulverized coal, cyclone, or circulating fluidized bed boilers.

In most of the "layered" control combination and emerging control cases, the NO_X control technology has been demonstrated to be capable of controlling the targeted pollutant(s) on either:

- a full-scale basis, but only with temporary equipment; or
- a full-scale basis, with permanent equipment but in a limited number of installations; or
- a commercial development basis with less than full-scale and full-time application.

The predominant method employed for control of NO_X emissions on dry bottom, wall-fired pulverized coal boilers is the application of low-NO_X burners (LNBs) and separated overfire air systems. Section 2.2 includes a summary of these control technologies available for potential use on LOS Unit 1, which uses existing low-NO_X burners and close-coupled overfire air. LOS Unit 1 appears to meet the current EPA BART presumptive NO_X emission level for dry bottom, wall-fired boilers burning pulverized lignite.

There are a number of coal-fired cyclone boilers around the country that have implemented or are planning to implement modifications to reduce NO_X emissions. Table 2.1-2 summarizes the various NO_X emission control system installations currently installed, or that have been demonstrated on a full-scale, short-term basis, in response to Acid Rain requirements, EPA's NO_X SIP call and local regulations, or a utility investigating the technology. The following section also includes a summary of these control technologies potentially available and applicable for use on LOS Unit 1 and Unit 2

TABLE 2.1-2 – Identified NO_X Control System Retrofits on Pulverized Coal and Cyclone Coal-Fired Boilers

No. of Units[1]	NO_X Control Technology Description[1]
	Pulverized Coal-Fired Boiler NO_X Control Technology Description
100+	Pulverized coal Low-NO_X Burners, w/ and w/o Separated Overfire Air (SOFA)
28	Selective Non-Catalytic Reduction, w/ and w/o Low NO_X Burners & SOFA
50+[2],[3]	High-dust or low-dust SCR, with or without other technologies
0[3]	Tail-gas SCR, with or without other technologies
8	Conventional fuel reburn (coal, gas, oil, orimulsion), w/ and w/o Low- NO_X Burners
1	Fuel lean gas reburn (FLGR), w/ and w/o Low- NO_X Burners
5	Amine-enhanced FLGR, w/ and w/o Low- NO_X Burners
2	Oxygen-enhanced combustion, w/ and w/o Low- NO_X Burners
	Cyclone Coal-Fired Boiler NO_X Control Technology Description
39[4]	Separated Overfire Air (SOFA)
22[3]	High-dust or low-dust SCR, with or without other technologies
1[3]	Tail-gas SCR, with or without other technologies
7[5]	Conventional fuel reburn (pulverized or micronized coal, gas), w/ SOFA
1[6]	Fuel lean gas reburn, with or without SOFA
2	Selective Non-Catalytic Reduction, with or without SOFA
2[7]	Rich Reagent Injection, with SOFA

(1) – This list of known NO_X control retrofit installations is primarily focused on units in the United States. There may be other installations that are similar but were not identified. Includes boilers retrofit for full-scale temporary demonstration testing and permanent installations. Does not include Powerspan's ECO™ multi-pollutant control pilot plant (commercial demonstration unit, or CDU) at FirstEnergy's R.E. Burger Station Units 4&5.

(2) – At least 85 existing SCRs have been installed on BART-eligible EGUs in the US, mostly on coal-fired boilers burning eastern bituminous fuels. No examples of boilers located in the United States that were retrofit for full-scale, permanent TG SCR installations were found. PSE&G's Mercer Station Units 1 & 2 have low-dust SCRs with flue gas reheat, but they do not have flue gas desulfurization systems upstream of the SCR reactor inlets. See Technical Literature Reference list and Appendix A for further details

(3) – High-dust SCR technology has been retrofitted on sixteen U.S. cyclone-fired boilers, all believed to have SOFA. Low-dust SCRs in U.S. have only been installed on pulverized coal-fired boilers, none on cyclones. One tail-gas SCR installation on a coal-fired cyclone boiler found in Germany; none in the U.S. See technical literature references in Appendix A1 and A3 for details.

(4) – Installed for NO_X control without fuel reburn. A list of known cyclone boiler SOFA installations is included in Appendix A3.

(5) – Several conventional coal and gas reburn retrofits have discontinued reburn demonstration or routine operation. See Technical Literature Reference list and Appendix A3 for further details.

(6) – Only one example of fuel lean gas reburn retrofit (without OFA) on a cyclone-fired boiler has been demonstrated. This system was installed for short-term reburn testing and has since been removed.

(7) – RRI has only been demonstrated with temporary equipment for testing. See Technical Literature Reference List and Appendix A3 for further details.

A more detailed description of the various NO_X control technology retrofits and their technical feasibility is included in Appendix A1, with the associated references for technical literature. A summary of several U.S. NO_X retrofit projects and their claimed emission control effectiveness are included in Appendix A3, with the associated technical literature references for the selected NO_X control projects' listed in Appendix A4.

2.2 TECHNICAL DESCRIPTIONS AND FEASIBILITY ANALYSIS OF NO_X CONTROL TECHNOLOGIES

The second step of the BART process is to evaluate the control processes that have been identified. The following paragraphs summarize the evaluation of the processes for technical feasibility for Leland Olds Station Unit 1 and Unit 2 NO_X controls.

2.2.1 FEASIBILITY OF PRE-COMBUSTION NO_X CONTROLS

Pre-combustion controls involve technologies that are usually applied to the fuel and occur prior to entering the boiler. Pre-combustion controls include:

- Fuel switching,
- Fuel blending, and
- Fuel cleaning.

These techniques have been practiced and performed at numerous utility power plants, typically for operational and sulfur emissions control reasons. These methods are feasible, but considering the current use of lower cost lignite fuel and approximately equal combustion performance, they are not expected to produce lower NO_X emissions, and were eliminated from further consideration for NO_X control at Leland Olds Station. These techniques were not included in the NO_X control cost-effectiveness analysis. For more details, refer to the technical feasibility description included in Appendix A1.

2.2.2 FEASIBILITY OF COMBUSTION NO_X CONTROLS AT LOS

2.2.2.1 COMBUSTION NO_X CONTROLS - UNIT 1

Combustion controls include technologies that are applied to a pulverized fuel-fired boiler. These are summarized as follows:

- Basic combustion control improvements such as low-NO_X burners and separated overfire air are feasible, primarily involving improvements to measuring and controlling fuel feed and combustion air distribution. Basic combustion control improvements and improved operating techniques have already been implemented on the Unit 1 boiler to lower NO_X emissions, so no significant further reductions are expected without being incorporated into another feasible alternative, such as separated overfire air. Basic combustion control improvements alone were eliminated from consideration for additional NO_X reduction at Leland Olds Station.
- Low-NO_X burners (LNBs) are commonly installed in place of original equipment provided prior to 1990. These are often, but not always, installed with some form of overfire air to allow for air-staged or "starved air" combustion to lower NO_X emissions. LOS Unit 1 already has second-generation replacement low NO_X burners suitable for good combustion performance and low NO_X emissions with pulverized lignite fuel. Installing the latest multi-zone LNBs would not significantly lower NO_X emissions without adverse operational consequences, such as unstable flame patterns and raising unburned carbon levels in the emitted flyash. Using the latest LNB technology was eliminated from consideration for additional NO_X reduction at LOS for Unit 1.
- Separated overfire air (SOFA) systems are very commonly applied to pulverized coal-fired boilers for combustion NO_X control. SOFA systems typically divert approximately 15-20% of the hot secondary combustion air admitted to the boiler through the burners to dedicated ports located at higher elevations of the furnace, above the top row of burners. The overall amount of excess air admitted to the boiler is not substantially different than prior to implementation of a SOFA system. SOFA systems are often installed and operated with low-NO_X burners to provide lower carbon monoxide (CO) emissions and unburned carbon (UBC) levels in flyash during air-staged burner operation for effective NO_X emissions control. Booster fans may use ambient or hot secondary combustion air to supply the SOFA ports for higher velocity air injection, which promotes better mixing with the furnace gases for lower CO emissions and flyash UBC content than may be achieved with diverted secondary air on boilers with low windbox air pressure.

  - Unit 1 at LOS already has close-coupled overfire air (CCOFA) and is capable of modest levels of additional NO_X emissions reduction by eliminating CCOFA and adding SOFA. Using SOFA was included in the control effectiveness analysis for additional NO_X reduction at LOS for Unit 1.
  - "Rotating Opposed Fired Air" (ROFA) is feasible for dry-bottom, wall-fired pulverized coal boilers such as LOS Unit 1. It is different than basic SOFA in that it includes a hot air booster fan and injects the high-pressure overfire air into the boiler in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row[9].
    - ROFA does not offer a significantly greater NO_X control reduction advantage compared with conventional SOFA to compensate for the higher costs of supplying, installing, and operating the booster fan for LOS Unit 1. This technology is subject to the same operating limitations as conventional air-staged or fuel-staged pulverized coal burners burning North Dakota lignite. (See Appendix A1 for details).
    - Alternatives with boosted overfire assume the installation of ROFA in the control effectiveness and cost evaluation for the Unit 1 boiler at Leland Olds Station.
- Fuel reburn, with and without overfire air:
  - Conventional gas reburn (CGR) and conventional pulverized or micronized coal reburn (PCR or MCR) have been installed and demonstrated as effective for NO_X control on pulverized coal boilers [10,11,12,13,15,16]. CGR or PCR/MCR replaces around 15-30% of total boiler fuel heat input with reburn fuel injected downstream of burners and upstream of SOFA, with or without air-staging the burners. CGR or PCR/MCR would likely involve operation with fewer active pulverized coal main burners.
    - Although LOS currently has no direct high volume supply of gaseous fossil fuels, conventional gas reburn is otherwise considered technically feasible for NO_X control at LOS. Compared with other similarly-effective NO_X controls, conventional gas reburn's expected high capital costs for a natural gas supply pipeline and on-going natural gas costs make gas-consuming alternatives economically unattractive for application at LOS. Conventional gas reburn alternatives were not evaluated further for consideration as NO_X control options for LOS Unit 1.
    - Powerhouse site space constraints would require dedicated buildings and grinding equipment for coal reburn fuel preparation for LOS Unit 1. PCR/MCR would require improvements to increase PM collection efficiency for LOS Unit 1 to prevent higher particulate matter emissions (described in more detail in Appendix A1).

    - Conventional pulverized/micronized coal reburn alternatives were included in the control effectiveness and cost evaluation for the Unit 1 boiler at Leland Olds Station.
  - Fuel-lean gas reburn (FLGR™) has been permanently installed on only a few dry-bottom, pulverized coal-fired boilers. FLGR™ replaces around 6-7% of total boiler fuel heat input with natural gas injection downstream of burners and overfire air, with or without air-staging the burners below stoichiometric ratio.
    - FLGR™ is considered technically feasible for application on LOS Unit 1, but compared with other equally-effective NO_X controls, the expected high capital costs for a natural gas supply pipeline and on-going natural gas costs make this alternative economically unattractive for application at LOS.
    - With much higher installation and operating costs compared with SOFA, FLGR™ alternatives were not evaluated further for consideration as NO_X control options for LOS Unit 1.
- Oxygen-enhanced combustion (OEC) has only been demonstrated and/or installed on a limited number of small pulverized coal-fired power plants[19,20].
  - OEC has not been demonstrated and does not have permanently installed experience on pulverized coal boilers in the same output range as LOS Unit 1. Compared with other equally-effective NO_X controls, expected high on-going oxygen costs make this alternative economically unattractive for application at LOS.
  - OEC was considered infeasible for NO_X control application at LOS on Unit 1.
- Flue gas recirculation (FGR) has been applied and practiced at numerous natural gas and fuel oil-fired utility and industrial power plants for NO_X emissions control. No examples of flue gas recirculation applied to dry-bottom wall-fired pulverized coal boilers for NO_X control were found. FGR has been applied to large coal-fired utility boilers, primarily for steam temperature control purposes, but not for emissions control. Lacking demonstrated experience on pulverized coal boilers for NO_X control purposes, FGR was considered infeasible for application at LOS on Unit 1
- Water/steam injection has been retrofit and intermittently practiced on older natural gas and oil-burning wall-fired utility boilers. This technique was not found to be permanently installed and continuously practiced on dry-bottom wall-fired pulverized coal boilers, especially those that fire high-moisture lignite or western subbituminous coals. Thus, water/steam injection was considered infeasible for permanent, full-time, long-term application for NO_X control on Unit 1.

2.2.2.2 COMBUSTION NO$_X$ CONTROLS - UNIT 2

Combustion controls include technologies that are applied to a cyclone-fired boiler. These are summarized as follows:

- Basic combustion control improvements and improved operating techniques have already been implemented on the Unit 2 boiler to lower NO$_X$ emissions, so no significant further reductions are expected without being incorporated into another feasible alternative, such as separated overfire air. Basic combustion control improvements were eliminated from consideration for additional NO$_X$ reduction at LOS for the Unit 2 boiler.
- Low-NO$_X$ burners (LNBs) are not applicable as replacements of cyclones for combustion NO$_X$ control[4]. This alternative was considered infeasible for application at LOS for the Unit 2 boiler.
- Separated overfire air (SOFA) systems have been retrofit to many cyclone boilers[4,5,6,7,8] for combustion NO$_X$ control. The amount of secondary combustion air diverted from the burners and function of a SOFA system applied to a cyclone boiler is generally the same as for a pulverized coal boiler. Supplying a booster fan for raising the pressure of the separated overfire air on a cyclone boiler is unnecessary, since cyclone boilers inherently require higher pressure combustion air than pulverized coal boilers.
  - "Advanced" SOFA (ASOFA) offers the highest performing version of this technology for lignite-fired cyclone boilers, and includes relocating lignite drying system vent ports and flue gas recirculation ports. Using ASOFA was included in the control effectiveness analysis for additional NO$_X$ reduction at LOS for Unit 2. Such NO$_X$ control improvements at LOS Unit 2 will be limited by potential adverse impacts on cyclone operation associated with air-staged (sub-stoichiometric air/fuel) cyclone operation, which are described in Appendix A1.
  - ROFA has not been demonstrated or permanently installed and operated on any cyclone boiler.
    - ROFA is subject to the same operating limitations as conventional air-staged or fuel-staged cyclones burning North Dakota lignite. (See Appendix A1).
    - Since a booster fan typically supplied with this technology is not necessary for cyclone boilers, ROFA does not appear to offer significant advantages for improved NO$_X$ control performance on LOS Unit 2 compared to conventional SOFA.
    - Although it may be possible to install some aspects of ROFA on a cyclone boiler, such as high-velocity offset overfire air ports without a booster fan, the lack of experience on cyclone boiler applications makes this alternative infeasible for LOS Unit 2. ROFA was not evaluated further for the Unit 2 boiler at Leland Olds Station.

- Fuel reburn, with and without overfire air:
  - Conventional gas reburn (CGR) and conventional pulverized or micronized coal reburn (PCR or MCR) have been installed and demonstrated as effective for NO_X control on cyclone boilers[10,11,12,13,14,15,16].
    - CGR or PCR/MCR replaces around 15-30% of total boiler fuel heat input with reburn fuel injected downstream of the cyclones and upstream of SOFA, with or without air-staging the cyclones.
    - CGR or PCR/MCR would likely involve operation with fewer active cyclones.
    - Operation of CGR or PCR/MCR with fewer active cyclones with limited use of advanced SOFA on LOS Unit 2 potentially avoids some adverse operational impacts and impairments associated with fuel- and air-staging cyclones burning North Dakota lignite.
    - Compared with other similarly-effective NO_X controls, conventional gas reburn's expected high capital costs for a natural gas supply pipeline and on-going natural gas costs make gas-consuming alternatives economically unattractive for application at LOS. CGR with ASOFA was not evaluated further for LOS Unit 2.
    - Powerhouse site space constraints would require dedicated buildings and grinding equipment for coal reburn fuel preparation for LOS Unit 2. PCR/MCR would require improvements to increase PM collection capacity additions for LOS Unit 2, for preventing higher particulate matter emissions (described in more detail in Appendix A1).
    - These conditions will make conventional PCR/MCR with basic or advanced versions of SOFA more expensive to install, operate, and maintain at LOS compared to previous retrofit coal reburn applications on existing cyclone-fired boilers. The conventional PCR/MCR with ASOFA alternative is the highest performing version considered technically feasible for NO_X control at Leland Olds Station, and was evaluated for LOS Unit 2.
  - Fuel-lean gas reburn (FLGR™) has not been permanently installed and operated on any cyclone-fired boilers. FLGR™ replaces around 6-7% of total boiler fuel heat input with natural gas injection downstream of cyclones and overfire air, with or without air-staging the cyclones below stoichiometric ratio.
    - For cyclone boilers, FLGR™ has only been demonstrated during a single short-term test[17,18] on a cyclone boiler without a SOFA system. This technology appears to offer limited NO_X control potential on cyclone boilers burning North Dakota lignite, especially for the current configuration of lignite drying system vent ports and flue gas recirculation

    ports in the lower furnace where the gas injectors would be located (described in more detail in Appendix A1).
    - FLGR™ may be technically feasible to be installed with an advanced form of SOFA on cyclone boilers designed to burn North Dakota lignite, however the expected high capital costs for a natural gas supply pipeline and on-going natural gas costs make this alternative economically unattractive for application at LOS. FLGR™ was not evaluated further as a combustion control option for LOS Unit 2 NO_X reduction.
- Oxygen-enhanced combustion (OEC) has not been demonstrated and/or installed on a cyclone-fired boiler. Lacking demonstrated experience on cyclone boilers, OEC was considered infeasible for NO_X control application at LOS on Unit 2.
- Flue gas recirculation (FGR) has been applied and practiced at numerous natural gas and fuel oil-fired utility and industrial power plants for NO_X emissions control. No examples of flue gas recirculation applied to coal-fired cyclone boilers for NO_X control were found. FGR has been applied to large coal-fired utility boilers, primarily for steam temperature control purposes, not for emissions control.
    - FGR is installed and practiced at LOS on Unit 2 for operational reasons, not for NO_X control. However, the advanced version of SOFA applied to cyclone boilers designed to burn North Dakota lignite using lignite drying systems would relocate the existing lower furnace FGR ports to minimize disruption of the in-furnace NO_X reduction process (described in more detail in Appendix A1). Due to the lack of use on cyclone boilers, using FGR alone for NO_X control at LOS Unit 2 was eliminated from further consideration.
- Water/steam injection has been retrofit and intermittently practiced on older natural gas wall-fired utility boilers, and at one natural gas-fired cyclone boiler[21]. Although it has been tested on eastern or midwestern bituminous coal-fired cyclone boilers[4], this technique was not found to be permanently installed and continuously practiced on coal-fired cyclone boilers, especially those that fire high-moisture lignite or western subbituminous coals. Thus, water/steam injection was considered infeasible for permanent, full-time, long-term application for NO_X control on lignite-fired boilers at LOS.

2.2.3 FEASIBILITY OF POST-COMBUSTION NO_X CONTROLS

2.2.3.1 POST-COMBUSTION NO_X CONTROLS - UNIT 1

Post-combustion controls involve technologies that are usually applied to the flue gas exiting the boiler. These are summarized as follows:

- Selective Non-Catalytic Reduction (SNCR) and variations for NO_X control at LOS Unit 1:
  - Injects ammonia or urea reagent into the upper furnace zone with suitable temperature conditions.
  - Chemical reactions of amine and NO_X are insensitive to fuel and boiler type; excess unreacted reagent is emitted from the boiler as "ammonia slip" and can contribute to fouling of air heaters when combined with sulfates.
  - SNCR can be implemented with or without other combustion and in-furnace and downstream post-combustion controls.
  - SNCR has been applied and practiced on numerous pulverized coal utility boilers.
  - SNCR, in combination with the existing close-coupled overfire air (CCOFA), is considered feasible for modest NO_X control on the Unit 1 pulverized coal boiler at LOS.
  - Hydrocarbon-enhanced SNCR (commercially available as NO_XStar^{TM}) uses high temperature steam and ammonia vapor with small quantities of gaseous hydrocarbon fuel (natural gas or propane) and offers potentially higher NO_X control performance than conventional SNCR. NO_XStar^{TM} has been demonstrated with the initial installation on one pulverized coal-fired boiler burning eastern coal, and commercially installed on another PC boiler burning eastern coal[25,26].
    - NO_XStar^{TM} is susceptible to major impairment of permanently-installed injection lances attached to convective heat transfer surfaces of the boiler due to severe fouling expected from lignite ash deposits.
    - NO_XStar^{TM} may be feasible for NO_X control on lignite-fired dry-bottom pulverized coal boilers such as LOS Unit 1. However, with much higher installation and operating costs compared with SOFA, and the lack of a experience on dry-bottom PC-fired boilers burning high fouling coals such as lignite, this alternative was considered infeasible as a NO_X control option for LOS Unit 1.
  - Rich Reagent Injection (RRI) injects aqueous urea into the high-temperature lower furnace zone and requires an "air-starved" atmosphere to avoid creating instead of reducing NO_X. RRI has not been developed nor demonstrated for NO_X control application on pulverized coal-fired boilers. This alternative is considered infeasible for LOS Unit 1.
- Selective Catalytic Reduction (SCR):
  - Injects ammonia reagent into the flue gas in a zone with suitable temperature conditions.
  - Chemical reactions of ammonia and NO_X in the presence of a catalyst are effective at much lower temperatures than SNCR, typically 600°F to 750°F. Very high NO_X control efficiencies are possible, with lower reagent consumption per ton of NO_X emission reduction

compared to SNCR. This technology has been applied to a variety of fuels and boiler types. Excess unreacted reagent is emitted from the boiler as "ammonia slip" and can contribute to fouling of air heaters when combined with sulfates.

  - Conventional SCR technology has been widely applied to pulverized coal fired boilers in the United States for NO_X control, primarily in a "hot-side, high-dust" arrangement.
    - There have been no installations of SCR systems (full-scale) on units that fire North Dakota lignite.
    - An evaluation of impacts of ash on SCR plugging and blinding was performed, which included the use of SCR slipstream testing on a North Dakota lignite-fired powerplant. This slipstream SCR testing examined the significance of ash accumulations on SCR catalyst on both the macroscopic and microscopic levels.
    - North Dakota lignite produces ash with severe deposition characteristics that are not typical with other fuels. These deposition characteristics will result in deposits and pluggage of the catalyst. SCR performance and catalyst life will be severely impacted.
    - Success of SCR technology on an EGU firing North Dakota lignite is considered technically infeasible. This is explained in more detail in Appendix A1 and A5.
    - SCR alternatives were not evaluated further for consideration as options for LOS Unit 1.
- Electro-Catalytic Oxidation (ECO®) is an emerging multi-pollutant control technology for coal-fired boilers that uses a barrier reactor for NO_X control upstream of an ammonia scrubber. A slip-stream pilot-scale commercial demonstration of ECO® is currently undergoing field development on a pulverized coal-fired power plant in Ohio. ECO® has not been installed on a full-scale, full-time basis on any coal-fired EGU, and has no commercial demonstration experience on western subbituminous or lignite coals. Thus, ECO® was considered commercially unavailable and technically infeasible for NO_X control at LOS. For more details, refer to the technical feasibility evaluation included in Appendix A1.

2.2.3.2 POST-COMBUSTION NO_X CONTROLS - UNIT 2

Post-combustion controls involve technologies that are usually applied to the flue gas exiting the boiler. These are summarized as follows:

- Selective Non-Catalytic Reduction (SNCR) and variations for NO_X control at LOS Unit 2:
  - SNCR has been applied and practiced on several cyclone-fired boilers[22,23,24] since 1995.
  - SNCR is considered feasible for modest NO_X control on the Unit 2 cyclone boiler at LOS.

  - SNCR without SOFA, with much higher installation and operating costs compared with SOFA alone, is not economically attractive for application at LOS Unit 2 and was eliminated from further consideration for control and cost-effectiveness.
  - Hydrocarbon-enhanced SNCR (commercially available as NO_XStar^{TM}) has not been demonstrated on any cyclone-fired boilers. It is susceptible to major impairment of permanently-installed injection lances attached to convective heat transfer surfaces of the boiler due to severe fouling expected from lignite ash deposits. NO_XStar^{TM} was considered infeasible for application on North Dakota lignite-fired cyclone boilers for NO_X control.
  - Rich Reagent Injection (RRI) injects aqueous urea into the high-temperature lower furnace zone and requires an "air-starved" atmosphere to avoid creating instead of reducing NO_X. RRI has been developed and demonstrated with application intended only on cyclone boilers[27,28,29,30]. RRI but has not been permanently installed but is commercially available from two sub-licensees (Fuel Tech and Combustion Components Associates) of the technology licensed by EPRI to Reaction Engineering International, Inc..
    - RRI is susceptible to impairment due to fouling by ash slag deposits and heat-related damage of injection nozzles, located near the cyclones in the lower furnace.
    - RRI may be feasible for application at LOS for Unit 2's cyclone-fired boiler operating under substoichiometric conditions with modest air-staged cyclones using ASOFA for limited NO_X control. Because RRI in combination with ASOFA without SNCR is expected to be less effective for NO_X reduction and have higher reagent consumption than SNCR with ASOFA, RRI+ASOFA was not included in the control and cost effectiveness analysis in this evaluation for LOS Unit 2. (see Section 2.2.4)
    - Basic SOFA for North Dakota lignite cyclone boilers is incompatible with Rich Reagent Injection. Such combinations are technically infeasible, and thus were eliminated from further consideration for LOS Unit 2. For more details, refer to the technical feasibility evaluation included in Appendix A1.
- Selective Catalytic Reduction (SCR):
  - SCR technology has been installed on 22 cyclone-fired boilers in the U.S.[34], mostly applied in conventional "hot-side, high-dust" arrangements.
  - Catalyst is susceptible to fouling and deactivation from sodium and sulfur deposits, which are expected to be severe from the firing of North Dakota lignite in the LOS Unit 2 cyclone boiler. This conventional arrangement of SCR technology is considered technically infeasible for application at LOS for the Unit 2 cyclone boiler. For more details, refer to the technical feasibility evaluation included in Appendix A1.

- "Low-dust" SCR (LD-SCR) technology (hot-side or cold-side) has been installed on 10 pulverized coal-fired boilers, but no cyclone boilers, in the U.S.[34]. LD-SCRs are typically located downstream of a hot-side electrostatic precipitator. LD-SCR in a cold-side application requires flue gas reheat prior to the catalyst reactor, typically involving supplemental gaseous fuel firing and large regenerative gas-to-gas heat exchanger equipment. LD-SCR is also susceptible to catalyst fouling and deactivation from sodium and sulfur deposits not removed by the particulate matter control device upstream. This fouling is expected to be sufficient to cause significant impairment on ND lignite-fired cyclone boilers. LD-SCR was considered technically infeasible for application at LOS Unit 2. For more details, refer to the technical feasibility evaluation included in Appendix A1.
- "Tail gas" SCR (TG-SCR) technology has been installed on several coal-fired boilers in Europe, but not in the United States[34]. In such cases, TG-SCRs are located downstream of the air preheater, particulate matter control device and flue gas desulfurization (FGD) scrubber. This requires supplemental fuel or steam heat with a large gas-to-gas heat exchanger to reheat the flue gas to an appropriate temperature prior to the SCR reactor. There are serious concerns about the susceptibility of TG-SCR catalyst to fouling from sodium and sulfur deposits not removed by the particulate matter control device and FGD scrubber sufficient to cause significant impairment on ND lignite-fired cyclone boilers. TG-SCR technology was considered technically infeasible for application on Unit 2 at LOS. For more details, refer to the technical feasibility evaluation included in Appendix A1.

2.2.4 FEASIBILITY OF COMBINATIONS OF COMBUSTION AND POST-COMBUSTION NO_X CONTROLS

2.2.4.1 COMBUSTION AND POST-COMBUSTION NO_X CONTROLS - UNIT 1

Combination controls involve simultaneous use of multiple types of technologies that were described in Section 2.2.2 above. These are briefly summarized as follows:

- Separated Overfire Air + Selective Non-Catalytic Reduction (SNCR) and variations:
  - Basic or boosted SOFA + SNCR combinations are technically feasible for application on pulverized coal-fired boilers for NO_X control, and were included in the control and cost effectiveness analysis for LOS Unit 1.
  - Basic and boosted SOFA + Hydrocarbon-enhanced SNCR (commercially available as NO_XStar^{TM}) may be capable of NO_X control on lignite-fired dry-bottom pulverized coal boilers such as LOS Unit 1. However, with much higher installation and operating costs

compared with conventional SNCR, and the lack of a experience on dry-bottom PC-fired boilers burning high fouling coals such as lignite, this alternative was considered infeasible as a NO_X control option for LOS Unit 1.

  - A version of SNCR combined with a boosted form of separated overfire air is currently being marketed commercially as "Rotating Mixing" (Rotamix, using ROFA or Rotating Opposed Fired Air). This has been applied only to pulverized coal-fired boilers. It is different than basic SOFA + SNCR in that it includes a hot air booster fan and a small ambient air fan, and injects ammonia (or urea) reagent into the high-pressure overfire air stream which is introduced into the boiler in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row. At least eight tangentially-fired and five wall-fired pulverized coal utility boilers have been retrofitted with Rotamix, with results published for three "T"-fired boilers burning eastern bituminous coal or Illinois bituminous coal [31,32,33].
    - Since it uses ROFA, Rotamix technology is subject to the same operating limitations as conventional air-staged or fuel-staged pulverized coal burners firing North Dakota lignite. (See Appendix A1).
    - Use of Rotamix on some coal-fired boilers may not produce the levels of NO_X control capable of being achieved with separate SNCR and SOFA injection ports located to optimize each individual technique's performance. This applies to the Unit 1 boiler at LOS.
    - Rotamix is generally considered feasible for NO_X control on small to medium-sized dry-bottom wall-fired pulverized coal boilers.
    - The boosted overfire and SNCR NO_X control alternative assumes the installation of Rotamix in the control effectiveness and cost evaluations for the Unit 1 boiler at Leland Olds Station.
- Fuel Reburn + Selective Non-Catalytic Reduction (SNCR) and variations:
  - Fuel-lean gas reburn + SNCR with basic or boosted SOFA is considered technically feasible on dry-bottom, wall-fired pulverized coal boilers. However, with much higher installation and operating costs compared to other options with similar control effectiveness, such combinations of technologies were not evaluated for consideration as NO_X control options for LOS Unit 1.
  - Conventional Gas Reburn (CGR) + SNCR with basic SOFA combination has only been installed on one tangentially-fired pulverized coal boiler in the United States. This combination of technologies may be technically feasible for LOS Unit 1, but there have been

no commercial installations on dry-bottom, wall-fired pulverized coal boilers. Also, with much higher installation and operating costs compared to other options with similar control effectiveness, this alternative was not evaluated for consideration as a layered controls option for LOS Unit 1.

- Conventional pulverized / micronized coal reburn (PCR or MCR) + SNCR with basic or boosted SOFA combination may be technically feasible for LOS Unit 1, but has not been demonstration tested or commercially sold for a dry-bottom, wall-fired pulverized coal boiler application in the United States. A dedicated building with grinding equipment for coal reburn fuel preparation, and the need to control higher particulate matter emissions through increased collection efficiency improvements would be required to implement this alternative on LOS Unit 1. With a lack of demonstrated success and much higher installation and operating costs compared with other demonstrated combinations of NOx control technologies with similar control effectiveness, this option was eliminated from further consideration for NO_X control on LOS Unit 1.

The results of Step 2 of the NO_X BART Analysis for determining the technical feasibility of NO_X emission control technologies potentially applicable to lignite-fired pulverized coal-fired boilers are summarized in Table 2.2-1, and for cyclone boilers in Table 2.2-2 located in the following report section. Every possible combination of all the various techniques, i.e. "layered technologies", is not listed, in keeping with the EPA's BART Guidelines that they do not "expect a source owner to conduct extended trials to learn how to apply a technology" and "would not consider technologies in the pilot scale stages of development as "available" for the purposes of a BART review" [70 FR 39165]. Also, it "is not the [EPA's] intention to require analysis of each possible level of efficiency for a control technique, as such an analysis would result in a large number of options" and [the States] "should consider recent regulatory decisions and performance data (e.g. manufacturer's data, engineering estimates, and the experience of other sources) when identifying emissions performance level or levels to evaluate" [70 FR 39166].

TABLE 2.2-1 – Technical Feasibility of Potential NO_X Control Technologies for Leland Olds Station Unit 1

Control Technology(1)	**In Permanent, Full-Scale Service on Existing Pulverized Coal-Fired Utility Boilers?**	**Technically Feasible on Leland Olds Station Unit 1 boiler?**
Selective Catalytic Reduction (SCR) (high dust); Low-dust SCR; Tail-gas SCR	Yes(2) / Yes / Yes(3)	No. See discussion in text and footnote
Electro-Catalytic Oxidation (ECO®)	No	No; has not been demonstrated full-scale; See discussion in text and footnote(3).
SNCR	Yes(2)	Yes; can be combined w/ other technologies.
HE-SNCR (NO_XStar™)	Yes(4)	No(4). See discussion in text and footnote(5).
Rich Reagent Injection (RRI)	No(6)	No(6). Not applicable to pulverized coal-firing.
Rotamix (ROFA + SNCR)	Yes	Yes. See discussion in text and footnote.
Conventional Gas Reburn (CGR)	Yes(7)	Yes(7); Requires SOFA. See discussion in text and footnote(5).
Conventional Gas Reburn + SNCR w/ SOFA	Yes(7)	Yes. Only one CGR w/ SNCR application on PC firing. See discussion in text and footnote(5).
Coal Reburn	Yes(8)	Yes(8); Requires SOFA.
Coal Reburn + SNCR	No	No. Has not been demonstrated on PC-firing.
FLGR™	No(7)	Yes[7] (w/ or w/out SOFA). See discussion in text and footnote[5].
Fuel Lean Gas Reburn + SNCR (AEFLGR™)	Yes[7]	Yes. Five installations in PC-fired U.S. boilers. See discussion in text and footnote(5).
Boosted SOFA (or ROFA)	Yes(9),(10)	Yes(9). See discussion in text and footnote.
Separated OFA (SOFA)	Yes(10)	Yes, commonly applied with LNBs.
Low NO_X Burners (LNBs)(latest technology)	Yes	Yes, commonly applied with CCOFA or SOFA. See discussion in text.
Combustion Improvements	Yes	Yes(11); typically included with separated OFA.
OEC	No(12)	No(12). See discussion in text and footnote.
Water Injection	No(13)	No(13)
Flue Gas Recirculation	Not for NO_X control	No(14)
Fuel Switching (from lignite to 100% PRB)	Yes	Yes(15) (not expected to reduce NO_X further)

See technical feasibility details in Appendix A1 and literature References in Appendix A3 for details.

1 – All potential combinations of technologies not listed. See discussion of "layered" technologies.

2 – Limited number of active installations on pulverized-fired boilers burning western subbituminous coal.

3 – No identified full-scale permanent installations operating continuously on coal-fired boilers in the United States.

4 – Hydrocarbon-enhanced SNCR has been demonstrated on two pulverized coal-fired boilers, but not on any boiler firing western subbituminous coal or lignite with severe fouling characteristics.

5 – Much higher installation and operation costs expected compared with other options with similar control effectiveness, this alternative was not evaluated for consideration as a NO_X control option for LOS Unit 1.

6 – Rich Reagent Injection has only been successfully demonstrated for brief periods with SOFA+SNCR at two cyclone power plants. It is not intended nor has it been successfully demonstrated on pulverized coal-fired boilers.

7 – No conventional gas reburn (CGR) demonstrations or installations on pulverized coal-fired boilers burning western subbituminous coal or lignite. No demonstrations or installations of FLGR™ have been performed on a pulverized coal-fired boiler burning western subbituminous coal or lignite. Only one installation of conventional gas reburn with SNCR on PC-fired boiler burning eastern bituminous coal. Several installations of FLGR™ with and without SNCR on PC-fired boilers burning eastern bituminous coal. Most conventional gas reburn and FLGR™ systems are not currently active.

8 – No conventional pulverized or micronized coal reburn (PCR/MCR) demonstrations or installations on pulverized coal-fired boilers burning western subbituminous coal or lignite. Three active coal reburn systems on PC-fired boilers burning eastern bituminous coal.
9 – Several active commercial installations of boosted SOFA on pulverized coal-fired boilers.
10 –No wall-fired PC boilers burning North Dakota lignite have installed separated OFA or boosted OFA.
11 –Considered part of SOFA installation for coal boilers without improved combustion controls for NO_X reduction.
12 – Oxygen-enhanced combustion has been applied on two modestly-sized pulverized coal-fired boilers firing bituminous coal, but has not been demonstrated on 100% western subbituminous coal or lignite-fired boilers.
13 – No permanently installed examples of using this technique continuously on coal-fired boilers were found in available technical literature. Not suitable for high-moisture lignite fuels.
14 – No examples of using recirculated flue gas on coal-fired boilers for NO_X emissions control were found in available technical literature. Zero additional NO_X reduction potential expected from this technique alone for LOS Unit 1.
15 – Zero additional NO_X reduction potential expected from this technique alone for LOS Unit 1.

2.2.4.2 COMBUSTION AND POST-COMBUSTION NO_X CONTROLS - UNIT 2

Combination controls involve simultaneous use of multiple types of technologies that were described in Section 2.2.3 above. These are briefly summarized as follows:

- Separated Overfire Air + Selective Non-Catalytic Reduction (SNCR) and variations:
  - Because advanced SOFA + SNCR is the highest performing feasible form of this post-combustion NO_X control combination for North Dakota lignite cyclone boilers, it was evaluated for control and cost effectiveness on LOS Unit 2. Basic SOFA + SNCR together is a feasible combination but is not the highest performing version, and thus was eliminated from further consideration for LOS Unit 2.
  - Basic or advanced SOFA + Hydrocarbon-enhanced SNCR (commercially available as NO_XStar^{TM}) alternatives lack demonstrated experience on cyclone boilers. These combinations are susceptible to major impairment of permanently-installed reagent injection lances attached to convective heat transfer surfaces of the boiler due to severe fouling expected from lignite ash deposits. NO_XStar^{TM} with basic or advanced SOFA combinations were considered infeasible for application on North Dakota lignite-fired cyclone boilers such as LOS Unit 2 for NO_X control.
  - Rich Reagent Injection may be technically feasible for application with and without SNCR combinations at LOS for Unit 2's cyclone-fired boiler operating under substoichiometric conditions with ASOFA, although the expected modest amount of cyclone air-staging will substantially reduce the NO_X control potential of RRI at LOS Unit 2. Because RRI + SNCR with advanced SOFA is the highest performing form of this post-combustion NO_X control combination, it was evaluated for control and cost effectiveness on LOS Unit 2.
  - RRI with advanced SOFA (without SNCR) is not the highest performing version, and thus was eliminated from further consideration for LOS Unit 2.

  - Basic SOFA for North Dakota lignite cyclone boilers is incompatible with Rich Reagent Injection with SNCR, so this combination is technically infeasible, and thus was eliminated from further consideration for LOS Unit 2. For more details, refer to the technical feasibility evaluation included in Appendix A1.
  - SNCR combined with a boosted form of separated overfire air is currently being marketed commercially as "Rotating Mixing" (Rotamix, using ROFA or Rotating Opposed Fired Air). This has been applied only to pulverized coal-fired boilers[31,32,33].
    - Since it uses ROFA, Rotamix technology is subject to the same operating limitations as conventional air-staged or fuel-staged cyclones burning North Dakota lignite. (See Appendix A1).
    - Use of Rotamix on some coal-fired boilers may not produce the levels of NO_X control capable of being achieved with separate SNCR and SOFA injection ports located to optimize each individual technique's performance. This applies to the LOS Unit 2 boiler.
    - There has been no Rotamix experience on cyclone-fired boilers. Rotamix also does not offer a significant performance advantage for cyclone NO_X control at LOS for Unit 2 compared to the levels of NO_X control capable of being achieved with separate SNCR and SOFA injection ports located to optimize each individual technique's performance. Although it may be possible to install some aspects of Rotamix on a cyclone boiler, such as high-velocity offset overfire air ports with SNCR but without a booster fan, the lack of experience on cyclone boiler applications makes this alternative infeasible for LOS Unit 2. Rotamix was not evaluated further for the LOS Unit 2 boiler.
- Fuel Reburn + Selective Non-Catalytic Reduction (SNCR) and variations:
  - FLGR™ + SNCR (with basic or advanced SOFA) has not been demonstrated or permanently installed and operated on a coal-fired cyclone boiler. This combination may be technically feasible but would appear to offer limited NO_X control potential on cyclone boilers burning North Dakota lignite (see Appendix A1). FLGR™'s expected high capital costs for a natural gas supply pipeline and on-going natural gas costs make this alternative economically unattractive for application at LOS. FLGR™ + SNCR (with basic or advanced SOFA) were eliminated from further consideration for NO_X control on LOS Unit 2.
  - Conventional Gas Reburn (CGR) + SNCR with basic or advanced SOFA may be technically feasible for LOS Unit 2, but there have been no successfully demonstrated or commercial installations on cyclone boilers. This combination of technologies lacks

experience. Expected high capital costs for a natural gas supply pipeline and on-going natural gas costs make this alternative economically unattractive compared with similar NO_X reduction available with other demonstrated or commercially available controls. This combination was eliminated from further consideration on LOS Unit 2.

- Conventional pulverized / micronized coal reburn (PCR or MCR) + SNCR with basic or advanced SOFA combination may be technically feasible for LOS Unit 2, but has not been demonstration tested or commercially sold for a cyclone boiler application. A dedicated building with grinding equipment for coal reburn fuel preparation, and the need to control higher particulate matter emissions through increased PM collection capacity with flyash handling and storage capacity additions would be required to implement this alternative on LOS Unit 2. Since this combination of technologies lacks experience, PCR or MCR + SNCR with basic or advanced SOFA were eliminated from further consideration for NO_X control on LOS Unit 2.

TABLE 2.2-2 – Technical Feasibility of Potential NO_X Control Technologies for Leland Olds Station Unit 2

Control Technology(1)	In Permanent, Full-Scale Service on Existing Coal-Fired Cyclone Utility Boilers?	Technically Feasible on Leland Olds Station Unit 2 boiler?
Selective Catalytic Reduction (SCR) (high dust); Low-dust SCR; Tail-gas SCR	Yes(2) / No / Yes(3)	No - Unresolvable fouling and catalyst deactivation problems expected. See discussion of SCR feasibility for ND lignite.
Electro-Catalytic Oxidation (ECO®)	No	No, has not been demonstrated full-scale; commercial availability not confirmed
SNCR	Yes(2)	Yes; can be combined with other technologies
HE-SNCR (NO_XStar™)(with or without SOFA or ASOFA)	No(4)	No(4). Has not been demonstrated on cyclone.
Rich Reagent Injection (RRI) with ASOFA	No(5)	Yes(5). Requires Advanced SOFA for lignite, can be combined w/ SNCR.
Rotamix (ROFA + SNCR)	No	No. Has not been demonstrated on cyclone.
Conventional Gas Reburn (ACGR) + SNCR	No(6)	No. Has not been demonstrated on cyclone. Would require ASOFA.
Conventional Gas Reburn	Yes(6)	Yes(7); Requires ASOFA
Coal Reburn	Yes(8)	Yes(8); Requires ASOFA
Coal Reburn + SNCR	No	No. Has not been demonstrated on cyclone.
FLGR™	No(6)	Yes(7) (w/ or w/out SOFA or ASOFA)
Fuel Lean Gas Reburn + SNCR (AEFLGR™)	No(6)	No. Has not been demonstrated on cyclone.
Advanced SOFA	No(9)	Yes(9)
Separated OFA (SOFA)	Yes(9)	Yes(9)
ROFA	No(10)	No(10). No significant advantages over SOFA.
Combustion Improvements	Yes	Yes(11) ; typically included with separated OFA
OEC[12]	No(12)	No - has not been demonstrated on cyclone boiler
Water Injection	No(13)	No(13)
Flue Gas Recirculation	Not for NO_X control	Yes(14) (not expected to reduce NO_X further)
Fuel Switching (from lignite to 100% PRB)	Yes	Yes(15) (not expected to reduce NO_X further)
Low NO_X Burners	No	No – Not Feasible

See technical feasibility details in Appendix A1 and literature References in Appendix A3 for details.

1 – All potential combinations of technologies not listed. See discussion of "layered" technologies.

2 – Limited number of active installations on cyclone-fired boilers burning western subbituminous coal.

3 – No identified full-scale permanent installations operating continuously on coal-fired boilers in the United States.

4 – Hydrocarbon-enhanced SNCR has been demonstrated on two pulverized coal-fired boilers, but not on any boiler, including cyclones, firing western subbituminous coal or lignite with severe fouling characteristics.

5 – Rich Reagent Injection has only been successfully demonstrated for brief periods with SOFA+SNCR at two cyclone power plants. It is not intended nor has it been successfully demonstrated on pulverized coal-fired boilers.

6 – Limited number of conventional gas reburn (CGR) demonstrations or installations on cyclone-fired boilers burning western subbituminous coal. One demonstrations (no permanent installations) of FLGR™ have been performed on a cyclone-fired boiler. Only one installation of conventional gas reburn with SNCR on PC-fired boiler burning eastern bituminous coal. Several installations of FLGR™ with and without SNCR on PC-fired boilers burning eastern bituminous coal. Most conventional gas reburn and FLGR™ systems are not currently active.

7 – Much higher installation and operation costs expected compared with other options with similar control effectiveness, this alternative was not evaluated for consideration as a NO_X control option for LOS Unit 2.

8 – One conventional pulverized (PCR/MCR) demonstration on cyclone-fired boilers burning western subbituminous coal has been discontinued. Only one active micronized coal reburn system on cyclone boiler burning eastern bituminous coal. Three active coal reburn systems on PC-fired boilers burning eastern bituminous coal.

9 – No cyclone or wall-fired PC boilers burning North Dakota lignite have installed separated OFA or boosted OFA.

10 – Several active commercial installations of boosted SOFA (or ROFA) on pulverized coal-fired boilers, none on cyclone boilers.

11 –Considered part of SOFA installation for coal boilers without improved combustion controls for NO_X reduction.

12 – Oxygen-enhanced combustion has been applied on two modestly-sized pulverized coal-fired boilers firing bituminous coal, but has not been demonstrated on any cyclone boilers or 100% western subbituminous coal or lignite-fired PC boilers.

13 – This technique has been demonstrated but no permanently installed examples of using this technique continuously on cyclone coal-fired boilers were found in available technical literature. Not suitable for high-moisture lignite fuels.

14 – No examples of using recirculated flue gas on coal-fired boilers for NO_X emissions control were found in available technical literature. Zero additional NO_X reduction potential expected from this technique alone for LOS Unit 2. Potential NO_X reduction improvement on LOS Unit 2 considered part of “advanced” SOFA.

15 – Zero additional NO_X reduction potential expected from this technique alone for LOS Unit 2.

2.3 CONTROL EFFECTIVENESS EVALUATION OF NO_X CONTROL TECHNOLOGIES

Several feasible NO_X control alternatives previously listed in Tables 2.2-1 and 2.2-2 have been removed from the control effectiveness ranking in Tables 2.3-1 and 2.3-2 for LOS Unit 1, and Tables 2.3-3 and 2.3-4 for LOS Unit 2. This control option ranking approach recognizes that those feasible alternatives that appear to offer zero or very small control performance for a significant cost impact (e.g. fuel switching), should not be included in the control and cost effectiveness impact analysis. Alternatives that include natural gas firing, or are similar in predicted emission reduction percentage but are more expensive to install and operate, or have more substantial operational limitations compared to other feasible alternatives were also eliminated from further analysis.

The emission reduction (control effectiveness) percentages developed for ranking the feasible alternatives shown for LOS Unit 1 and LOS Unit 2 are estimates based upon engineering judgments with considerations of:

- the general combustion properties of North Dakota lignite;
- published and available emission reduction performance achieved at other similar utility power plants (dry-bottom pulverized coal and wet-bottom cyclone-fired boilers);
- computer-derived predictions; and
- inclusion of performance margins to allow for variations in fuel, weather, equipment condition, and other factors that prevent the ultimate peak short-term performance from being reliably sustained over the course of long-term operation.

These NO_X emission level and percent reduction estimates include adjustments of previously demonstrated or predicted performance that reflect differences between North Dakota lignite and eastern or midwestern bituminous and western subbituminous coals. The numbers assume the maximum short-term potential capability of the employed technique, demonstrated or installed elsewhere, is not achievable or sustainable long-term. As such, the expressed control percentages reflect the use of engineering judgment, based on the listed technique or technology application.

2.3.1 CONTROL EFFECTIVENESS OF COMBUSTION NO_X CONTROLS – LOS UNIT 1

Only close-coupled overfire air with low NO_X burners have been previously installed for reducing NO_X emissions from the LOS Unit 1 boiler. NO_X emission control options considered feasible were evaluated for the LOS Unit 1 boiler, are listed in Table 2.3-1 and Table 2.3-2. The existing LNBs with a retrofit of separated overfire air in place of CCOFA were estimated to produce a modest NO_X control reduction for LOS Unit 1 beyond the presumptive BART NO_X level. Pre-retrofit levels of NO_X emissions for Leland Olds Station's Unit 1 boiler in Table 2.3-1 are relative to an equivalent unit emission baseline rate of 0.285 lb/mmBtu (historic highest 24-month average rate, years 2000-2004), with a corresponding average heat input rate of 2,443 mmBtu/hr for 8,510 hours per year. This is compared to the estimated post-control equivalent average NO_X unit emission rates (lb/mmBtu) for a boiler design capacity heat input rate of 2,622 mmBtu/hr for 8,760 hrs/yr operation under the future Potential To Emit (PTE) scenario.

Feasible, demonstrated pulverized coal-fired boiler NO_X controls which allow or enhance further reductions when separated overfire air is combined with other combustion or post-combustion control alternatives that did not involve gas-consuming technologies were evaluated.

Based upon Burns & McDonnell's experience, applying SOFA technology to LOS Unit 1 boiler is expected to produce a reduction percentage from the pre-control baseline NO_X emission rate approximately half as great as is typically achieved when PC-fired boilers burning western subbituminous coal implement SOFA and operate low-NO_X burners at fairly low burner air/fuel ratios (around 0.90). This reduction estimate relates to the pre-control baseline NO_X emission rate which reflects the modest amount of burner air-staging that is believed can be sustained when firing lignite at full unit output capacity when operating existing low-NO_X burners with SOFA.

Predictions of NO_X emission reduction percentages for incremental NO_X emission reductions from CCOFA-, and basic and boosted SOFA-controlled levels for SNCR alternatives were estimated from a vendor proposal of Selective Non-Catalytic Reduction[46].

Coal reburn with basic and boosted SOFA is estimated to reduce NO_X emissions around 60 percent, based upon estimated uncontrolled baseline NO_X levels and demonstrated coal-reburn retrofits on PC-fired boilers. The reduction estimates from pre-retrofit baseline levels of NO_X emissions for Leland Olds Station's Unit 1 boiler in Tables 2.3-1 and 2.3-2 reflect the modest amount of burner air-staging with existing LNBs and CCOFA that can be sustained when firing lignite at full unit output capacity.

TABLE 2.3-1 – Historic Baseline and Estimated Control Options' PTE NO_X Emission Rates Evaluated for LOS Unit 1 Boiler

Alt. No.(1)	NO_X Control Technique	LOS Unit 1 Emission Rate(2) (lb/mmBtu)	Control Percentage(2)	LOS Unit 1 Hourly Emission(2) (lb/hr)	LOS Unit 1 Annual Emission(2) (tons/yr)
G	Coal Reburn with boosted SOFA (future PTE case)	0.147	48.7	384	1,666
F	Coal Reburn with basic SOFA (future PTE case)	0.154	46.2	403	1,746
E	SNCR with boosted SOFA (Rotamix) (future PTE case)	0.157	45.1	411	1,782
D	SNCR with basic SOFA (future PTE case)	0.166	42.0	434	1,883
C	SNCR with Close-Coupled OFA (future PTE case)	0.216	24.5	565	2,450
B	Boosted Separated Overfire Air (ROFA), (future PTE case)	0.216	24.3	567	2,483
A	Separated Overfire Air (SOFA, basic), (future PTE case)	0.230	19.4	603	2,642
--	Baseline, based on annual operation at highest historic 24-mo average pre-control NO_X emission rate	0.285	--	697	2,967

1 – Alternative designation has been assigned from highest to lowest annual NO_X emissions.

2 – Emissions are calculated from unit emission rates, control percentage, 2,443 mmBtu/hr hourly heat input rate, and 8,510 annual hrs/yr of operation at future PTE conditions compared to historic pre-control baseline.

Table 2.3-2 shows an average pre-control equivalent NO_X baseline unit emission rate of 0.29 lb/mmBtu and post-control unit emission rates (lb/mmBtu), each applied to the LOS Unit 1 boiler at a fuel heat input rate of 2,622 mmBtu/hr (boiler design capacity rating) for 8,760 hrs/yr of operation under steady-state operating conditions relative to the future PTE case. Note that the order of SNCR with CCOFA and Boosted SOFA (ROFA) are switched in the latter case versus historic baseline.

TABLE 2.3-2 – Pre-Control Presumptive BART Baseline and Estimated Control Options' NO_X Emission Rates Evaluated for Future PTE Scenario, LOS Unit 1 Boiler

Alt. No.(1)	NO_X Control Technique	LOS Unit 1 Emission Rate(2) (lb/mmBtu)	Control Percentage(2)	LOS Unit 1 Hourly Emission(2) (lb/hr)	LOS Unit 1 Annual Emission(2) (tons/yr)
G	Coal Reburn with boosted SOFA (future PTE case)	0.149	48.7	390	1,693
F	Coal Reburn with basic SOFA (future PTE case)	0.156	46.2	409	1,774
E	SNCR with boosted SOFA (Rotamix) (future PTE case)	0.159	45.1	418	1,811
D	SNCR with basic SOFA (future PTE case)	0.168	42.0	441	1,913
C	Boosted Separated Overfire Air (ROFA), (future PTE case)	0.215	25.9	564	2,469
B	SNCR with Close-Coupled OFA (future PTE case)	0.219	24.5	574	2,490
A	Separated Overfire Air (SOFA, basic), (future PTE case)	0.230	20.7	603	2,641
--	Baseline, based on annual operation at presumptive BART NO_X pre-control emission rate for future PTE scenario	0.290	--	760	3,330

1 – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

2 – Emissions are calculated from unit emission rates, control percentage, 2,622 mmBtu/hr hourly heat input rate, and 8,760 annual hrs/yr of operation at future PTE conditions compared to presumptive BART NO_X pre-control baseline.

2.3.2 CONTROL EFFECTIVENESS OF COMBUSTION AND POST-COMBUSTION NO_X CONTROLS – LOS UNIT 2

None of the remaining control options have been installed on cyclone-fired boilers burning North Dakota lignite. This is particularly pertinent to all control options that involve air-staged combustion associated with advanced forms of separated overfire air, reburn, and Rich Reagent Injection. RRI requires the hot furnace environment where the reagent is injected to be essentially devoid of free oxygen. Alternatives with the advanced form of SOFA are estimated to reduce NO_X emission levels more effectively from the LOS Unit 2 pre-control baselines than those which do not employ the use of cyclone air-staging and overfire air. Feasible, demonstrated cyclone boiler NO_X controls which allow or enhance further reductions when ASOFA is combined with other combustion or post-combustion control alternatives that did not involve gas-consuming technologies were evaluated.

Based upon Burns & McDonnell's experience, applying the advanced version of SOFA to the LOS Unit 2 cyclone boiler's pre-control baseline NO_X emission rate is estimated to produce a reduction percentage approximately half as great as is typically achieved when cyclone-fired boilers burning western subbituminous coal implement SOFA and operate at fairly low cyclone air/fuel ratios (around 0.90). This reduction estimate relates to the pre-control baseline NO_X emission rate which reflects the modest amount of cyclone air-staging that is believed can be sustained when firing lignite at full unit output capacity, and the additional amount of control potential available from operating with relocated lignite drying system vent ports and FGR ports associated with ASOFA.

Prediction of NO_X emission reduction percentage for Rich Reagent Injection (RRI) is based on engineering judgment with consideration of a recent demonstration testing performed at Ameren's Sioux Unit 1 cyclone boiler, and published computational fluid dynamics (CFD) modeling of the Sioux Unit 1 cyclones and furnace zones. A 2002 technical paper by Reaction Engineering International[28] showing the results of CFD modeling and field demonstration testing of RRI at the Sioux Unit 1 boiler with modest cyclone air/fuel ratios (close to 0.95 to 0.99) was used as guidance for estimating the NO_X emission reduction percentages assumed for LOS Unit 2.

Incremental NO_X emission reductions from ASOFA-controlled levels for SNCR, and SNCR+RRI alternatives were estimated from a vendor proposal of Selective Non-Catalytic Reduction[46] and information in a 2002 technical paper by Reaction Engineering International[28] for RRI testing and CFD modeling of the Sioux Unit 1 boiler.

Coal reburn with ASOFA is estimated to reduce NO_X emissions slightly more than 50 percent, based upon control levels demonstrated by previous coal-reburn retrofits on cyclone-fired boilers. This reduction estimate relates to the pre-control baseline NO_X emission rate which reflects the modest amount of cyclone air-staging that is believed can be sustained when firing lignite at full unit output capacity, and the additional amount of control potential available from operating with relocated lignite drying system vent ports and FGR ports associated with ASOFA.

The potential operational limitations mentioned in the detailed feasibility discussions included in Appendix A1 for deeply air-staged cyclones associated with separated overfire air and Rich Reagent

Injection or coal reburn alternatives are expected to limit the amount of NO_X control potential possible from successful practice of the technique or technology.

A ranking of available NO_X emission control options considered feasible for Leland Olds Station Unit 2 boiler are listed in Table 2.3-3 and Table 2.3-4. Ranking of the alternatives in Table 2.3-4 assumes that the pre-retrofit level of NO_X emissions for the Leland Olds Station Unit 2 boiler is associated with the equivalent average unit emission rate of 0.67 lb/mmBtu. This baseline is based on the historic highest twenty-four consecutive months' summation between years 2000 and 2004, with a corresponding average heat input rate of 4,478 mmBtu/hr for 8,050 hours per year. The annual post-control estimated NO_X emissions are based on the stated percent reduction applied to the pre-control unit baseline emission rate (0.67 lb/mmBtu) and fuel heat input rate of 5,130 mmBtu/hr (boiler design capacity rating) for 8,760 hrs/yr operation for the future PTE scenario.

TABLE 2.3-3 – Historic Baseline and Estimated Control Options' NO_X Emission Rates Evaluated for Future PTE Scenario, LOS Unit 2 Boiler

Alt. No.[(1)]	NO_X Control Technique	LOS Unit 2 Emission Rate (lb/mmBtu)	Control Percentage[(1)]	LOS Unit 2 Hourly Emission[(1)] (lb/hr)	LOS Unit 2 Annual Emission[(1)] (tons/yr)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	0.265	60.3	1,359	5,895
C	SNCR (using urea) w/ ASOFA	0.304	54.5	1,557	6,762
B	Coal Reburn (conventional, pulverized) w/ ASOFA	0.32	51.8	1,649	7,115
A	Advanced Separated Overfire Air (ASOFA)	0.48	28	2,465	10,796
--	Baseline, based on annual operation at historic highest 24-month average pre-control NO_X emission rate	0.67	--	2,987	12,023

1 - Alternative designation assigned from highest to lowest unit NO_X emission rate. Emissions are calculated from unit emission rates, control percentage, hourly heat input rate of 4,478 mmBtu/hr, and 8,050 annual hrs/yr operation compared to pre-control baseline.

Table 2.3-4 shows NO_X emissions for a different pre-control baseline. The annual post-control maximum NO_X emissions are based on the stated percent reduction applied to the LOS Unit 2 boiler pre-control unit emission rate (0.67 lb/mmBtu) and 5,130 mmBtu/hr for 8,760 hrs/yr operation for the future PTE case.

TABLE 2.3-4 – Pre-Control Baseline and Estimated Control Options' NO_X Emission Rates Evaluated for Future PTE Scenario LOS Unit 2 Boiler

Alt. No.[(1)]	**NO_X Control Technique**	**LOS Unit 2 Emission Rate (lb/mmBtu)**	**Control Percentage**[(1)]	**LOS Unit 2 Hourly Emission**[(1)] **(lb/hr)**	**LOS Unit 2 Annual Emission**[(1)] **(tons/yr)**
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	0.265	60.3	1,359	5,895
C	SNCR (using urea) w/ ASOFA	0.304	54.5	1,557	6,762
B	Coal Reburn (conventional, pulverized) w/ ASOFA	0.32	51.8	1,649	7,115
A	Advanced Separated Overfire Air (ASOFA)	0.48	28	2,465	10,796
--	Baseline, based on annual operation at future PTE scenario pre-control emission rate	0.67	--	3,422	14,989

1 - Alternative designation assigned from highest to lowest unit NO_X emission rate. Emissions are calculated from unit emission rates, control percentage, hourly heat input of 5,130 mmBtu/hr, and 8,760 annual hrs/yr operation compared to pre-control baseline.

Combinations of individual technologies for most alternatives in Tables 2.3-3 and 2.3-4 apply "advanced" SOFA, which is expected to have significantly lower NO_X emissions than a typical SOFA system as applied to the LOS Unit 2 cyclone boiler. The distinction that "advanced" separated overfire air has drastically different expected NO_X emissions than a typical SOFA system affects the NO_X emissions predicted from application of the highest performing form of overfire air combined with other various combustion-related and post-combustion techniques and technologies. These figures indicate the expected additional NO_X emission reduction potential from installation of various forms of SNCR, or coal reburn, in combination with existing cyclones and advanced separated overfire air systems for modest levels of "starved air" substoichiometric cyclone combustion.

2.4 EVALUATION OF IMPACTS FOR FEASIBLE NO_X CONTROLS – LOS UNIT 1

The fourth step of a BART analysis is to evaluate the following impacts of feasible emission controls:

- The cost of compliance.
- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

The purpose of the impacts evaluation is to determine if there are any energy, economic, non-air quality environmental reasons, or aspects of the remaining useful life of the source, which would eliminate the remaining control technologies from consideration for LOS Unit 1.

2.4.1 COST IMPACTS OF NO_X CONTROLS – LOS UNIT 1

An evaluation was performed to determine the compliance costs of installing various feasible NO_X control alternatives on LOS Unit 1 boiler. This evaluation included estimates for:

- Capital costs;
- Fixed and variable operating and maintenance costs; and
- Levelized total annual costs

to engineer, procure, construct, install, startup, test, and place into commercial operation a particular control technology. The results of this evaluation are summarized in Tables 2.4-1 through 2.4-6.

2.4.1.1 CAPITAL COST ESTIMATES FOR NO_X CONTROLS – LOS UNIT 1

The capital costs to implement the various NO_X control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

A review of the unit capital cost factor range and single point unit capital cost factor for the feasible NO_X emission reduction technologies evaluated for LOS Unit 1 is presented in Table 2.4-1.

TABLE 2.4-1 – Unit Capital Cost Factors of NO_X Control Options for LOS Unit 1

NO_X Control Technique	**Range ($/kW)(1),(2)**	**Single Point Unit Capital Cost Factor(2), ($/kW) LOS Unit 1**
SNCR (using urea) w/ boosted SOFA (Rotamix)	27-45(3),(4)	43.3(5)
SNCR (using urea) w/ basic SOFA	15-30(4)	28.9(5),(6)
SNCR (using urea) w/ CCOFA	10-20(4)	22.6(5)
Coal Reburn (conventional, pulverized) w/ boosted SOFA	42-75(3)	178.8(3),(7)
Coal Reburn (conventional, pulverized) w/ basic SOFA	30-60(3)	164.4(6),(7)
Boosted Separated Overfire Air (ROFA)	17-25(3)	20.7(4)
Separated Overfire Air (SOFA, basic)	5-10(4)	6.3(6)

(1) – Range based on published values or vendor proposals. Single point cost factor is a reasonable estimate for determination of total capital cost for a particular technology or combination, assuming maximum unit capacity is based on MCR rating. In several cases, additional capital costs will be incurred that were not included in the published unit cost factors.
(2) – Unit capital cost factors of these individual technologies combined by simple addition. Actual costs may differ this due to positive or negative synergistic effects.
(3) – ROFA capital cost range from the 2005 WRAP Draft Report[44], posted at their website. See Appendix A for reference details
(4) – SNCR capital cost range from NESCAUM 2005 Technical Paper[43], posted at their website. See Appendix A for reference details.
(5) – Estimated capital cost for SNCR point estimate derived from December 2004 budgetary proposal by Fuel Tech.
(6) – Burns & McDonnell internal database was used for the point capital cost estimates of basic SOFA.
(7) – The single point unit capital cost factor shown for a coal reburn system is highly site-specific, and assumes that new pulverizers and building enclosures are required. The general cost range for pulverized coal-fired boilers is included in the NESCAUM 2005 Technical Paper[43]; the single point cost estimate is based on the same factor assumed for cyclone boilers included in the 2005 WRAP Draft Report[44], posted at their website. The single point unit capital cost factor for this alternative for increased PM collection capacity included in coal reburn options is 72.9 $/kW. See Appendix A for reference details.

Annualized capital cost, which includes the time value of capital monies and its recovery, is determined from the estimated capital cost and the methodology described in Section 1. Table 2.4-2 shows the estimated installed capital cost and annualized capital cost values for the NO_X emission reduction technologies evaluated for LOS Unit 1. These were developed from multiplying the unit capital cost single point factor for the control option by the nameplate output capacity rating of the respective unit.

TABLE 2.4-2 – Installed and Annualized Capital Costs Estimated for NO_X Control Options - LOS Unit 1

NO_X Control Alternative	Installed Capital Cost(1) ($1,000)	Annualized Capital Cost(2) ($1,000)
SNCR (using urea) w/ boosted SOFA (Rotamix)	9,342	814
SNCR (using urea) w/ basic SOFA	6,234	544
SNCR (using urea) w/ CCOFA	4,871	425
Coal Reburn (conventional, pulverized) w/ boosted SOFA	38,617(3)	3,367(3)
Coal Reburn (conventional, pulverized) w/ basic SOFA	35,509	3,096
Boosted Separated Overfire Air (ROFA)	4,471	390
Separated Overfire Air (SOFA, basic)	1,363	119

(1) – Installed capital cost is estimated for determination of total capital cost for a control technology, based on nameplate unit output capacity rating of 216,000 kW. Installed capital cost figures in 2005 dollars.

(2) – Annualized capital cost = Installed capital cost x 0.08718 capital recovery factor.

(3) – Costs for increased PM collection capacity included in coal reburn option are $15,740,000 for installed capital cost, and $1,372,000/yr annualized capital cost.

2.4.1.2 OPERATING AND MAINTENANCE COST ESTIMATES FOR NO_X CONTROLS – LOS UNIT 1

The operation and maintenance costs to implement the NO_X control technologies evaluated for LOS Unit 1 were largely estimated from cost factors established in the EPA's Air Pollution Control Cost Manual (OAQPS), and from engineering judgment applied to that control technology. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

Fixed and variable operating and maintenance costs considered and included in each NO_X control technology's Levelized Total Annual Costs are estimates of:

- Auxiliary electrical power consumption for operating the additional control equipment;
- Reagent consumption, and reagent unit cost for SNCR alternatives; and
- Reagent dilution water consumption and unit cost for SNCR alternatives.
- Increases or savings in auxiliary electrical power consumption for changes in coal preparation equipment and loading, primarily for fuel reburn cases;
- General operating labor, plus maintenance labor and materials devoted to the additional emission control equipment and its impact on existing boiler equipment.

- Reductions in revenue expected to result from loss of unit availability, i.e. outages attributable to the control option, which reduce annual net electrical generation available for sale (revenue).

Table 2.4-3 and Table 2.4-4 show the estimated annual operating and maintenance costs and levelized annual O&M cost values for the NO_X control options evaluated for LOS Unit 1. The cost methodology summarized in Section 1.3.5 provides more details for the levelized annual O&M cost calculations and cost factors. The annual operating and maintenance costs of the control options in Table 2.4-3 is based on LOS Unit 1 operation with the control options at 2,622 mmBtu/hr heat input and 8,760 hrs/yr operation. These O&M costs are relative to unit pre-control baseline operation at 0.285 lb/mmBtu for the highest 24-month NOx emission summation at 2,443 mmBtu/hr heat input for 8,510 hrs/yr operation of LOS Unit 1 with existing close-coupled overfire air and low-NO_X burners.

TABLE 2.4-3 – Estimated O&M Costs for NO_X Control Options (Relative to Historic Pre-Control Annual Emission Baseline) – LOS Unit 1

NO_X Control Alternative	**Annual O&M Cost$^{(1)}$ ($1,000)**	**Levelized Annual O&M Cost$^{(2)}$ ($1,000)**
SNCR (using urea) w/ boosted SOFA (Rotamix)	2,157	2,574
SNCR (using urea) w/ basic SOFA	1,702	2,030
SNCR (using urea) w/ CCOFA	1,195	1,426
Coal Reburn (conventional, pulverized) w/ boosted SOFA	3,072$^{(3)}$	3,665$^{(3)}$
Coal Reburn (conventional, pulverized) w/ basic SOFA	2,420$^{(3)}$	2,887$^{(3)}$
Boosted Separated Overfire Air (ROFA)	626	747
Separated Overfire Air (SOFA, basic)	21	25
Baseline, based on annual operation at historic 24-mo average pre-control emission rate	0	0

(1) – Annual O&M cost figures in 2005 dollars.

(2) – Levelized annual O&M cost = Annual O&M cost x 1.19314 Annualized O&M cost factor.

(3) – Costs for increased PM collection capacity included in coal reburn option are $901,000 for annual O&M cost, and $1,074,000/yr levelized annual O&M cost.

The annual operating and maintenance costs of the control options in Table 2.4-4 are based on LOS Unit 1 operation with the control option at 2,622 mmBtu/hr heat input and 8,760 hrs/yr operation. These O&M costs are relative to unit baseline operation at 0.29 lb/mmBtu for the highest 24-month

NO_X emission summation at 2,622 mmBtu/hr heat input for 8,760 hrs/yr operation of LOS Unit 1 with existing close-coupled overfire air and low-NO_X burners.

TABLE 2.4-4 – Estimated O&M Costs for NO_X Control Options (Relative to Presumptive BART Annual Emission Baseline – Future PTE Case) LOS Unit 1

NO_X Control Alternative	**Annual O&M Cost[(1)] ($1,000)**	**Levelized Annual O&M Cost[(2)] ($1,000)**
SNCR (using urea) w/ boosted SOFA (Rotamix)	2,157	2,574
SNCR (using urea) w/ basic SOFA	1,701	2,030
SNCR (using urea) w/ CCOFA	1,197	1,428
Coal Reburn (conventional, pulverized) w/ boosted SOFA	3,072(3)	3,665(3)
Coal Reburn (conventional, pulverized) w/ basic SOFA	2,420(3)	2,887(3)
Boosted Separated Overfire Air (ROFA)	626	747
Separated Overfire Air (SOFA, basic)	21	25
Baseline, based on annual operation at future PTE case pre-control emission rate	0	0

(1) – Annual O&M cost figures in 2005 dollars.
(2) – Levelized annual O&M cost = Annual O&M cost x 1.19314 O&M cost factor.
(3) – Costs for increased PM collection capacity included in coal reburn option are $901,000 for annual O&M cost, and $1,074,000/yr levelized annual O&M cost.

2.4.1.3 COST EFFECTIVENESS FOR NO_X CONTROLS – LOS UNIT 1

In order to compare a particular NO_X emission reduction alternative during the cost of compliance impact analysis portion of the BART determination process, the basic methodology defined in the BART Guidelines was followed [70 FR 39167-39168]. The sum of estimated annualized installed capital plus levelized annual operating and maintenance costs, which is referred to as "Levelized Total Annual Cost" (LTAC) of each alternative, was calculated. The LTAC for all NO_X control alternatives was calculated based on the same economic conditions and a 20 year project life (see Section 1.3.5 for cost methodology details).

The Average Cost Effectiveness (also called Unit Control Cost) was then determined as the LTAC divided by annual tons of pollutant emissions that would be avoided by implementation of the respective alternative. There are two different NO_X emission baselines; the first assumes the highest historic 24-month average NO_X emission rate expressed in tons per year. The second baseline derives tons per year from the maximum future PTE case average NO_X emission rate. This approach results in two different average cost effectiveness values for the control options evaluated for LOS Unit 1. The annual NO_X emission reduction is the difference between the pre-control baseline and post-control emissions in tons per year. Average control cost for a particular technology is LTAC divided by annual tons of expected emission reduction. A summary of the annual emissions, reductions, control and levelized annual costs for the two LOS Unit 1 baselines are presented in Table 2.4-5 and 2.4-6.

TABLE 2.4-5 – Estimated Annual Emissions and LTAC for NO_X Control Alternatives (Historic Pre-Control Annual Emission Baseline) – LOS Unit 1

Alt. No.(1)	**NO_X Control Alternative**	**Annual NO_X Emissions**(2) **(Tons/yr)**	**Annual NO_X Emissions Reduction**(2) **(Tons/yr)**	**Levelized Total Annual Cost**(3),(4) **($1,000)**	**Average Control Cost**(4) **($/ton)**
G	Coal Reburn with boosted SOFA (future PTE case)	1,666	1,301	7,032(5)	5,404(5)
F	Coal Reburn with basic SOFA (future PTE case)	1,746	1,221	5,983(5)	4,898(5)
E	SNCR with boosted SOFA (Rotamix) (future PTE case)	1,782	1,185	3,388	2,860
D	SNCR with basic SOFA (future PTE case)	1,883	1,084	2,574	2,373
C	SNCR with Close-Coupled OFA (future PTE case)	2,450	517	1,851	3,582
B	Boosted Separated Overfire Air (ROFA), (future PTE case)	2,483	484	1,137	2,347
A	Separated Overfire Air (SOFA, basic)	2,642	325	144	441
--	Baseline, based on annual operation at highest historic 24-mo average pre-control emission rate	2,967	0	0	

(1) – Alternative designation has been assigned from highest to lowest annual NO_X emissions.

(2) – NO_X emissions and control level reductions relative to the highest historic 24-month average pre-control annual baseline for LOS Unit 1.

(3) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #2 for Tables 2.4-2 and 2.4-3 for annualized cost factors.

(4) – Annualized cost figures in 2005 dollars.

(5) – LTAC for increased PM collection capacity included in coal reburn option are $1,372,000 for annualized capital cost plus $1,074,000 for annualized O&M cost, for a total of $2,446,000/yr. This results in an average control cost of $1,762/ton with boosted SOFA and $1,870/ton with basic SOFA.

TABLE 2.4-6 – Estimated Annual Emissions and LTAC for NO_X Control Alternatives (Presumptive BART Annual Emission Baseline – Future PTE Case)

LOS Unit 1

Alt. No.[1]	NO_X Control Alternative	Annual NO_X Emissions[2] Tons/yr	Annual NO_X Emissions Reduction[2] Tons/yr	Levelized Total Annual Cost[3],[4] $1,000	Average Control Cost[4] $/ton
G	Coal Reburn with boosted SOFA (future PTE case)	1,693	1,638	7,032[5]	4,293[5]
F	Coal Reburn with basic SOFA (future PTE case)	1,774	1,557	5,983[5]	3,844[5]
E	SNCR with boosted SOFA (Rotamix) (future PTE case)	1,811	1,519	3,388	2,230
D	SNCR with basic SOFA (future PTE case)	1,913	1,417	2,574	1,816
C	Boosted Separated Overfire Air (ROFA), (future PTE case)	2,469	862	1,137	1,298
B	SNCR with Close-Coupled OFA (future PTE case)	2,490	841	1,853	2,204
A	Separated Overfire Air (SOFA, basic)	2,641	689	144	208
	Baseline, based on annual operation at future PTE scenario pre-control emission rate	3,330	0	0	

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

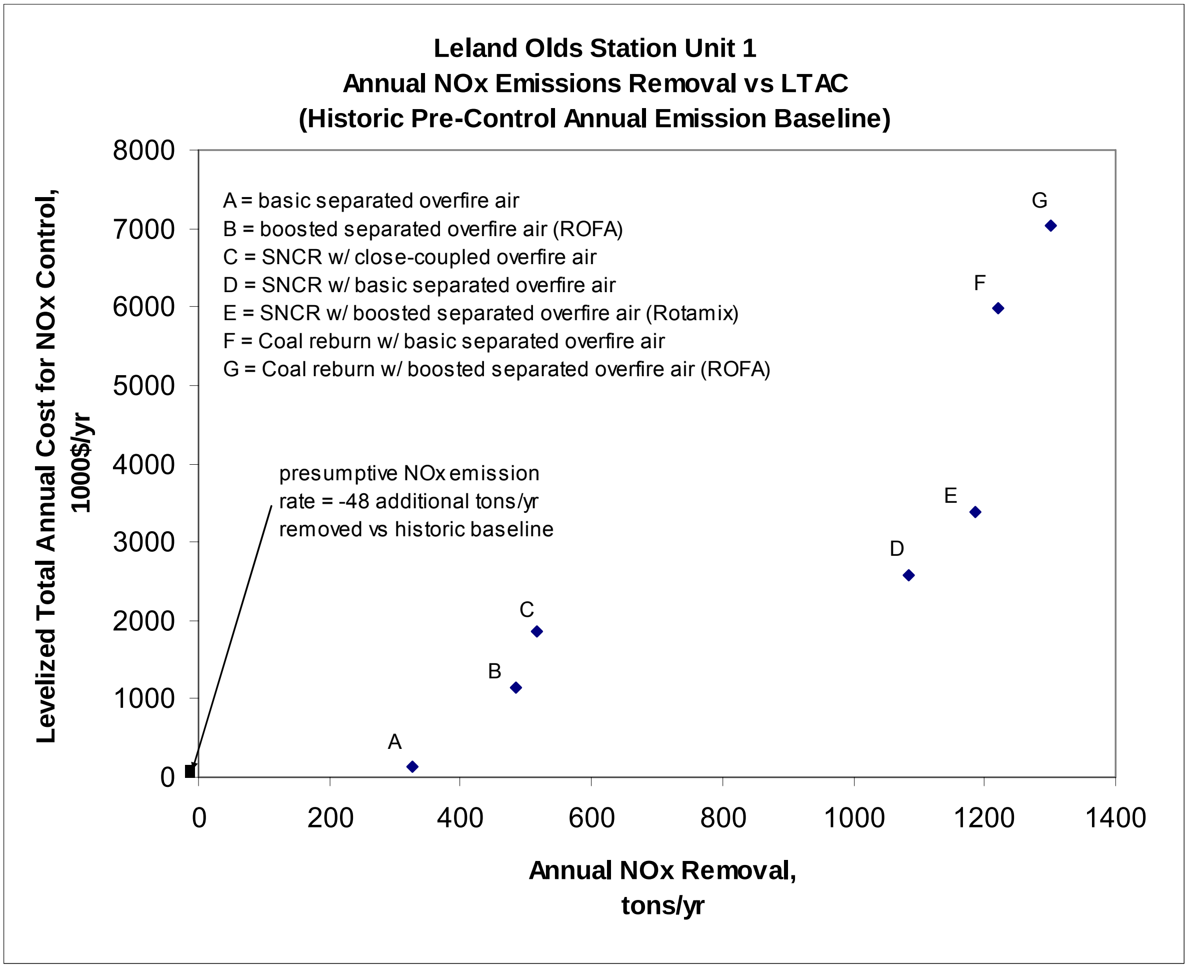
(2) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE scenario applied to LOS Unit 1.

(3) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #2 for Tables 2.4-2 and 2.4-4 for annualized cost factors.

(4) – Annualized cost figures in 2005 dollars.

(5) – LTAC for increased PM collection capacity included in coal reburn option are $1,372,000 for annualized capital cost plus $1,074,000 for annualized O&M cost, for a total of $2,446,000/yr. This results in an average control cost of $1,493/ton with boosted SOFA and $1,571/ton with basic SOFA.

Figure 2.4-1 – NO_X Control Cost Effectiveness – LOS Unit 1 (Historic Pre-Control Annual Emission Baseline)(1)



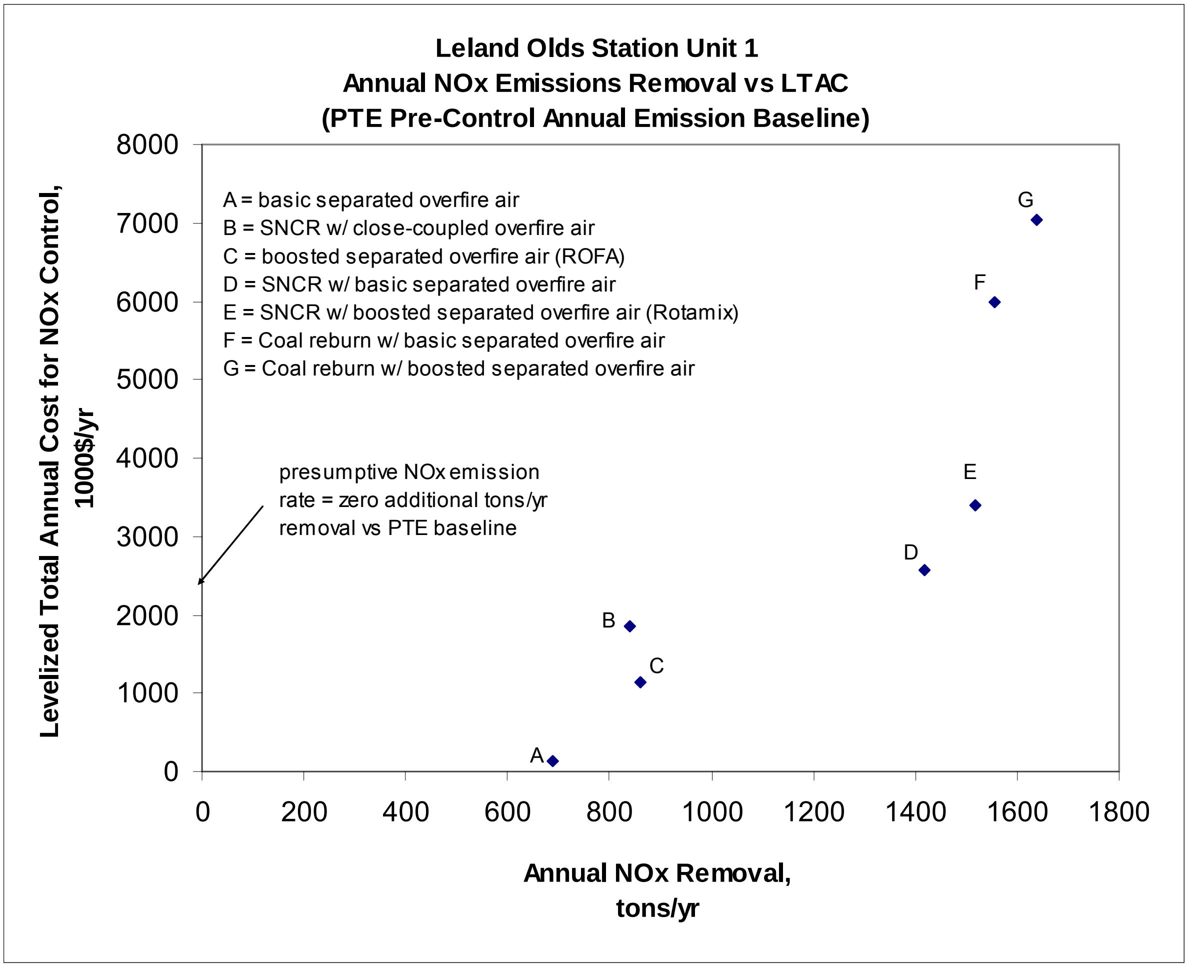
(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-5.

The comparison of the cost-effectiveness of the control options evaluated for LOS Unit 1 relative to two different NO_X emission baselines was made and is shown in Figures 2.4-1 and 2.4-2. The estimated annual amount of NO_X removal (emission reduction) in tons per year is plotted on the ordinate (horizontal axis) and the estimated levelized total annual cost in thousands of U.S. dollars per year on the abscissa (vertical axis).

Figure 2.4-1 is for the control options evaluated relative to the baseline historic pre-control annual baseline, compared to the post-control maximum annual NO_X emissions for operation of LOS Unit 1 under the future PTE case.

Figure 2.4-2 plots estimated levelized total annual costs versus estimated annual amount of NO_X removal (emission reduction) for the control options evaluated relative to the maximum pre-control annual baseline and future potential-to-emit post-control NO_X emissions for operation of LOS Unit ` under the future PTE case.

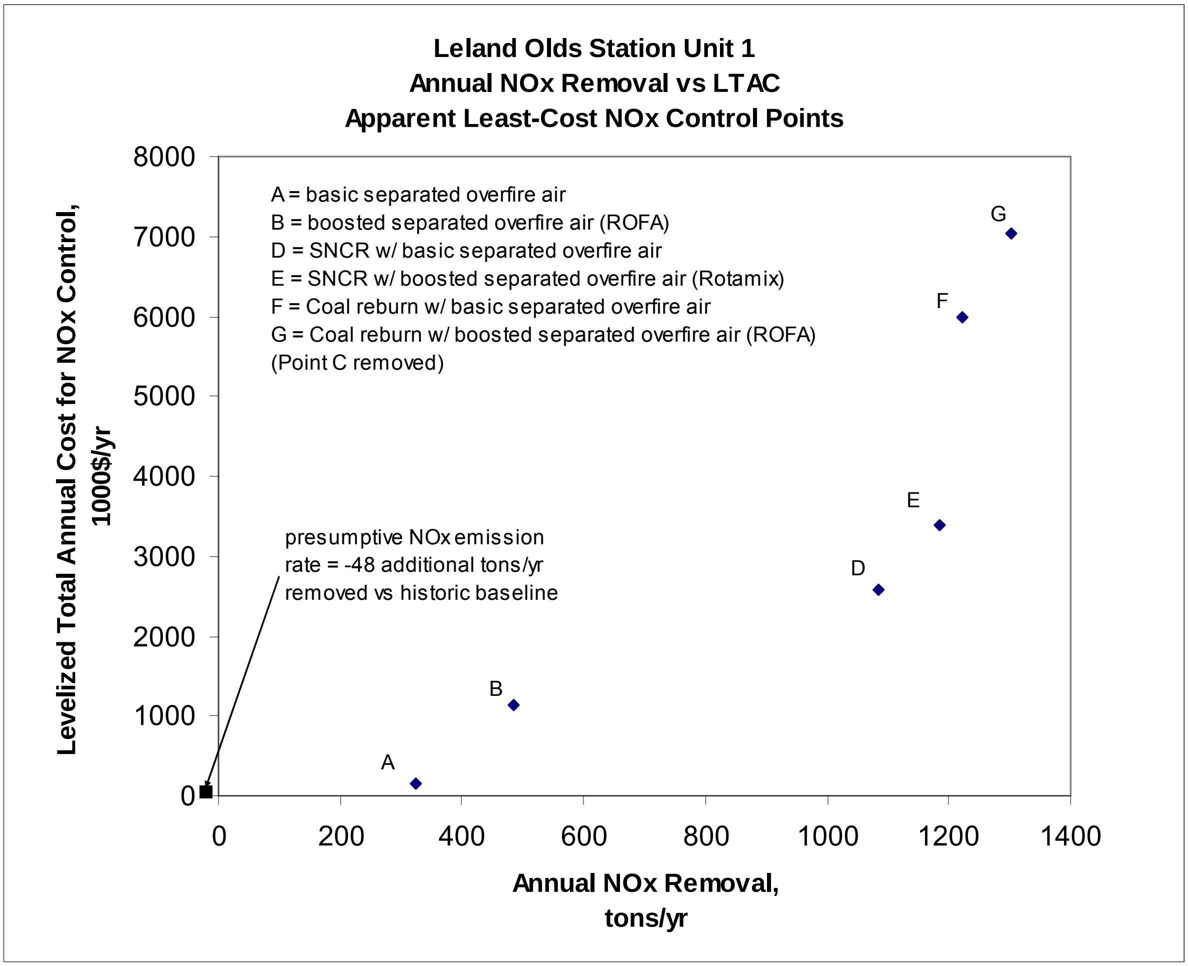
Figure 2.4-2 – NO_X Control Cost Effectiveness – LOS Unit 1 (PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-6.

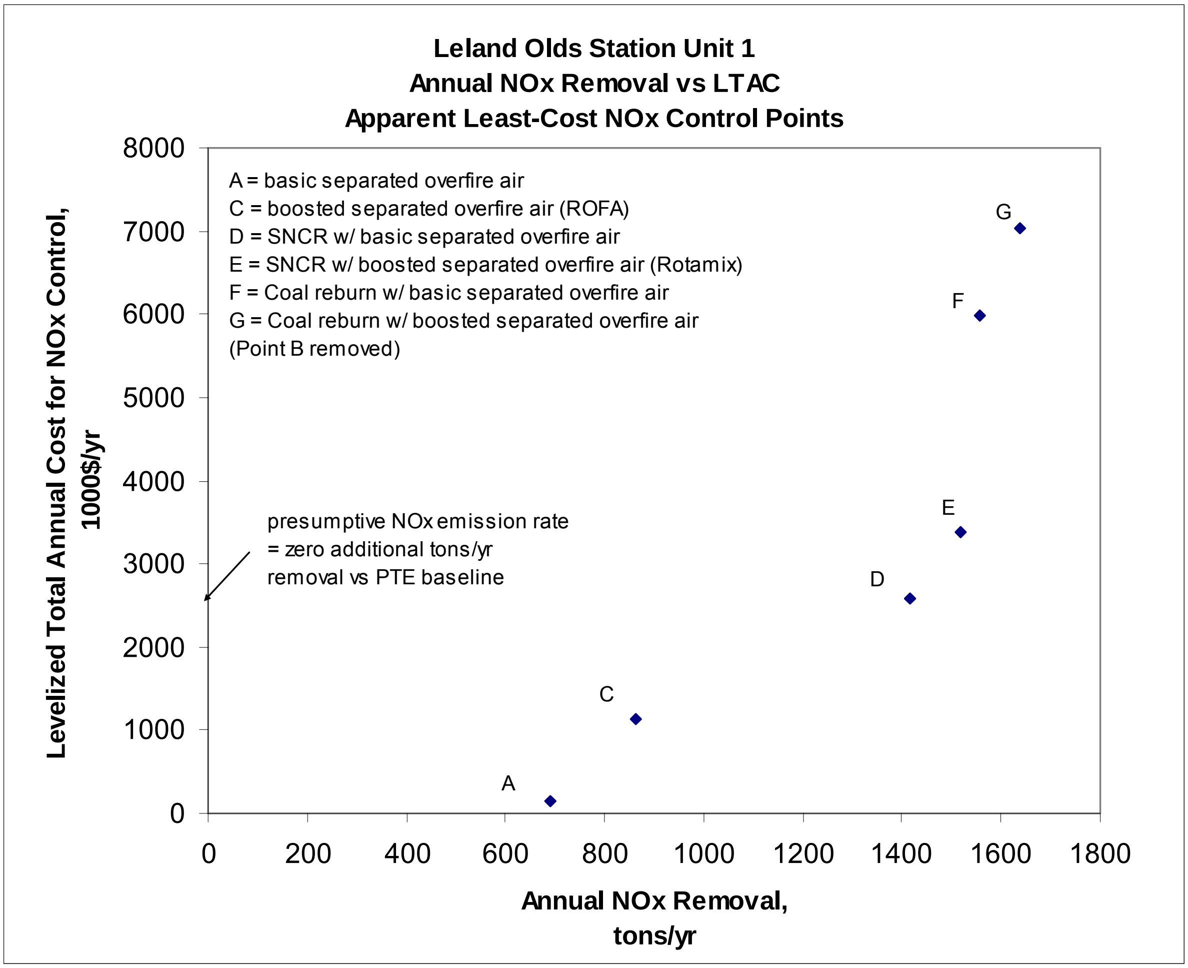
The purpose of Figures 2.4-1 and 2.4-2 is to show the range of control and cost for the evaluated NO_X reduction alternatives and identify the least-cost controls so that the Dominant Controls Curve can be created. The Dominant Controls Curve is the best fit line through the points forming the lower rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual NO_X removal tonnage for the various remaining BART alternatives. Points distinctly to the left of and above this curve are inferior control alternatives per the BART Guidelines and BART Guidelines on a cost effectiveness basis. Following a "bottom-up" graphical comparison approach, each of the NO_X control technologies represented by a data point to the left of and above the least cost envelope should be excluded from further analysis on a cost efficiency basis. Of the highest-performing versions of the technically feasible LOS Unit 1 NO_X control alternatives evaluated for cost-effectiveness, the data point for SNCR with close-coupled OFA is seen to be more costly for fewer tons of NO_X removed than for boosted separated overfire air (ROFA). SNCR with CCOFA appears to be an inferior control, and thus should not be included on the least cost and Dominant Controls Curve boundary. Note that cost-effectiveness points for conventional gas reburn and fuel-lean gas reburn alternatives would be distinctly left and significantly above the least cost-control envelope, so these options were not included in the cost-effectiveness analysis. Figures 2.4-3 and 2.4-4 show the revised least-cost control points without SNCR with CCOFA.

Figure 2.4-3 – NO_X Control Cost Effectiveness – LOS Unit 1
Apparent Least-Cost NOx Control Points
(Historic Pre-Control Annual Emission Baseline)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-5.

Figure 2.4-4 – NO_X Control Cost Effectiveness – LOS Unit 1
Apparent Least-Cost NOx Control Points
(PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



1 - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-6.

The next step in the cost effectiveness analysis for the BART NO_X control alternatives is to review the incremental cost effectiveness between remaining least-cost alternatives. Figure 2.4-5 and Figure 2.4-6 contain a repetition of the levelized total annual cost and NO_X control information from Figure 2.4-3 and Figure 2.4-4 with SNCR with CCOFA removed (Point C in Figure 2.4-1, and Point B in Figure 2.4-2), and shows the incremental cost effectiveness between each successive set of least-cost NO_X control alternatives. The incremental NO_X control tons per year, divided by the incremental levelized annual cost, yields an incremental average unit cost ($/ton). This represents the slope of a line, if drawn, from one least-cost point as compared with another least-cost point.

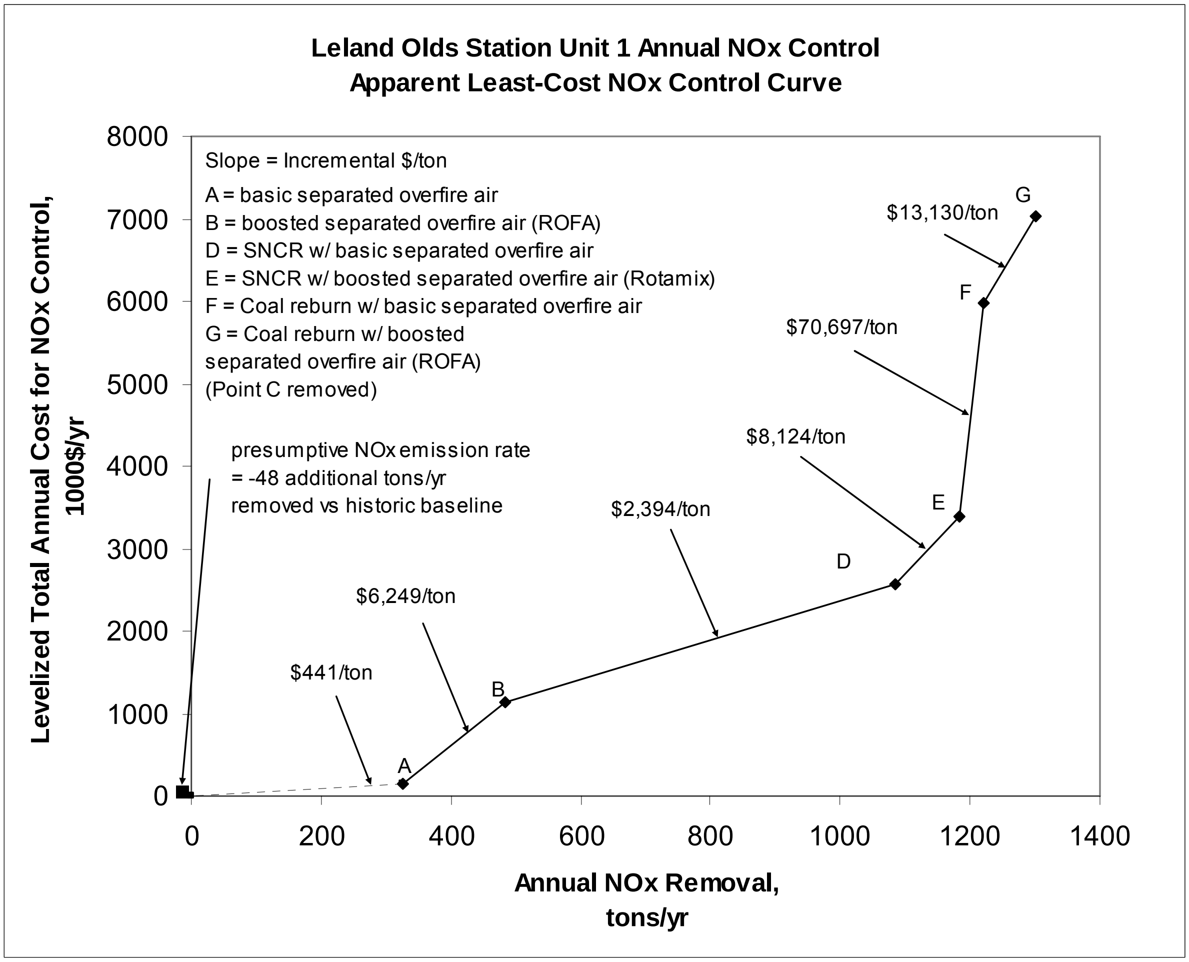
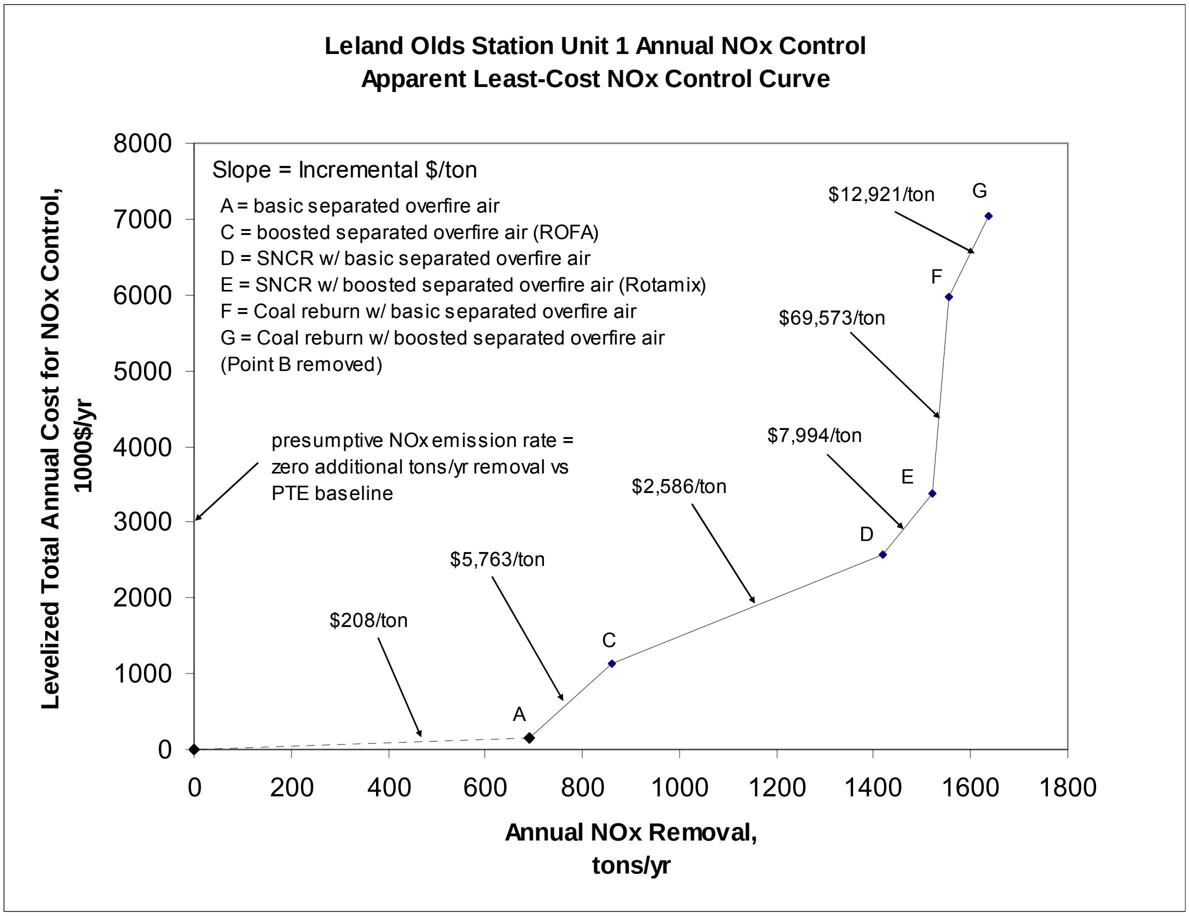
(4) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 1.
(5) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest.
(6) – Incremental control cost effectiveness is incremental LTAC divided by incremental annual emission reduction (tons per year).

Figure 2.4-5 – NO_X Control Cost Effectiveness – LOS Unit 1 Apparent Least-Cost Controls Curve (Historic Pre-Control Annual Emission Baseline)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-7.

Figure 2.4-6 – NO_X Control Cost Effectiveness – LOS Unit 1 Apparent Least-Cost Controls Curve (PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-8.

In the comparison displayed in Figure 2.4-5 and Figure 2.4-6, for the data shown in Table 2.4-7 and Table 2.4-8, the boosted SOFA (ROFA) NO_X control alternative (Point B in Figure 2.4-5, Point C in Figure 2.4-6) had a significantly higher incremental unit NO_X control cost (slope, $6,249/ton and $5,763/ton, respectively) compared against basic SOFA alternative (Point A) versus SNCR with basic SOFA (Points D) compared against ROFA. Also, Coal Reburn with basic SOFA (Points F) was significantly more incrementally expensive ($70,697/ton and $69,573/ton) compared against SNCR with boosted SOFA (Points E) versus Coal Reburn with boosted SOFA (Points G) compared against Coal Reburn with basic SOFA alternatives (Point F) ($13,130/ton and $12,921/ton). This indicates that Points C and Points F are inferior controls and do not occupy the Dominant Cost Control Curves.

After removal of Points C and F, the modified least-cost controls curve is the Dominant Cost Control Curve for NO_X emissions alternatives for each of the LOS Unit 1 pre-control baselines evaluated.

--	Baseline, based on annual operation at future PTE case pre-control emission rate	0	0			

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost.
See footnote #3 for Tables 2.4-2 and 2.4-3 for annualized cost factors.
Costs for increased PM collection capacity are included in coal reburn option.
(3) – Annualized cost figures in 2005 dollars.
(4) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 1.
(5) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest.
(6) – Incremental control cost effectiveness is incremental LTAC divided by incremental annual emission reduction (tons per year).

The cost impact analysis for historic and PTE baseline conditions identifies those control alternatives that are on the Dominant Controls Cost Curve. Those alternatives are scrutinized for cost-effectiveness on both relative and absolute bases. In the comparison displayed in Figure 2.4-7 and Figure 2.4-8, for the data shown in Table 2.5-9 and Table 2.5-10, the SNCR with basic SOFA NO_X control alternative (Points D) had a significantly higher incremental unit NO_X control cost (slope, $3,202/ton and $3,338/ton, respectively, for historic and PTE baseline conditions) compared against basic SOFA alternative (Point A) versus baseline ($441/ton and $208/ton, respectively). The incremental cost-effectiveness of the least-cost SNCR alternative on the Dominant Cost Control Curve is on the order of seven to sixteen times the magnitude of basic SOFA. SNCR with boosted SOFA (Point E) had a significantly higher incremental unit NO_X control cost compared against the

SNCR with basic SOFA alternative (Point D) ($8,124/ton and $7,994/ton, vs $3,202/ton and $3,338/ton respectively). Coal Reburn with boosted SOFA was even more incrementally costly.
In the final BART Guidelines, the EPA neither proposes hard definitions for reasonable or unreasonable Unit Control Costs nor for incremental cost effectiveness values. As can be seen from a review of Table 2.4-5, the average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the highest 24-hour historic baseline NO_X emission ranges from $441/ton to $5,404/ton. Table 2.4-6 shows average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the presumptive NO_X emission level ranges from $208/ton to $4,293/ton. The latter has lower costs per ton of NO_X emission removal due to the higher number of tons removed for the maximum emissions for pre-control baseline and additional controls under the future PTE case.

Various combinations of NO_X control technologies evaluated for control and cost-effectiveness are considered to be technically feasible for LOS Unit 1, but have much higher installation and operating costs compared with basic SOFA alone. This confirms the analysis performed by the EPA for establishing the presumptive limits for BART NO_X emissions from pulverized coal-fired EGUs: that the application of current combustion control technology, [primarily low-NOx burners and overfire air] is generally, but not always, more cost-effective than post-combustion controls. Based on the cost impact analysis and the premise that LOS Unit 1's historic and PTE annual average baseline emissions already meet the presumptive BART NO_X level of 0.29 lb/mmBtu, only the least-cost alternative of basic separated overfire air was considered for further impact and visibility impairment evaluations for LOS Unit 1 NO_X emissions control.

The other elements of the fourth step of a BART analysis after the cost impact analysis include evaluating the following impacts:

- Energy impacts.
- Non-air quality environmental impacts.
- Remaining useful life of the source.

For the purposes of this BART analysis, the remaining useful life of the source was assumed to exceed the 20-year project life utilized in the levelized annual cost impact estimates. The other impacts for the single LOS Unit 1 NO_X emissions control alternative chosen to be evaluated further are discussed in Section 2.4.2 and Section 2.4.3. Visibility impairment impacts for the single LOS Unit 1 NO_X emissions control are summarized in Section 2.4.4.

2.4.2 ENERGY IMPACTS OF NO_X CONTROL ALTERNATIVES – LOS UNIT 1

The single feasible NO_X control alternative was reviewed for significant or unusual energy penalties or benefits associated with its use. There are several basic kinds of energy impacts for NO_X emissions controls:

- Potential increase or decrease in power plant energy consumption resulting from a change in thermal (heat) energy to net electrical output conversion efficiency of the unit, usually expressed as an hourly unit heat rate (Btu/kW-hr) or the inverse of pounds of pollutant per unit electrical power output (MW-hr). This may or may not change the net electrical output (MW) capacity of the EGU, depending on if there are physical or imposed limits on the total heat input to the boiler or electrical power output.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in physical operational limitations imposed on the ability to sustain a fuel heat input rate (mmBtu/hr) which results in a potentially lower or higher unit net electrical output (MW) capacity. This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in auxiliary electrical power demand and usage (kW, kW-hrs). This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in reliability and availability to generate electrical power. This results in a change to the number of hours of annual operation, not necessarily a change in net electrical output (MW) capacity of the EGU.

Separated overfire air was the only NOX control technology evaluated further for LOS Unit 1. SOFA does not significantly change the total amount of air introduced into the boiler, only the location where it is introduced. To provide effective volumes and velocities of separated overfire air at the injection ports may require slightly higher forced draft fan power consumption resulting from higher fan discharge pressure. Combustion air damper actuators' electrical power demand would be an insignificant (+ 1 kW) change in net electrical power consumption from LOS Unit 1. Higher windbox pressure and ductwork pressure drop impacts of the SOFA system on the forced draft fans' and induced draft fans' auxiliary electrical power consumption are expected to be negligible (less than 1% of the annual auxiliary power consumed by these fans) so that unit net electrical output (MW) capacity is essentially the same as the current nameplate rating.

Operation of a SOFA system may cause a small increase in levels of unburned carbon in the flyash emitted from the boiler compared with current operation. This represents a slight amount of lost potential electrical power generation from the incompletely burned fuel, so this inefficiency could have a small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kW-hr). This impact was not quantified, as the historical variation in coal heat content that influences plant unit heat rate is expected to have more significant impacts.

Boiler furnace exit gas temperature and superheater steam / reheater steam outlet temperatures may be slightly elevated during air-staged burner operation with SOFA. This impact on the boiler's operation is typically small, and within the design capabilities of the boiler from a heat transfer and mechanical stress standpoint. This small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kW-hr) was not quantified, as the historical variation in coal heat content that influences plant unit heat rate is expected to have more significant impacts.

SOFA is not expected to significantly reduce unit reliability and availability to generate electrical power. There may be some changes in the degradation rate of the boiler's furnace waterwall tubes resulting from exposure of more area of the furnace walls to slightly air-starved conditions during SOFA operation. Such conditions can promote corrosion of the steel waterwall tubes by sulfur compounds in the furnace gases being created above the burners and below the SOFA injection ports. Due to the moderate sulfur content in the lignite and modest amount of air-staging during firing of the existing low-NO_X burners expected during SOFA operation, this potential change in corrosion rate of the boiler tubes is expected to be minor. This degradation is expected to occur over many years of operation, and normally requires periodic replacement of the deteriorated sections of boiler furnace waterwall tubes to avoid forced outages to repair tube leaks or failed sections. The potential change in the frequency of furnace wall tube failures and changeouts is difficult to estimate, and has not been quantified.

Table 2.4-11 summarizes the gross demand and usage of auxiliary electrical power estimated for the single NO_X control alternative evaluated for LOS Unit 1. This assumes annual operation for 8,760 hours at a heat input rate of 2,622 mmBtu/hr at the future PTE case conditions.

TABLE 2.4-11 – Expected Auxiliary Electrical Power Impacts for NO_X Controls – LOS Unit 1

Alt. No.	NO_X Control Technique	NO_X Control Equipment Estimated Annual Average Auxiliary Electrical Power Demand and Usage		
		Aux. Power Demand (1) (kW)	Generation Reduction from Aux. Power Demand(2) (kW-hrs/yr)	Generation Reduction from Reduced Unit Availability(3) (kW-hrs/yr)
A	Separated OFA	1	8,760	0

(1) – The NO_X control equipment gross auxiliary electrical power demand is estimated.

(2) – The annual change in NO_X equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.

(3) – The estimated total hours per year of unit unavailability multiplied by average gross generation multiplied by annual running plant capacity factor for the particular control alternative. For this analysis, SOFA was not expected to reduce annual hours of possible operation.

2.4.3 NON AIR QUALITY AND OTHER ENVIRONMENTAL IMPACTS OF NO_X CONTROL ALTERNATIVES – LOS UNIT 1

Nitrogen oxides react with oxygen in the atmosphere to produce elemental nitrogen and ozone (O_3). This is one of the common causes of visible pollution in the atmosphere referred to as “smog”. Operation of the various NO_X control technologies considered for potential application at the Leland Olds Station impose direct and indirect impacts on the environment. The most pronounced environmental impact expected from operation of any of the NO_X control options considered is the reduction of ozone and improvement in atmospheric visibility (i.e. reduced visibility impairment) downwind of the facility. This is discussed in detail in the Visibility Impacts section.

2.4.3.1 ENVIRONMENTAL IMPACTS OF SOFA

The amount of unburned carbon in the flyash produced by the boiler, collected for disposal or potentially emitted to the atmosphere, may increase by small increments due to operation of LOS Unit 1 using separated overfire air for NO_X emissions control. The potential changes in the annual amounts of flyash emissions and disposal rates are expected to be inconsequential, and have not been quantified.

The operation of a system using a basic form of separated overfire air for NO_X emissions control may increase carbon monoxide concentrations in the stack flue gas emitted from the LOS Unit 1 boiler.

This potential air emission increase does not qualify as a non-air environmental impact evaluated for the BART impact analysis, and therefore has not been quantified.

There were no other adverse or significant changes in non-air quality or other environmental impacts identified for LOS Unit 1 as a result of using separated overfire air for NO_X emissions control. Predicted visibility impacts are discussed in the next section.

2.4.4 VISIBILITY IMPAIRMENT IMPACTS OF LELAND OLDS STATION NO_X CONTROLS – UNIT 1

The fifth step in a BART analysis is to conduct a visibility improvement determination for the source.

For this BART analysis, there were two baseline NO_X emission rates modeled for LOS Unit 1 – one for the historic pre-control NO_X emission rate listed in the NDDH BART protocol[3], and one applying the presumptive BART NO_X emission rate. The historic pre-control emission baseline was the 24-hour average actual NO_X emission rate from the highest emitting day of the years 2000-2002 (meteorological period modeled per the NDDH BART protocol[3]). The historic (protocol) NO_X baseline condition emission rate was modeled simultaneously with the highest 24-hour average SO_2 emission rate, and the highest 24-hour average PM emission rate of the 2000-2002 time period.

The historic (protocol) baseline hourly NO_X emission rate used for modeling visibility impacts due to LOS Unit 1 under the conditions stated above was 813 lb/hr. Visibility impact modeling was performed using the CALPUFF model with the difference between the impacts from historic pre-control baseline and post-control average hourly NO_X emission rates representing the visibility impairment impact reduction. Three CALPUFF model runs were conducted with the same presumptive BART NO_X emission baseline rate, constant PM emissions, and various levels of SO_2 control assuming the Potential-To-Emit (PTE) boiler design rating for heat input (2,622 mmBtu/hr). The presumptive BART unit NO_X emission baseline rate of 0.29 lb/mmBtu multiplied by the boiler PTE heat input rating of 2,622 mmBtu/hr yields 760 lb/hr for LOS Unit 1 under the future PTE case. The model used an average unit NO_X emission rate of 0.23 lb/mmBtu with the PTE boiler heat input rating to yield 603 lb/hr. This was the post-control hourly NO_X emission rate representing basic SOFA applied to the future PTE case for LOS Unit 1.

In keeping with the NDDH BART visibility impairment impact modeling protocol, the BART NO_X presumptive emission rate (760 lb/hr) and SOFA alternative both have a different boiler heat input basis than the historic highest 24-hour pre-control NO_X emission baseline (813 lb/hr). The post-control conditions both assume operation at the boiler PTE capacity rating (future PTE case).

The results of the historic pre-control baseline presumptive BART NO_X PTE baseline emission rate, and post-control SOFA-enhanced PTE NO_X emission rate, modeled with the PTE 90% sulfur emission control rate for LOS Unit 1 are shown in Table 2.4-12. The results of the visibility impairment modeling at the pre-control (protocol) baseline emission rate for LOS Unit 1 showed that Lostwood National Wildlife Refuge exceeded 0.5 deciView for the highest predicted visibility impairment impact (90th percentile, averaged for 2000-2002). Average predicted visibility impairment impacts decreased significantly for the presumptive BART NO_X PTE baseline emission rate, and slightly more with post-control SOFA-enhanced PTE NO_X emission rates, modeled with any of the three PTE sulfur emission control rates for LOS Unit 1. The comparison of the incremental average visibility impairment impacts that are predicted for the three PTE sulfur emission control rates for LOS Unit 1 is shown in Section 3.4.4.

TABLE 2.4-12 – Average Visibility Impairment Impacts from NO_X Controls – LOS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts(1)		
	Historic Pre-Control (Protocol) Baseline (dV)	Presumptive BART NO_X PTE Baseline(2) (dV)	PTE Emissions with SOFA NO_X Control(2) (dV)
TRNP-South Unit	0.423	0.107	0.099
TRNP-North Unit	0.450	0.118	0.111
TRNP-Elkhorn Ranch	0.287	0.080	0.073
Lostwood NWR	0.639	0.171	0.153

(1) - Average predicted visibility impairment impacts (90th percentile) relative to background for years 2000-2002. Pre-control baseline impacts are from highest historic 24-hour NO_X, SO_2, and PM emission rates (NDDH BART protocol). Presumptive BART NO_X and SOFA NO_X impacts are from PTE heat input emission rates. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - SO_2 emissions reduced by 90% over pre-control PTE heat input baseline for the future PTE case.

The results of the visibility impairment modeling at the presumptive BART NO_X PTE emission rate (760 lb/hr) with the PTE 90% sulfur emission control rate for LOS Unit 1 again showed that Lostwood National Wildlife Refuge had the highest predicted improvement in visibility impairment compared to the pre-control (protocol) baseline levels. Average predicted visibility impairment reduction also increased with SOFA-enhanced post-control NO_X PTE emission rate from LOS Unit 1 for Lostwood NWR (approximately 0.5 deciView reduction). This is shown in Table 2.4-13.

TABLE 2.4-13 – Average Visibility Impairment Impact Reductions from NO_X Controls – LOS Unit 1 (Post-Control PTE Emissions vs Historic Baseline)

	Visibility Impairment Reductions(1)	
Federal Class 1 Area	**Presumptive BART NO_X PTE Baseline(2) (dV)**	**PTE Emissions, SOFA NO_X Control(2) (dV)**
TRNP-South Unit	0.316	0.323
TRNP-North Unit	0.332	0.339
TRNP-Elkhorn Ranch	0.207	0.214
Lostwood NWR	0.467	0.486

(1) - Average predicted visibility impairment impact reductions (90th percentile) relative to historic pre-control emission rates (NDDH BART protocol) for years 2000-2002. Presumptive BART NO_X and SOFA NO_X impacts are from PTE heat input emission rates.

(2) - SO_2 emissions reduced by 90% over pre-control PTE heat input baseline for the future PTE case scenario.

This analysis includes a determination of the incremental control effectiveness of reducing the predicted visibility impairment impact for presumptive BART NO_X and SOFA alternatives' PTE emission levels evaluated for the future PTE case operation of LOS Unit 1. The average predicted visibility impairment reduction resulting from LOS Unit 1 NO_X PTE emissions expected to result from separated overfire air (SOFA) emissions versus presumptive BART NO_X levels for the future PTE case are shown in Table 2.4-14.

TABLE 2.4-14 –Visibility Impairment Reduction from NO_X Controls (vs Presumptive BART NO_X Baseline Emissions) – LOS Unit 1

Federal Class 1 Area	Incremental Visibility Impairment Reduction(1) PTE Emissions, SOFA NO_X Control(2) (dV)
TRNP-South Unit	0.00733
TRNP-North Unit	0.00733
TRNP-Elkhorn Ranch	0.00733
Lostwood NWR	0.0183

(1) - Incremental average predicted visibility impairment impact reductions (90th percentile) relative to presumptive BART NO_X PTE baseline emission rates for years 2000-2002. SOFA NO_X impacts are from PTE heat input emission rates.

(2) - SO_2 emissions reduced by 90% over pre-control PTE heat input baseline for the future PTE case.

Table 2.4-14 shows that incremental visibility impairment improvements predicted to result from applying the SOFA alternative to the presumptive BART NO_X PTE emission rate for LOS Unit 1 are very small. The amount of visibility impairment predicted for natural background conditions is much greater in magnitude than the amount predicted from LOS Unit 1's contribution alone. The data also shows that reductions in predicted visibility impairment impacts that result from a combination of presumptive BART NO_X PTE emissions and SO_2 PTE emissions at the 90 percent (or better) control levels compared to the pre-control (protocol) emission conditions are much greater in significance than the incremental improvements of predicted visibility impairment from additional reductions in NO_X emissions.

This analysis also includes a determination of the incremental cost-effectiveness of reducing predicted visibility impairment impact for the SOFA alternative evaluated for LOS Unit 1. The estimated LTAC for reducing NO_X emissions from LOS Unit 1 expected to result from separated overfire air (SOFA) for the future PTE case are shown in Table 2.4-6. The comparison in Table 2.4-15 shows that the ratio of the estimated additional annualized costs of installing and operating SOFA with the future PTE case to the average predicted visibility impairment improvement relative to the presumptive BART NO_X PTE baseline emission rate for the future PTE case applied to LOS Unit 1 would result in millions of dollars per deciView of visibility impairment improvement.

TABLE 2.4-15 – Cost Effectiveness of Visibility Impairment Reduction from NO_X Controls (vs Presumptive NO_X Baseline Emissions) – LOS Unit 1

Federal Class 1 Area	Incremental Visibility Impairment Reduction Unit Cost PTE Emissions, SOFA NO_X Control(1),(2) ($/dV-yr)
TRNP-South Unit	19,640,000
TRNP-North Unit	19,640,000
TRNP-Elkhorn Ranch	19,640,000
Lostwood NWR	7,860,000

(1) - Average predicted visibility impairment impact reductions (90th percentile) relative to presumptive BART NO_X PTE baseline emission rates for years 2000-2002. SOFA NO_X impacts are from PTE heat input emission rates. Control costs are levelized annual values for installed capital + O&M for SOFA NO_X control. All cost figures in 2005 dollars. See Table 2.4-6 for details.

(2) - SO_2 emissions reduced by 90% over pre-control baseline for the future PTE case.

The number of days predicted to have visibility impairment due to LOS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the historic pre-control (protocol) hourly NO_X, SO_2, and PM emission rates described previously in this Section. The results are summarized and presented in Table 3.4-15. Similarly, the same information for the post-control SO_2 and PM alternatives with presumptive BART NO_X PTE emission rates was summarized and is shown in Table 3.5-16. The differences in average visibility impairment impact and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between presumptive BART NO_X emission rates versus SOFA-controlled NO_X emission rates with post-control SO_2 and PM alternatives are summarized and shown in Table 2.4-16.

The magnitude of predicted visibility impairment impacts and number of days predicted to have visibility impairment impact greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 area. The highest number of days in which the predicted visibility impairment impact above background exceeded 0.5 deciViews was for the pre-control (protocol) emission case in year 2000 for Lostwood NWR. A series of bar charts showing the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for both the pre-control and post-control model results is included in Section 3.4.

The post-control SO_2 and PM alternatives with SOFA for NO_X control were only slightly lower for the predicted visibility impairment impacts and number of days predicted to have visibility impairment impacts greater than 0.50 and 1.00 deciViews compared to the same post-control SO_2 and PM conditions with presumptive BART NO_X PTE emission rates. The number of days are presented in Appendix D. A series of bar charts showing the difference in the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the SOFA-controlled PTE emission rates compared to presumptive BART NO_X PTE emission rates with post-control SO_2 and PM alternatives is included in Figures 2.4-9, 2.4-10, and 2.4-11.

2.4.5 SUMMARY OF IMPACTS OF LOS NO_X CONTROLS – UNIT 1

Table 2.4-17 summarizes the various quantifiable impacts discussed in Sections 2.4.1 through 2.4.4 for the single BART NO_X alternative evaluated for LOS Unit 1.

Table 2.4-16 – Visibility Impairment Reductions – SOFA vs Presumptive BART NO_X Control with SO_2 and PM Controls

NO_X Control Technique w/ SO_2 Control Level	NO_X Control Efficiency (%)	Annual NO_X Emissions Reduction (tpy)	Levelized Total Annual Cost(1) ($)	Unit Control Cost ($/ton)	Visibility Impairment Impact Reduction		Incremental Visibility Impairment Reduction Unit Cost(1),(3) ($/dV)	Energy Impact (kW)	Non Air Quality Impacts
					Class 1 Area	Incremental(2) ΔdV			
SOFA w/ 90% SO_2 Control	20.7%	689	$144,000	$289	TRNP-S	0.00733	$19,640,000	1	Flyash unburned carbon increase
					TRNP-N	0.00733	$19,640,000		
					TRNP-Elk	0.00733	$19,640,000		
					LNWR	0.0183	$7,860,000		

(1) - All cost figures in 2005 dollars. See Table 2.4-6 for details.

(2) - Average predicted visibility impairment impact improvements (incremental, 90th percentile) for years 2000-2002 relative to presumptive BART NO_X emission level of 0.29 lb/mmBtu for all SO_2 and PM post-control alternatives at PTE heat input emission rates (future PTE case). This case assumes 90% SO_2 control over pre-control baseline.

(3) - LTAC for SOFA NO_X control divided by Incremental ΔdV.

2.5 EVALUATION OF IMPACTS FOR FEASIBLE NO_X CONTROLS – LOS UNIT 2

The fourth step of a BART analysis is to evaluate the following impacts of feasible emission controls:

- The cost of compliance.
- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

The purpose of the impacts evaluation is to determine if there are any energy, economic, non-air quality environmental reasons, or aspects of the remaining useful life of the source, which would eliminate the control technologies from consideration for Leland Olds Station Unit 2.

2.5.1 COST IMPACTS OF NO_X CONTROLS – LOS UNIT 2

An evaluation was performed to determine the compliance costs of installing various feasible NO_X control alternatives on LOS Unit 2 boiler. This evaluation included estimates for:

- Capital costs;
- Fixed and variable operating and maintenance costs; and
- Levelized total annual costs

to engineer, procure, construct, install, startup, test, and place into commercial operation the particular control technology. The results of this evaluation are summarized in Tables 2.5-1 through 2.5-8. From Step 3 of the BART analysis, compared with other similarly-effective NO_X controls, conventional gas reburn alternatives would have high expected capital costs for a natural gas supply pipeline and on-going natural gas costs. Thus, otherwise technically feasible gas-consuming alternatives are considered economically unattractive for application at LOS on the Unit 2 boiler.

Although the BART Guidelines prescribes following a "top down" analysis approach for BART determination, the development of a least cost envelope with dominant controls[1] [70 FR 39168] clearly labels points with lower emissions reductions and total annual costs first, i.e. "A", "B", etc. then proceeding with labeling and connecting points plotted further away from the zero emission reduction point. This "bottom-up" approach is for plotting the least-cost (dominant) control curve. The labeling of each unit's NO_X control technique alternative has followed this approach.

2.5.1.1 CAPITAL COST ESTIMATES FOR NO_X CONTROLS - LOS UNIT 2

The capital costs to implement the various NO_X control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. In the cases involving SNCR, preliminary vendor budgetary cost information was obtained and used in place of, or to adjust, the published unit output cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

A review of the unit capital cost factor range and single point unit capital cost factor for the feasible NO_X emission reduction technology evaluated for LOS Unit 2 are presented in Table 2.5-1.

TABLE 2.5-1 – Unit Capital Cost Factors of Feasible NO_X Control Options for LOS Unit 2

Alt. No. (1)	NO_X Control Technique	Range(2) ($/kW)	Single Point Unit Capital Cost Factor(3), ($/kW) LOS Unit 2
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	20 + ?(4)	46(4),(5),(6)
C	SNCR (using urea) w/ ASOFA	20-35(7)	38(5),(6)
B	Coal Reburn (conventional, pulverized) w/ ASOFA	30-60(7)	153(6),(8)
A	Advanced Separated Overfire Air (ASOFA)	5-10(7)	23(6)

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Unit capital cost factors ($/kW) of these individual technologies combined by simple addition. Actual installed costs may differ due to positive or negative synergistic effects. Range based on published values or vendor proposals.
(3) – Single point cost factor is best estimate for determination of total capital cost for a particular technology or combination, assuming maximum unit capacity is based on existing nameplate rating. Single point cost figures in 2005 dollars.
(4) – No published RRI unit capital cost factor was found in available technical literature. The installed capital costs for RRI are expected to be similar to SNCR. If both RRI and SNCR are installed together, capital cost of the RRI+SNCR portion was assumed to be 1.5x the capital cost of SNCR alone, due to commonality between the two systems sharing certain equipment and systems.
(5) – Estimated capital cost for SNCR point estimate derived from December 2004 budgetary proposal by Fuel Tech. See Appendix A for details.
(6) – The single point unit capital cost factor shown for the "advanced" version of SOFA derived from Burns & McDonnell internal database and cost estimate for North Dakota lignite-fired cyclone boilers.
(7) – NESCAUM 2005 Technical Paper, posted at their website for basic SOFA. See Appendix A for details.
(8) – The single point unit capital cost factor shown for a coal reburn system is highly site-specific, and assumes that new pulverizers and building enclosures are required. The general cost range for pulverized coal-fired boilers is included in the NESCAUM 2005 Technical Paper; for cyclone boilers is included in the 2005 WRAP Draft Report, posted at their website. The single point unit capital cost factor for this alternative for increased PM collection capacity included in coal reburn options is 57.5 $/kW. See Appendix A for details.

Annualized capital cost, which includes the time value of capital monies and its recovery, is determined from the estimated capital cost and the methodology described in Section 1. Table 2.5-2 shows the estimated installed capital cost and annualized capital cost values for the highest-performing form of the various feasible NO_X emission reduction technologies applied to LOS Unit 2. These were developed by multiplying the unit capital cost single point factors for the control option by the nameplate output capacity rating of the respective unit. These are listed in order of control effectiveness, with the highest ranked options at the top.

TABLE 2.5-2 – Installed and Annualized Capital Costs Estimated for NO_X Control Alternatives - LOS Unit 2

Alt. No. (1)	**NO_X Control Alternative**	**Installed Capital Cost(2) ($1,000)**	**Annualized Capital Cost(3) ($1,000)**
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	20,200	1,760
C	SNCR (using urea) w/ ASOFA	16,800	1,470
B	Coal Reburn (conventional, pulverized) w/ ASOFA	67,400(4)	5,880(4)
A	Advanced Separated Overfire Air (ASOFA)	10,100	883
	Baseline	0	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – Installed capital cost is estimated for determination of total capital cost for a control technology, assuming maximum unit output capacity is based on existing nameplate rating of 440,000 kW. Installed capital cost figures in 2005 dollars.

(3) – Annualized capital cost = Installed capital cost x 0.08718 Capital Recovery Factor.

(4) – Costs for increased PM collection capacity included in coal reburn option are $25,300,000 for installed capital cost, and $2,200,000/yr annualized capital cost.

2.5.1.2 OPERATING AND MAINTENANCE COST ESTIMATES FOR NO_X CONTROLS – LOS UNIT 2

The operation and maintenance costs to implement the various NO_X control technologies were largely estimated from cost factors (percentages of installed capital costs) established in the EPA's Air Pollution Control Cost Manual (OAQPS), and from engineering judgment applied to that control technology. In the cases including various forms of SNCR, preliminary vendor quotes were obtained and used in place of, or to adjust the OAQPS cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

Fixed and variable operating and maintenance costs considered and included in each NO_X control technology's Levelized Total Annual Costs are estimates of:

- Auxiliary electrical power consumption for operating the additional control equipment;
- Reagent consumption, and reagent unit cost for SNCR and RRI alternatives; and
- Reagent dilution water consumption and unit cost for SNCR and RRI alternatives.
- Increases or savings in auxiliary electrical power consumption for changes in coal preparation equipment and loading, primarily for fuel reburn cases;
- General operating labor, plus maintenance labor and materials devoted to the additional emission control equipment and its impact on existing boiler equipment.
- Reductions in revenue expected to result from loss of unit availability, i.e. outages attributable to the control option, which reduce annual net electrical generation available for sale (revenue).

Table 2.5-3 and Table 2.5-4 show the estimated annual operating and maintenance costs and levelized annual O&M cost values for the highest-performing form of the various feasible NO_X emission reduction technologies. These are listed in order of control effectiveness, with the highest ranked options at the top. The cost methodology summarized in Section 1.3.5 provides more details for the levelized annual O&M cost calculations and cost factors.

TABLE 2.5-3 – Estimated O&M Costs for NO_X Control Options (Relative to Historic Pre-Control Annual Emission Baseline) – LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Annual O&M Cost(2) ($1,000)	Levelized Annual O&M Cost(3) ($1,000)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	11,000	13,100
C	SNCR (using urea) w/ ASOFA	6,570	7,830
B	Coal Reburn (conventional, pulverized) w/ ASOFA	5,730(4)	6,830(4)
A	Advanced Separated Overfire Air (ASOFA)	152	182
	Baseline, based on annual operation at historic 24-mo average pre-control emission rate	0	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Annual O&M cost figures in 2005 dollars.
(3) – Levelized annual O&M cost = Annual O&M cost x 1.19314 Annualized O&M cost factor.
(4) – Costs for increased PM collection capacity included in coal reburn option are $1,740,000 for annual O&M cost, and $2,080,000/yr levelized annual O&M cost.

Annual operating and maintenance costs of the NO_X control options in Table 2.5-3 and Table 2.5-4 are based on LOS Unit 2 operation with the control option at 5,130 mmBtu/hr heat input and 8,760 hrs/yr operation. The Table 2.5-3 O&M costs are relative to unit pre-control baseline operation at 0.667 lb/mmBtu for the highest 24-month NO_X emission summation at 4,478 mmBtu/hr heat input for 8,050 hrs/yr operation of LOS Unit 2. The Table 2.5-4 O&M costs are relative to unit pre-control baseline operation at 0.667 lb/mmBtu for the maximum NO_X emissions associated with the future PTE case at 5,130 mmBtu/hr heat input for 8,760 hrs/yr operation of LOS Unit 2.

TABLE 2.5-4 – Estimated O&M Costs for NO_X Control Options (Relative to PTE Pre-Control Annual Emission Baseline – Future PTE Case) – LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Annual O&M Cost(2) ($1,000)	Levelized Annual O&M Cost(3) ($1,000)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	11,000	13,100
C	SNCR (using urea) w/ ASOFA	6,580	7,830
B	Coal Reburn (conventional, pulverized) w/ ASOFA	5,730(4)	6,830(4)
A	Advanced Separated Overfire Air (ASOFA)	152	182
	Baseline, based on annual operation at future PTE case pre-control emission rate	0	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Annual O&M cost figures in 2005 dollars.
(3) – Levelized annual O&M cost = Annual O&M cost x 1.19314 Annualized O&M cost factor.
(4) – Costs for increased PM collection capacity included in coal reburn option are $1,740,000 for annual O&M cost, and $2,080,000/yr levelized annual O&M cost.

The majority of the annual operating and maintenance costs for the alternatives using chemical reagent injection (urea) for NO_X emissions control are for the delivered reagent and dilution water. Both RRI and SNCR are assumed to dilute the 50% aqueous urea solution as-received to a 10% aqueous urea concentration for direct injection into the targeted furnace areas. Higher than theoretical normalized (molar) stoichiometric ratios (NSRs) for the moles of equivalent reagent injected (urea) per mole of inlet NO_X emission were assumed for SNCR with ASOFA, and for RRI+SNCR with ASOFA due to inefficiencies inherent in their use. These annual costs reflect a significant increase in reagent consumption above the theoretical rates based on expected amounts of reagent utilization.

In order to compare a particular NO_X emission reduction alternative during the cost of compliance impact analysis portion of the BART selection process, the basic methodology defined in the BART

Guidelines was followed [70 FR 39167-39168]. The sum of estimated annualized installed capital plus levelized annual operating and maintenance costs, which in this analysis is referred to as "Levelized Total Annual Cost" (LTAC) of expected pollutant removal incurred by implementing that alternative, was calculated. The LTAC for these NO_X control alternatives was calculated based on the same economic conditions and a 20 year project life (see Section 1.3.5 of this BART evaluation for methodology details).

The Average Cost Effectiveness (also called Unit Control Cost) was then determined as the LTAC divided by baseline annual tons of pollutant emissions that would be avoided by implementation of the respective alternative. The feasible control alternatives were also compared by calculating the change in LTAC per incremental ton of pollutant removed for the next most stringent alternative (incremental cost effectiveness). This identified which alternatives produced the highest increment of expected pollutant reduction for the estimated lowest average LTAC increment compared with the pre-control baseline emission rate. The expected annual number of tons of pollutant removed versus estimated LTAC for each remaining control alternative was then plotted. These incremental and average control costs relative to the historic pre-control annual NO_X emission baseline for LOS Unit 2 are shown in Table 2.5-5. The incremental and average control costs relative to the PTE pre-control annual NO_X emission baseline for LOS Unit 2 are shown in Table 2.5-6.

TABLE 2.5-5 – Estimated Annual Emissions and LTAC for NO_X Control Alternatives (Historic Pre-Control Annual Emission Baseline) – LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Annual NO_X Emissions(2) (Tons/yr)	Annual NO_X Emissions Reduction(2) (Tons/yr)	Levelized Total Annual Cost(3),(4) ($1,000)	Average Control Cost(4) ($/ton)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	5,895	6,128	14,900	2,430
C	SNCR (using urea) w/ ASOFA	6,762	5,261	9,300	1,770
B	Coal Reburn (conventional, pulverized) w/ ASOFA	7,115	4,908	12,700^5	2,590^5
A	Advanced Separated Overfire Air (ASOFA)	10,796	1,227	1,060	867
	Baseline, based on annual operation at historic 24-mo average pre-control emission rate	12,023	0	0	

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – NO_X emissions and control level reductions relative to the historic pre-control annual baseline for LOS Unit 2.

(3) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #3 for Tables 2.5-2 and 2.5-3 for annualized cost factors.

(4) – Annualized cost figures in 2005 dollars.

(5) – LTAC for increased PM collection capacity included in coal reburn option are $2,200,000 for annualized capital cost plus $2,080,000 for annualized O&M cost, for a total of $4,280,000/yr. This results in an average control cost of $873 per ton of NO_X removed.

TABLE 2.5-6 – Estimated Annual Emissions and LTAC for NO_X Control Alternatives (PTE Pre-Control Annual Emission Baseline – Future PTE Case)
LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Annual NO_X Emissions(2) (Tons/yr)	Annual NO_X Emissions Reduction(2) (Tons/yr)	Levelized Total Annual Cost(3),(4) ($1,000)	Average Control Cost(4) ($/ton)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	5,895	9,094	14,900	1,640
C	SNCR (using urea) w/ ASOFA	6,762	8,226	9,300	1,130
B	Coal Reburn (conventional, pulverized) w/ ASOFA	7,115	7,873	12,700[5]	1,610[5]
A	Advanced Separated Overfire Air (ASOFA)	10,796	4,193	1,060	254
	Baseline, based on annual operation at future PTE case pre-control emission rate	14,989	0	0	

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 2.

(3) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #3 for Tables 2.5-2 and 2.5-4 for annualized cost factors.

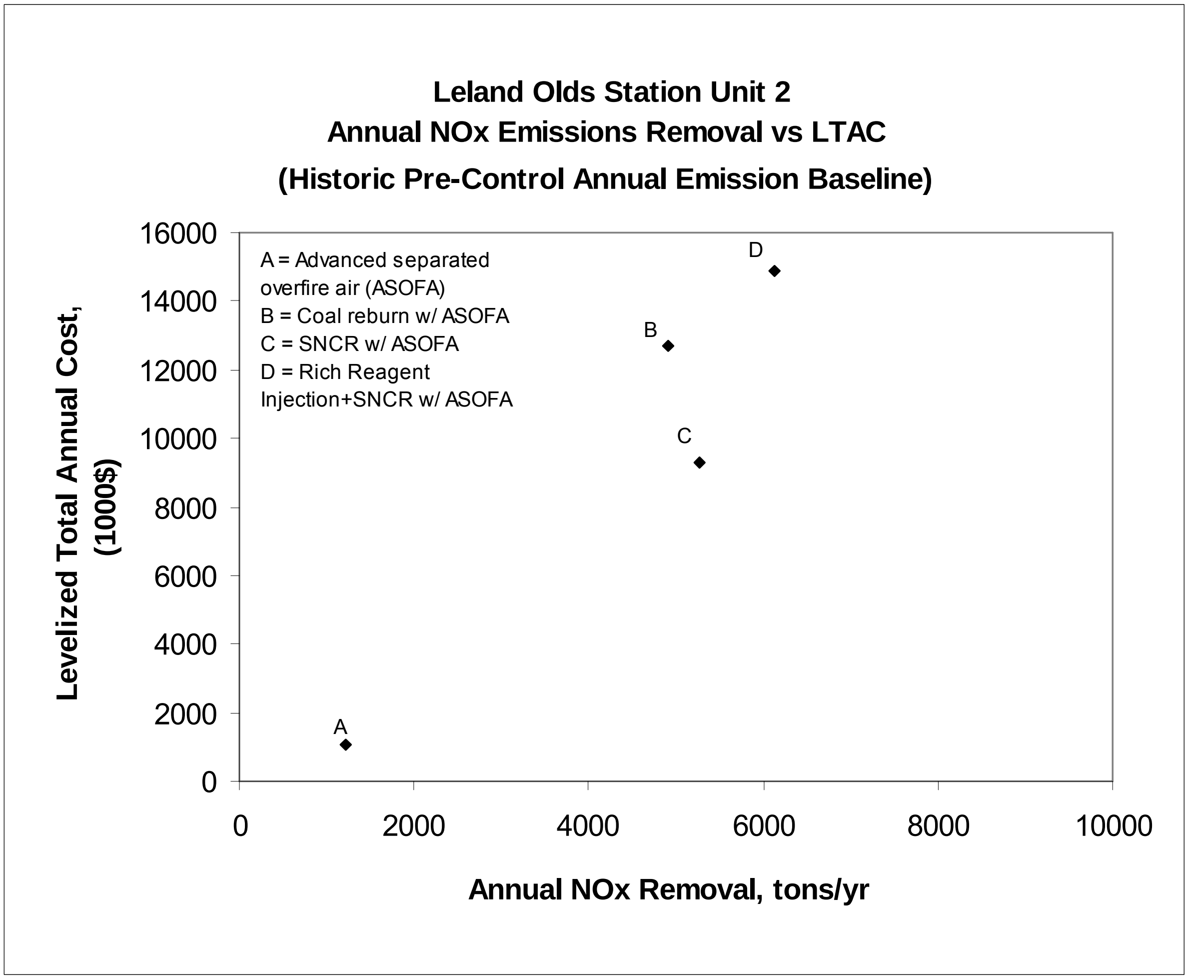
(4) – Annualized cost figures in 2005 dollars.

(5) – LTAC for increased PM collection capacity included in coal reburn option are $2,200,000 for annualized capital cost plus $2,080,000 for annualized O&M cost, for a total of $4,280,000/yr. This results in a average control cost of $544 per ton of NO_X removed.

The comparison of the cost-effectiveness of the control options evaluated for LOS Unit 2 relative to two different NO_X emission baselines was made and is shown in Figures 2.5-1 and 2.5-2. The estimated annual amount of NO_X removal (emission reduction) in tons per year is plotted on the ordinate (horizontal axis) and the estimated levelized total annual cost in thousands of U.S. dollars per year on the abscissa (vertical axis).

Figure 2.5-1 is for the control options evaluated relative to the baseline historic pre-control annual baseline, compared to the post-control maximum annual NO_X emissions for operation of LOS Unit 2 under the future PTE case.

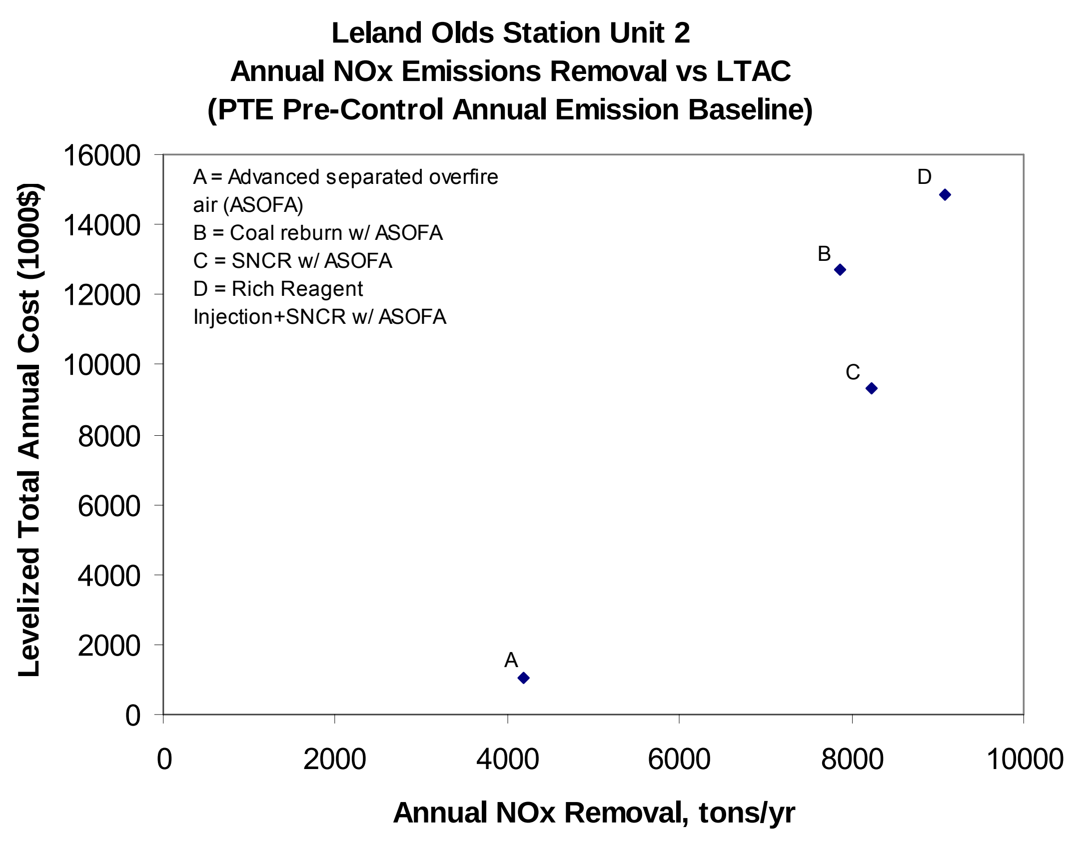
Figure 2.5-1 – NO_X Control Cost Effectiveness – LOS Unit 2 (Historic Pre-Control Annual Emission Baseline)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.5-5.

Figure 2.5-2 plots estimated levelized total annual costs versus estimated annual amount of NO_X removal (emission reduction) for the control options evaluated relative to the maximum pre-control annual baseline and future potential-to-emit post-control NO_X emissions for operation of LOS Unit 2 under the future PTE case.

Figure 2.5-2 – NO_X Control Cost Effectiveness – LOS Unit 2 (PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.5-6.

The purpose of Figures 2.5-1 and 2.5-2 is to show the range of control and cost for the evaluated NO_X reduction alternatives and identify the least-cost controls so that the Dominant Controls Curve can be created. The Dominant Controls Curve is the best fit line through the points forming the lower rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual NO_X removal tonnage for the various remaining BART alternatives. Points distinctly to the left of and above this curve are inferior control alternatives per the BART Guidelines and BART Guidelines on a cost effectiveness basis. Following a "bottom-up" graphical comparison approach, each of the NO_X control technologies represented by a data point to the left of and above the least cost envelope should be excluded from further analysis on a cost efficiency basis. Of the highest-performing versions of the technically feasible LOS Unit 2 NO_X control alternatives evaluated for cost-effectiveness, the data point for coal reburn with ASOFA is seen to be more costly for fewer tons of NO_X removed than for SNCR with ASOFA. This appears to be an inferior control, and thus should not be included on the least cost and Dominant Controls Curve boundary. Note that cost-effectiveness points for conventional gas reburn and fuel-lean gas reburn alternatives would be distinctly left and significantly above the least cost-control envelope, so these options were not included in the cost-effectiveness analysis.

The next step in the cost effectiveness analysis for the BART NO_X control alternatives is to review the incremental cost effectiveness between remaining least-cost alternatives. Figure 2.5-3 and Figure 2.5-4 contains a repetition of the levelized total annual cost and NO_X control information from Figure 2.5-1 and Figure 2.5-2 with Point B removed, and shows the incremental cost effectiveness between each successive set of least-cost NO_X control alternatives. The incremental NO_X control tons per year, divided by the incremental levelized annual cost, yields an incremental average unit cost ($/ton). This represents the slope of a line, if drawn, from one least-cost point as compared with another least-cost point. This modified least-cost controls curve is the Dominant Controls Cost Curve for NO_X emissions alternatives for each of the LOS Unit 2 pre-control baselines evaluated.

TABLE 2.5-7 – Estimated Incremental Annual Emissions and LTAC for NO_X Control Alternatives (Historic Pre-Control Annual Emission Baseline) – LOS Unit 2

Alt. No.(1)	NO_X Control Technique	Levelized Total Annual Cost(2),(3) ($1,000)	Annual Emission Reduction(4) (Tons/yr)	Incremental Levelized Total Annual Cost(3),(5) ($1,000)	Incremental Annual Emission Reduction(4),(5) (Tons/yr)	Incremental Control Cost Effectiveness ($/ton)(3),(6)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	14,900	6,128	5,570	867	6,420
C	SNCR (using urea) w/ ASOFA	9,300	5,261	8,240	4,034	2,040
A	Advanced SOFA (ASOFA)	1,060	1,227	1,060	1,227	867
	Baseline, based on annual operation at historic 24-month average pre-control emission rate	0	0			

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost.
See footnote #3 for Tables 2.5-2 and 2.5-3 for annualized cost factors.
Costs for increased PM collection efficiency are included in coal reburn option.
(3) – Annualized cost figures in 2005 dollars.
(4) – NO_X emissions and control level reductions relative to the historic pre-control annual baseline for LOS Unit 2.
(5) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest.
(6) – Incremental control cost effectiveness is incremental LTAC divided by incremental annual emission reduction (tons per year).

TABLE 2.5-8 – Estimated Incremental Annual Emissions and LTAC for NO_X Control Alternatives (PTE Pre-Control Annual Emission Baseline – Future PTE Case) LOS Unit 2

Alt. No.[1]	NO_X Control Technique	Levelized Total Annual Cost[2],[3] ($1,000)	Annual Emission Reduction[4] (Tons/yr)	Incremental Levelized Total Annual Cost[3],[5] ($1,000)	Incremental Annual Emission Reduction[4],[5] (Tons/yr)	Incremental Control Cost Effectiveness ($/ton)[3],[6]
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	14,900	9,094	5,570	867	6,420
C	SNCR (using urea) w/ ASOFA	9,300	8,226	8,240	4,034	2,040
A	Advanced SOFA (ASOFA)	1,060	4,193	1,060	4,193	254
	Baseline, based on annual operation at future PTE case pre-control emission rate	0	0			

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost.
See footnote #3 for Tables 2.5-2 and 2.5-3 for annualized cost factors.
Costs for increased PM collection capacity are included in coal reburn option.

(3) – Annualized cost figures in 2005 dollars.

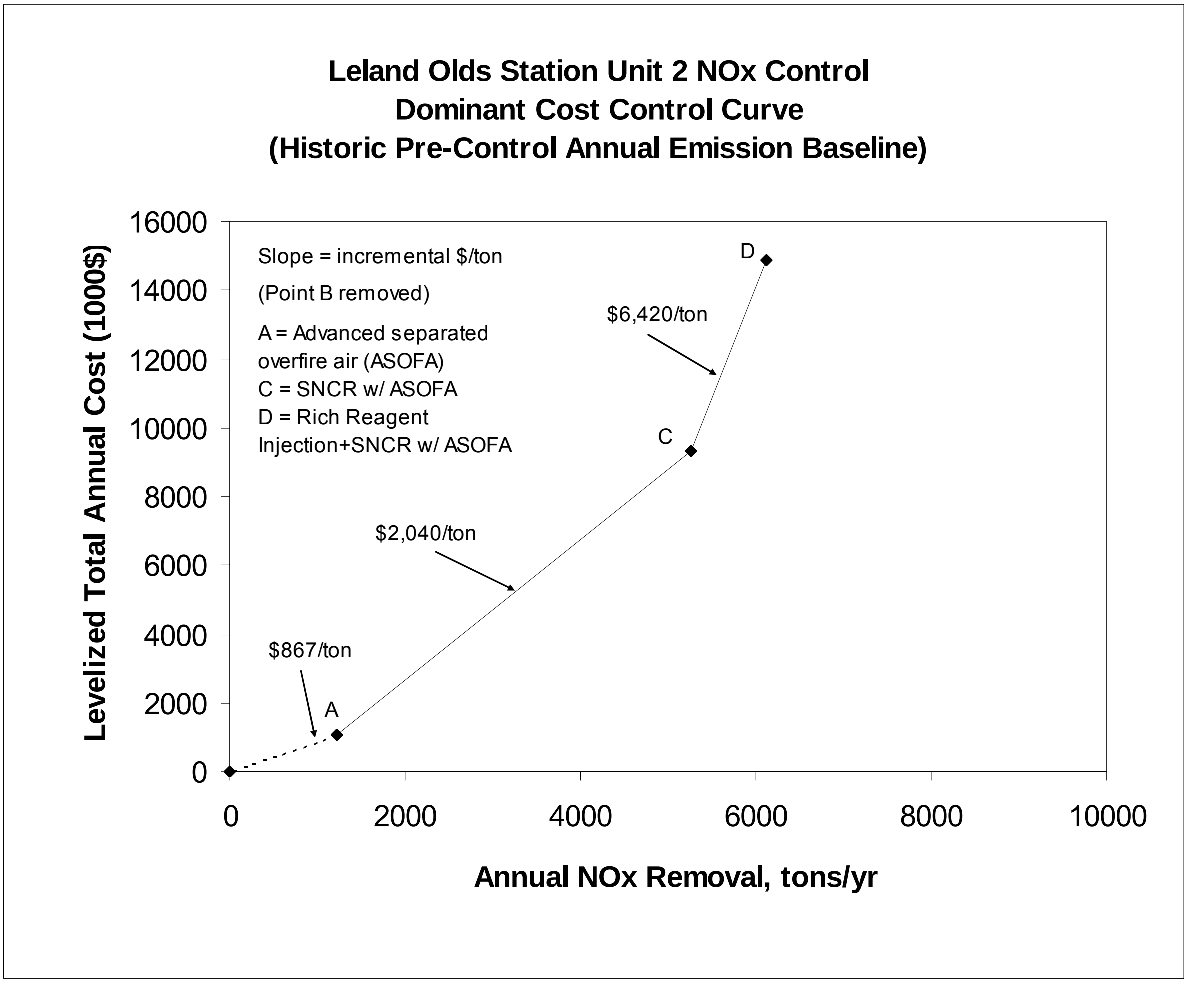
(4) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 2.

(5) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest.

(6) – Incremental control cost effectiveness is incremental LTAC divided by incremental annual emission reduction (tons per year).

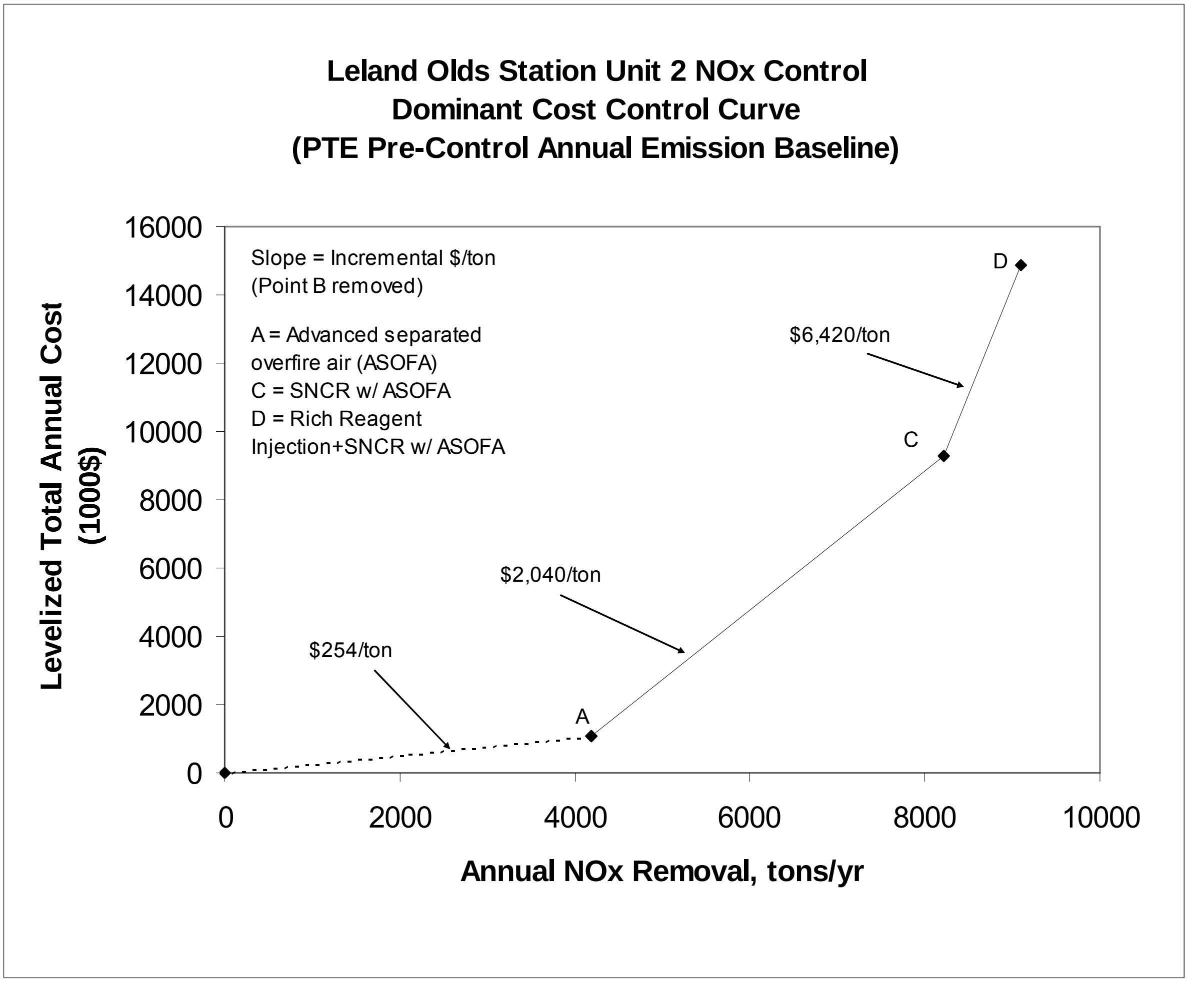
In the comparison displayed in Figure 2.5-3 and Figure 2.5-4, for the data shown in Table 2.5-7 and Table 2.5-8, the RRI+SNCR with Advanced SOFA NO_X control alternative (Point D) had a significantly higher incremental unit NO_X control cost (slope, $6,420/ton) compared against SNCR with ASOFA alternative (Point C) versus SNCR with ASOFA (Point C) compared against the ASOFA alternative (Point A) ($2,040/ton).

Figure 2.5-3 – NO_X Control Cost Effectiveness – LOS Unit 2 Dominant Cost Control Curve (Historic Pre-Control Annual Emission Baseline)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.5-7.

Figure 2.5-4 – NO_X Control Cost Effectiveness – LOS Unit 2 Dominant Cost Control Curve (PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.5-8.

In the final BART Guidelines, the EPA neither proposes hard definitions for reasonable, or unreasonable Unit Control Costs nor for incremental cost effectiveness values. As can be seen from a review of Table 2.5-5, the average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the highest 24-hour historic baseline NO_X emission ranges from $867/ton to $2,430/ton. Table 2.5-6 shows average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the presumptive NO_X emission level ranges from $254/ton to $1,640/ton. The latter has lower costs per ton of NO_X emission removal due to the higher number of tons removed for the maximum emissions for pre-control baseline and additional controls under the future PTE case.

The incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the Dominant Control Cost Curve) between successively more effective alternatives. The incremental cost analysis indicates that from a cost effectiveness viewpoint, the highest performing alternative is Rich Reagent Injection + SNCR with ASOFA (Point D). This control option is considered technically feasible for Leland Olds Station Unit 2 boiler, incurs a significant annual (levelized) incremental cost compared to the next highest feasible NO_X control technique, SNCR with ASOFA (Point C, slope from C to D =6,470 \$/ton) compared against the next lowest alternative, ASOFA (Point A, slope from A to C = 2,040 \$/ton).

The other elements of the fourth step of a BART analysis following cost of compliance are to evaluate the following impacts of feasible emission controls:

- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

For the purposes of this BART analysis, the remaining useful life of the source was assumed to exceed the 20-year project life utilized in the cost impact estimates. The other impacts for the LOS Unit 2 NO_X emissions control alternatives from the Dominant Control Cost Curve are discussed in Section 2.5.2 and Section 2.5.3. Visibility impairment impacts for these LOS Unit 2 NO_X emissions controls are summarized in Section 2.5.4.

2.5.2 ENERGY IMPACTS OF NO_X CONTROL ALTERNATIVES – LOS UNIT 2

Operation of the top NO_X control technologies considered feasible for potential application at the Leland Olds Station impose direct impacts on the consumption of energy required for the production of electrical power at the facility. The details of estimated energy usage and costs for the various LOS Unit 2 NO_X control alternatives are summarized in Appendix A.

Control alternatives for reduction of NO_X emissions were reviewed to determine if the use of the technique or technology will result in any significant or unusual energy penalties or benefits. There are several basic kinds of energy impacts for NO_X emissions controls:

- Potential increase or decrease in power plant energy consumption resulting from a change in thermal (heat) energy to net electrical output conversion efficiency of the unit, usually expressed as an hourly unit heat rate (Btu/kW-hr) or the inverse of pounds of pollutant per unit electrical power output (MW-hr). This may or may not change the net electrical output (MW) capacity of the EGU, depending on if there are physical or imposed limits on the total heat input to the boiler or electrical power output.

- Potential increase or decrease in net electrical output of the unit, resulting from changes in physical operational limitations imposed on the ability to sustain a fuel heat input rate (mmBtu/hr) which results in a potentially lower or higher unit net electrical output (MW) capacity. This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in auxiliary electrical power demand and usage (kW, kW-hrs). This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in reliability and availability to generate electrical power. This results in a change to the number of hours of annual operation, not necessarily a change in net electrical output (MW) capacity of the EGU.

2.5.2.1 ENERGY IMPACTS OF SOFA ALTERNATIVES

There should not be a major impact on energy consumption by the operation of the advanced variation of a separated overfire air system. ASOFA was the only NO_X control technology common to all four alternatives evaluated for LOS Unit 2. SOFA does not significantly change the total amount of air introduced into the boiler, only the location where it is introduced. Combustion air damper actuators' electrical power demand would be insignificant (+ 1 kW) change in net electrical power consumption from LOS Unit 2. For cyclone boilers, providing effective volumes and velocities of separated overfire air at the injection ports should not require higher forced draft fan power consumption resulting from higher fan discharge pressure. Higher lignite drying system vent ductwork pressure drop impacts of the advanced SOFA system on the forced draft fans' auxiliary electrical power consumption are expected to be negligible (less than 1% of the annual auxiliary power consumed by these fans) so that unit net electrical output (MW) capacity is essentially the same as the current nameplate rating.

Operation of a SOFA system may cause a small increase in levels of unburned carbon in the flyash emitted from the boiler compared with current operation. This represents a slight amount of lost potential electrical power generation from the incompletely burned fuel, so this inefficiency could have a small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kw-hr). This impact was not quantified, as the historical variation in coal heat content that influences plant unit heat rate may be more significant.

Boiler furnace exit gas temperature and superheater steam / reheater steam outlet temperatures may be slightly elevated during air-staged cyclone operation with SOFA. This impact on the boiler's operation is typically small, and within the design capabilities of the boiler from a heat transfer and mechanical stress standpoint. This small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kW-hr) was not quantified, as the historical variation in coal heat content that influences plant unit heat rate is expected to have more significant impacts.

SOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, once the amount of secondary combustion air that can be withdrawn from the cyclones is established for consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for LOS Unit 2. There may be some changes in the degradation rate of the boiler's furnace waterwall tubes resulting from exposure of more area of the furnace walls to slightly air-starved conditions during SOFA operation. Such conditions can promote corrosion from sulfur compounds in the furnace gases being created above the cyclones and below the SOFA injection ports. Due to the relatively moderate amounts of sulfur content in the lignite, modest amount of air-staging of the existing cyclones during SOFA operation, and the potential use of recirculated flue gas along the lower furnace walls, the expected change in corrosion rate of the boiler tubes should be minor. This degradation is expected to occur over many years of operation, and normally requires periodic replacement of the deteriorated sections of boiler furnace waterwall tubes to avoid forced outages to repair tube leaks or failed sections. The potential change in the frequency of furnace wall tube failures and changeouts is difficult to estimate, and has not been quantified.

2.5.2.2 ENERGY IMPACTS OF SNCR ALTERNATIVES

For SNCR-related NO_X control alternatives (with or without Rich Reagent Injection), the injection of a diluted urea solution requires some additional auxiliary power for heating and pumping the liquid, and using compressed air for atomization and cooling the reagent injection nozzles/lances, on the order of 150 to 400 kW. The injection of water (used for urea dilution) into the boiler flue gas also has a small negative impact on the plant heat rate (higher Btu/kw-hr), which is approximately equal to the heat released from the reaction of the reagent with NO_X or oxygen. The impact of additional flue gas created by operation of an SNCR-related system on induced draft fan power consumption should be insignificant.

Table 2.5-9 summarizes the gross demand and usage from auxiliary electrical power estimated for the NO_X control alternatives evaluated for LOS Unit 2.

TABLE 2.5-9 – Expected Auxiliary Electrical Power Impacts for NO_X Controls – LOS Unit 2

		NO_X Control Equipment Estimated Annual Average Auxiliary Electrical Power Demand and Usage		
Alt. No.(1)	**NO_X Control Technique**	**Aux. Power Demand (2) (kW)**	**Generation Reduction from Aux. Power Demand(2),(3) (kW-hrs/yr)**	**Generation Reduction from Reduced Unit Availability(4) (kW-hrs/yr)**
D	RRI + SNCR (using urea) w/ ASOFA	284	2,455,500	38,500,000
C	SNCR (using urea) w/ ASOFA	155	1,340,800	38,500,000
A	Advanced Separated Overfire Air (ASOFA)	1	8,760	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – The NO_X control equipment gross auxiliary electrical power demand is estimated.
(3) – The annual change in NO_X equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.
(4) – The estimated total hours per year of unit unavailability multiplied by average gross generation multiplied by annual running plant capacity factor for the particular control alternative. For this analysis, SOFA was not expected to reduce annual hours of possible operation.

2.5.3 NON-AIR QUALITY AND OTHER ENVIRONMENTAL IMPACTS OF NO_X CONTROL ALTERNATIVES – LOS UNIT 2

Nitrogen oxides react with oxygen in the atmosphere to produce elemental nitrogen and ozone (O_3). This is one of the common causes of visible pollution in the atmosphere referred to as “smog”. Operation of the various NO_X control technologies considered for potential application at the Leland Olds Station impose direct and indirect impacts on the environment. The most pronounced environmental impact expected from operation of any of the NO_X control options considered is the reduction of ozone and improvement in atmospheric visibility (i.e. reduced visibility impairment) downwind of the facility. This is discussed in detail in the Visibility Impacts section for LOS Unit 2.

2.5.3.1 ENVIRONMENTAL IMPACTS OF SOFA

The amount of unburned carbon in the flyash produced by the boiler, collected for disposal or potentially emitted to the atmosphere, may increase by small increments due to operation of LOS Unit 2 using separated overfire air for NO_X emissions control. The potential changes in the annual amounts of flyash emissions and disposal rates are expected to be inconsequential, and have not been quantified.

The operation of an advanced form of separated overfire air system is expected to slightly increase carbon monoxide concentrations in the stack flue gas. This potential air emission increase does not qualify as a non-air environmental impact evaluated for the BART impact analysis, and therefore has not been quantified.

There were no other adverse or significant changes in non-air quality environmental impacts identified for LOS Unit 2 as a result of using separated overfire air for NO_X emissions control.

2.5.3.2 ENVIRONMENTAL IMPACTS OF SNCR ALTERNATIVES

The operation of a conventional SNCR system is not expected to significantly impact emissions of CO or volatile organic compounds (VOCs). The chemical form of the reagent will affect the amount of carbon dioxide emitted, since urea contains CO which is readily converted to CO_2 in the boiler-furnace and convection sections by combining with available free oxygen. One mole of carbon dioxide (CO_2) will be created and emitted for every mole of urea injected for reaction with NO_X. This is a relatively small increase in the total amount of CO_2 produced as part of the combustion of carbon-based fossil fuel in the form of lignite. As CO_2 is not currently a regulated pollutant, this increase has not been calculated.

Operation of an SNCR-related system will normally create a small amount of unreacted urea or ammonia to be emitted. The amount of ammonia slip produced by SNCR, with or without RRI, depends on the amount of reagent utilization and location of the injection points. Rich Reagent Injection operation typically does not produce any significant amount of ammonia slip, as the remainder of the reagent not reacted with NO_X is usually oxidized prior to leaving the boiler. Higher

SNCR NO_X reduction performance involves greater amounts of reagent usage and ammonia slip. This is typically controlled to less than 10 ppmvd, especially since the possible formation of sulfates such as ammonium sulfate [$(NH_4)_2SO_4$] and ammonium bisulfate [NH_4HSO_4] will be more problematic at higher slip levels. Sulfur trioxide (SO_3) formed during combustion in the boiler can combine with ammonia during passage through the flue gas ductwork to form the sulfates.

Some of the unreacted ammonia from SNCR operation will be collected with the flyash in the electrostatic precipitator. Any remaining ammonia slip that is not collected or condensed in the air pollution control system will be emitted from the stack as an aerosol or condensable particulate. This has the potential to increase atmospheric visibility impairment downwind of the facility compared with a pristine condition. Although the predicted amount of such potential impact from ammonia slip emissions has not been determined, it is expected to be small in comparison with the significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NO_X emission reductions from the use of SNCR-related alternatives.

Storage of urea or ammonia reagent on-site creates the potential for accidents, leaks, and subsequent releases to air, ground, and surface water immediately surrounding the facility. Regulation of storage and containment of such reagents as hazardous substances will be under the requirements of various federal Acts, which are not part of this BART impact analysis.

Visibility impairment improvement impacts are discussed in the next section.

2.5.4 VISIBLITY IMPAIRMENT IMPACTS OF LELAND OLDS STATION NO_X CONTROLS – UNIT 2

The fifth step in a BART analysis is to conduct a visibility improvement determination for the source. For this BART analysis, there were two baseline NO_X emission rates assumed for LOS Unit 2 – one for the historic pre-control NO_X emission rate listed in the NDDH BART protocol[3], and one applying the Potential-To-Emit (PTE) pre-control annual NO_X emission rate associated with the future PTE case. The historic pre-control emission baseline was the 24-hour average NO_X emission rate from the highest emitting day of the years 2000-2002 (meteorological period modeled per the NDDH protocol[3]). The historic (protocol) NO_X baseline condition emission rate was modeled simultaneously with the highest 24-hour average SO_2 emission rate, and the highest 24-hour average PM emission rate of the 2000-2002 time period. The historic (protocol) baseline hourly NO_X emission rate used for modeling visibility impacts due to LOS Unit 2 under the conditions stated above was 3,959 lb/hr.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from historic (protocol) pre-control baseline and post-control average hourly emission rates representing the visibility impairment impact reduction for LOS Unit 2. Three post-control CALPUFF model runs for LOS Unit 2 were conducted with the same presumptive BART SO_2 emission baseline rate of 95%, constant PM emissions, and various levels of NO_X control assuming the same boiler design rating for heat input (5,130 mmBtu/hr). For the three post-control alternatives representing LOS Unit 2 PTE annual emissions associated with the future PTE case, the model used average unit NO_X emission rates of 0.48, 0.304, and 0.265 lb/mmBtu (corresponding to the design parameter in Table 1.2-1 and control rates in Table 1.4-1) multiplied by the boiler heat input rating of 5,130 mmBtu/hr to yield average hourly NO_X emission rates 2,462, 1,560, and 1,360 lb/hr. The boiler heat input basis for LOS Unit 2's historic highest 24-hour pre-control NO_X emission baseline, in keeping with the NDDH BART visibility impairment impact modeling protocol, is different than assumed for the PTE annual post-control conditions of the NO_X control alternatives evaluated for visibility impairment impacts.

The results of the visibility impairment modeling at the historic pre-control (protocol) baseline NO_X emission rate for LOS Unit 2 showed that all four of the designated Class 1 areas exceeded 0.5 deciView for highest predicted visibility impairment impact (90th percentile, averaged for 2000-2002). Lostwood National Wildlife Refuge (LNWR) showed the biggest predicted visibility impairment impact, which averaged 0.98 dV for the three years modeled (2000-2002). Average predicted visibility impairment impacts decreased significantly with presumptive BART SO_2 emission rate combined with constant PM emissions and various post-control ASOFA-enhanced NO_X emission rates for LOS Unit 2. This is shown in Table 2.5-10.

TABLE 2.5-10 – Average Visibility Impairment Impacts from Emission Controls – LOS Unit 2

Federal Class 1 Area	Visibility Impairment Impacts(1) (deciView)			
	Historic Pre-Control Baseline	PTE Emissions, ASOFA(2)	PTE Emissions, SNCR w/ ASOFA(2)	PTE Emissions, RRI+SNCR w/ ASOFA(2)
TRNP-South Unit	0.807	0.221	0.158	0.143
TRNP-North Unit	0.756	0.180	0.139	0.129
TRNP-Elkhorn Ranch	0.535	0.120	0.093	0.087
Lostwood NWR	0.979	0.285	0.206	0.191

(1) - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - SO_2 emissions reduction by 95% over pre-control PTE heat input baseline for the future PTE case. This case assumes existing ESP for PM collection.

Analysis of the reduction in visibility impairment impact included a comparison of the emission controls' effectiveness of reducing predicted visibility impairment impacts for the conditions of the future PTE case operation of LOS Unit 2 versus the historic pre-control (protocol) baseline that was modeled. LNWR again showed the highest average predicted visibility impairment impact reduction resulting from LOS Unit 2 emissions controls during PTE (future PTE case) heat inputs versus historic pre-control baseline emissions. These comparisons are shown in Table 2.5-11.

TABLE 2.5-11 –Average Visibility Impairment Impact Reductions From Emission Controls – LOS Unit 2 (vs Historic Maximum 24-Hour Average Hourly Emission Baseline)

Federal Class 1 Area	Visibility Impairment Reductions(1) (deciView)		
	PTE Emissions, ASOFA(2)	PTE Emissions, SNCR w/ ASOFA(2)	PTE Emissions, RRI+SNCR w/ ASOFA(2)
TRNP-South Unit	0.586	0.649	0.664
TRNP-North Unit	0.577	0.617	0.628
TRNP-Elkhorn Ranch	0.415	0.441	0.447
Lostwood NWR	0.694	0.773	0.788

(1) - Difference of average 90th percentile predicted post-control visibility impairment impact versus historic pre-control (protocol) baseline visibility impairment impact. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - SO_2 emissions reduction by 95% over pre-control PTE heat input baseline for the future PTE case. This case assumes existing ESP for PM collection.

The comparison in Table 2.5-12 shows the reduction of average visibility impairment impact from LOS Unit 2 NO_X emissions expected to result from ASOFA combined with SNCR with and without RRI relative to the average visibility impairment impact from post-control ASOFA NO_X emission rates applied to LOS Unit 2.

TABLE 2.5-12 – Incremental Average Visibility Impairment Reductions from NO_X Controls – LOS Unit 2 (vs ASOFA Post-Control PTE Emission Visibility Impairment Impact)

Federal Class 1 Area	Incremental Visibility Impairment Impact Reductions, from NO_X Emission Controls(1)	
	PTE Emissions, SNCR w/ ASOFA (dV)	PTE Emissions, RRI+SNCR w/ ASOFA (dV)
TRNP-South Unit	0.063	0.078
TRNP-North Unit	0.040	0.051
TRNP-Elkhorn Ranch	0.027	0.033
Lostwood NWR	0.079	0.094

(1) - Incremental average 90th percentile predicted post-control visibility impairment impact, compared to ASOFA for NO_X control with 95% SO_2 emissions control and existing ESP for PM emissions control at PTE heat input rate (future PTE case). A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

This analysis included a determination of the cost-effectiveness of reducing predicted visibility impairment impact for a particular NO_X emission rate associated with the control alternatives evaluated on LOS Unit 2. The basis of comparison was the average predicted visibility impairment impact and estimated levelized total annual cost (LTAC) for the advanced form of separated overfire air (ASOFA) alone under the future PTE case conditions. The estimated additional annualized costs of installing and operating each NO_X control alternative with PTE heat input (future PTE case) relative to the LTAC from post-control ASOFA NO_X emission rates applied to LOS Unit 2 are shown in Table 2.5-13.

TABLE 2.5-13 – LTAC for NO_X Controls – LOS Unit 2 (vs ASOFA Post-Control PTE Emission LTAC)

Incremental LTAC Change for NO_X Emission Reduction(1)	
PTE Emissions, SNCR w/ ASOFA ($/yr)	**PTE Emissions, RRI+SNCR w/ ASOFA ($/yr)**
8,250,000	13,820,000

1 - Incremental Levelized Total Annual Cost for NO_X control alternatives compared to ASOFA for PTE heat input rate (future PTE case). All cost figures in 2005 dollars. See Table 2.5-8 for details.

The comparison in Table 2.5-14 shows that the additional annualized costs of installing and operating each NO_X control alternative with PTE heat input (future PTE case) divided by the additional average predicted visibility impairment impact reduction relative to the post-control ASOFA NO_X emission rates and LTAC applied to LOS Unit 2 would result in hundreds of millions of dollars per deciview of control cost visibility impairment impact effectiveness.

TABLE 2.5-14 – Cost Effectiveness for Incremental Average Visibility Impairment Reductions from NO_X Controls – LOS Unit 2 (vs ASOFA Post-Control PTE Emission LTAC and Visibility Impacts)

	Incremental Visibility Impairment Reduction Unit Cost, from NO_X Emission Controls(1)	
Federal Class 1 Area	**PTE Emissions, SNCR w/ ASOFA ($/deciView-yr)**	**PTE Emissions, RRI+SNCR w/ ASOFA ($/deciView-yr)**
TRNP-South Unit	131,700,000	177,900,000
TRNP-North Unit	204,600,000	271,000,000
TRNP-Elkhorn Ranch	309,000,000	423,000,000
Lostwood NWR	104,900,000	147,500,000

(1) - Incremental Levelized Total Annual Cost divided by incremental average 90th percentile predicted post-control visibility impairment impact, compared to ASOFA for NO_X control with 95% SO_2 emissions control and existing ESP for PM emissions control at PTE heat input rate (future PTE case). All cost figures in 2005 dollars.

The number of days predicted to have visibility impairment due to LOS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the historic pre-control (protocol) NO_X, SO_2, and PM emission rates described previously in this Section. The results were summarized and presented in Table 3.4-15. Similarly, the same information for the post-control SO_2 and PM alternatives with presumptive BART NO_X PTE emission rates was summarized and is shown in Table 3.5-16. The differences in average visibility impairment impact and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between post-control SO_2 and PM alternatives with SNCR with ASOFA-controlled and RRI+ SNCR with ASOFA-controlled NO_X emission rates versus ASOFA-controlled NO_X emission rates are summarized and shown in Table 2.5-15.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 area. The highest number of days in which the predicted visibility impairment impact above background exceeded 0.5 deciViews was for the pre-control (protocol) emission case in year 2002 for TRNP's South Unit. A series of bar charts showing the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the pre-control model results is included in Section 3.5. The pair of post-control SO_2 and PM alternatives combined with SNCR with ASOFA or RRI+SNCR with ASOFA for NO_X control were only slightly lower for the predicted visibility impairment impacts and number of days predicted to have visibility impairment impacts greater than 0.50 and 1.00 deciViews compared to the same pair of post-control SO_2 and PM conditions with ASOFA-controlled NO_X emission rates. A series of bar charts showing the difference in the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the RRI+SNCR with ASOFA-controlled PTE emission rates and SNCR with ASOFA-controlled PTE emission rates compared to ASOFA NO_X PTE emission rates with post-control SO_2 and PM alternatives is included in Figures 2.5-5, 2.5-6, and 2.5-7.

2.5.5 SUMMARY OF IMPACTS OF LELAND OLDS STATION NO_X CONTROLS – UNIT 2

Table 2.5-16 summarizes the various quantifiable impacts discussed in Sections 2.5.1 through 2.5.4 for the NO_X control alternatives evaluated for LOS Unit 2.

Table 2.5-15 – Visibility Impairment Improvements – Post Control vs ASOFA NO_X Control with SO_2 and PM Controls LOS Unit 2

Class 1 Area	NO_X Control Technique w/ SO_2 Control Level(1)	Visibility Impairment Reduction(2) (ΔdV)	ΔDays(3) Exceeding 0.5 dV in 2000	ΔDays(3) Exceeding 0.5 dV in 2001	ΔDays(3) Exceeding 0.5 dV in 2002	ΔDays(3) Exceeding 1.0 dV in 2000	ΔDays(3) Exceeding 1.0 dV in 2001	ΔDays(3) Exceeding 1.0 dV in 2002	ΔConsecutive Days(3) Exceeding 0.5 dV 2000	ΔConsecutive Days(3) Exceeding 0.5 dV 2001	ΔConsecutive Days(3) Exceeding 0.5 dV 2002
TRNP South	RRI+SNCR w/ ASOFA	0.078	4	8	9	2	2	8	0	1	0
	SNCR w/ ASOFA	0.063	3	7	6	2	2	7	0	1	0
TRNP North	RRI+SNCR w/ ASOFA	0.051	6	8	4	2	2	8	0	0	0
	SNCR w/ ASOFA	0.040	4	6	4	2	2	6	0	0	0
TRNP Elkhorn	RRI+SNCR w/ ASOFA	0.033	2	3	3	0	1	2	0	1	0
	SNCR w/ ASOFA	0.027	2	2	3	0	1	2	0	1	0
Lostwood NWR	RRI+SNCR w/ ASOFA	0.094	12	10	6	5	7	2	0	0	1
	SNCR w/ ASOFA	0.079	9	6	6	5	5	2	0	0	1

(1) - SO_2 emissions reduction by 95% over pre-control PTE heat input baseline for the future PTE case. This case assumes existing ESP for PM collection. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - Difference in average predicted visibility impairment impacts (90th percentile) for 2000-2002 for alternatives' post-control NO_X emission levels versus ASOFA-controlled NO_X emission level with same PTE heat input SO_2 and PM post-control alternatives' emission rate (future PTE case).

(3) - Difference in number of days is 100th percentile level for predicted visibility impairment impacts provided in Appendix D1.

3.0 SO_2 BART EVALUATION

The BART determination process has five predefined steps as described in Section 1. In this section, steps 1 through 5 of the BART determination for Leland Olds Station (LOS) are described for SO_2 and a presentation is made of the results. Potentially applicable SO_2 control technologies are first identified. A brief description of the processes and their capabilities are then reviewed for availability and feasibility. A detailed technical description of each control technology is provided in Appendix B1. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to nominal SO_2 control capability. The impacts analysis then reviews the estimated capital and O&M costs for each alternative, including taking a look at Balance Of Plant (BOP) requirements. Following the cost determination, the energy impacts and non-air quality impacts are reviewed for each technology. The impact based on the remaining useful life of the source is reviewed as part of the cost analysis. In the final step of the analysis, feasible and available technologies are assessed for their potential visibility impairment impact reduction capability via visibility modeling results. The results of the impact analyses are tabulated and potential BART control options are listed.

3.1 IDENTIFICATION OF RETROFIT SO_2 CONTROL TECHNOLOGIES

The initial step in the BART determination is the identification of retrofit SO_2 control technologies. In order to identify the applicable SO_2 control technologies, several reference works were consulted, including "Controlling SO_2 Emissions: A Review of Technologies (EPA-600/R-00-093, October 2000) and the RACT/BACT/LAER Clearinghouse (RLBC). From these and other literature sources, a preliminary list of control technologies and their estimated capabilities was developed. Table 3.1-1 contains the results of this effort.

TABLE 3.1-1 – SO_2 Control Technologies Identified for BART Analysis

Control Technology	Approximate Control Efficiency
Fuel Switching	≤77%
Coal Cleaning	≤30%
Wet Flue Gas Desulfurization	95%
Spray Dryer Absorber (SDA)	90%
Circulating Dry Scrubber (CDS)	93%
Flash Dryer Absorber (FDA)	90%
Powerspan ECO™	98%

SO_2 emissions from the combustion of coal are due to the sulfur content of the coal participating in the combustion process. Sulfur is present in coal in both organic and inorganic forms. Upon combustion, these compounds disassociate and the sulfur component is oxidized to SO_2 and SO_3. For the purpose of BART determination, it is assumed that 100% of the sulfur content of the coal is oxidized and present in the flue gas stream as SO_2. Removal of SO_2 from flue gas can either be accomplished prior to combustion, or post combustion. Pre-combustion methods include coal washing and fuel switching. Post-combustion methods include wet Flue Gas Desulfurization (FGD) with limestone and three semi-dry FGD technologies using lime. Additionally, there are developing multi-pollutant technologies such as the PowerSpan Electro-Catalytic Oxidation (ECO™) system which targets SO_2, NO_X, and mercury. Following are descriptions and technical analyses of the identified technologies for application to LOS.

3.2 TECHNICAL DESCRIPTION AND FEASIBLITY ANALYSIS

The second step in the BART analysis procedure is a technical feasibility analysis of the options identified in Step 1. The BART guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology. A control technology is considered available, “if it has reached the stage of licensing and commercial availability.” (70 FR 39165) On the contrary, a control technology is not considered available, “if it is in the pilot scale testing stages of development.” (70 FR 39165) When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” (70 FR 39165) The technical and feasibility analysis is presented below for each identified option.

3.2.1 PRE-COMBUSTION FUEL TREATMENTS

3.2.1.1 FUEL SWITCHING

Fuel switching can be a viable method of fuel sulfur content reduction in certain situations. Often, fossil fuel fired EGUs are constructed to take maximum advantage of the particular combustion characteristics of a specific fuel. In the case of LOS, both boilers were designed and constructed specifically for firing North Dakota lignite, which is a low Btu content, high ash, high moisture, medium sulfur content fuel. For this analysis, fuel switching would consist of changing from North Dakota lignite to Powder River Basin (PRB) sub-bituminous coal. Technical characteristics associated with fuel switching are described in Appendix B1.

Basin Electric Power Cooperative conducted a short term test burn of PRB coal at LOS Unit 1 and 2 on February 5-12, 1997.[1] An analysis of this coal is provided in Table 1.2-2. Approximately 50,000 tons of PRB were burned during the test. Approximately one half of the test period was at high load conditions and the remainder at low load. Because the test period was short, the long term effects of a PRB coal conversion were not evaluated. However, several short term effects were observed including the following:

- Coal delivery problems related to delivery train length were observed and rail system modifications would be required for a complete conversion.
- Little risk of coal fires in the coal receiving and handling systems were encountered, or expected for long term conversion. However, additional coal fire suppression systems would likely be required for the coal bunkers as a safety precaution.
- Due to the greater heat content, a 20% reduction in fuel quantity (mass) was observed. Operating requirements, including fuel handling system power and maintenance were estimated to decrease 15% during the test period.
- Coal dust generation was observed to increase with PRB coal, which may necessitate additional dust control measures on coal handling equipment.
- Reduced ash quantities were observed during the tests, but not quantified. Minor adjustments to the ash handling systems were required to achieve satisfactory operation.
- Stack opacity conditions were stable, but were observed to deteriorate somewhat during the high load portion of the test, despite lower ash quantities. The cause of this was thought to be higher ash resistivity effects on electrostatic precipitator performance. Flue gas conditioning might be required for a full conversion to mitigate this effect.
- Air heater performance decreased, most likely due to reduced flue gas flow rates. While firing PRB total flue gas flow dropped approximately 15% on Unit 1. A similar reduction in flue gas flow was not observed on Unit 2.
- Induced Draft and Forced Draft fan power requirements decreased slightly during all parts of the test burn. Total air required for PRB coal was approximately 88% of that required for lignite under the same conditions. Specifically for Unit 1, current draw (amps) on the forced draft fan remained unchanged while the primary air and induced draft fan current demands decreased approximately 11%.
- On Unit 2, Gas Recirculation fan power requirements increased by approximately 4% during high load tests and almost 31% during low load testing.

- Boiler efficiency increased approximately 2.4%, primarily due to lower fuel moisture content in the as-received condition. As a result the Net Plant Heat Rate decreased by approximately 300 Btu/kW for Unit 1 and 350 Btu/kW for Unit 2.
- Station service requirements decreased approximately 2% with PRB coal. This was primarily attributed to lower combustion air requirements.
- Stable operating conditions, observed as similar main and reheat steam temperatures and attemperator flows, were observed at both high and low loads.
- Due to the test's brevity, it was not possible to observe changes in slag deposition locations or rates and possible effects on boiler operation.
- During an URGE (Uniform Rating of Generating Equipment) test for Unit 2, the unit became unstable and the test had to be discontinued. The URGE test is a test at maximum operating conditions.

Switching to a fuel such as PRB coal will achieve significant SO_2 emission reductions. The PRB coal listed in Table 1.2-2 is one of the lower sulfur coals available in the U.S. Switching to this coal would nominally achieve a 77% reduction in SO_2 emissions for the same heat input. However, additional SO_2 control measures, such as the post combustion controls listed in Table 3.1-1 might be required to achieve BART.

As shown during the short test in 1997, conversion of LOS to fire PRB coal is feasible, although several long term effects were not assessed during the test and some currently unidentified plant modifications may be required for a full conversion. Therefore, for the purpose of this BART analysis, fuel switching is considered a viable option for SO_2 control.

3.2.1.2 COAL CLEANING

The effectiveness of coal cleaning is strongly dependent upon the chemical form of sulfur in the coal. Traditional coal cleaning methods consist of crushing the coal and then separating and removing inorganic impurities including much of the inorganic sulfur and ash content using a gravimetric separation process. However, sometimes the majority of the sulfur is contained in the organic matrix of the coal and is difficult or impossible to remove using this process. While gravimetric processes can reduce the sulfur and ash content of a given coal, at the time of this report, no commercial scale, gravimetric coal cleaning systems are in operation that can significantly reduce the sulfur content of North Dakota lignite. Due to lack of commercial experience, traditional coal cleaning systems were determined not to be commercially available as a BART alternative and were not analyzed further.

Another form of coal cleaning that specifically targets low-rank coals, like lignite, uses a different process to reduce sulfur emissions. The K-Fuel™ process, developed by KFx, uses patented heating and pressurization methods to reduce the moisture content of the fuel and remove some of the pollutants. Although the process may remove some of the sulfur components in the coal, the main focus of the process is to remove moisture and increase the coal heating value. By increasing the coal heating value, less of the treated fuel will be required to achieve an equivalent boiler heat input. By burning less fuel there will be fewer emissions. KFx estimates that the K-Fuel™ coal cleaning process might effectively reduce the sulfur content of the lignite fuel by up to 30%. To simplify cost estimates associated with coal cleaning and due to the uncertainties associated with application of the K-Fuel™ process to North Dakota lignite, the analysis assumes that stated efficiencies translate directly to operations. In other words, a 30% reduction efficiency for sulfur content results in a 30% reduction in SO_2 and a 30% increase in heat content results in a 30% decrease in fuel usage. A test burn, which would be required to provide more specific data related to burning the K-Fuel™ product, was not available. Technical characteristics associated with the process can be found on the KFx website at kfx.com. Based on the estimated 30% control being significantly less efficient than the presumptive limits and the control efficiencies of the other control technologies, the K-Fuel™ process was identified as having insufficient SO_2 reduction for BART. Due to the lower removal efficiency, the K-Fuel™ process is not considered a reasonable BART alternative and is not analyzed further.

3.2.2 POST-COMBUSTION FLUE GAS DESULFURIZATION

Five different post-combustion processes for reducing SO_2 emissions were evaluated as BART alternatives in this analysis. These include two well established Flue Gas Desulfurization (FGD) processes (wet and semi-dry); two recent variations of the semi-dry technology, the Circulating Dry Scrubber (CDS) and the Flash Dryer Absorber™ (FDA) as well as the Power-Span Electro Catalytic Oxidation (ECO™) process.

Commercially-available wet and semi-dry FGD processes achieve SO_2 removal by absorption of the SO_2 into an aqueous slurry which contains a neutralizing agent, normally either lime or ground limestone. Chemical reaction(s) between the SO_2 and the neutralizing agent convert the SO_2 to a stable compound that can be readily sold or disposed of in a permitted facility.

One significant difference between the wet and semi-dry systems is the degree of saturation of the flue gas that is achieved in the process. The wet FGD process saturates the flue gas as a result of water evaporation from the slurry utilized to absorb and neutralize SO_2. Wet FGD process design must take into account both corrosion and scale formation in the wet parts of the system which can interfere with process operations. The flue gas saturation zone, where the hot dry flue gas first enters the absorber vessel and encounters the wet FGD slurry spray, is an area of constantly shifting chemistry. With the shifting back and forth between hot, dry conditions and cooler, wet conditions, this area experiences the most aggressive corrosion of any part of the scrubbing system. Consequently, exotic materials of construction are used in the wet FGD system to combat the corrosive environment.

The semi-dry FGD process utilizing a spray dryer absorber (SDA) utilizes an aqueous slurry as well, but the degree of flue gas saturation due to evaporation is controlled to a point well above the saturation temperature so that the semi-dry FGD byproducts are a dry free flowing solid leaving the absorber and corrosion problems are minimized. CDS' and FDAs operate similarly to the SDA, except that they utilize greater amounts of recycled flyash mixed with dry hydrated lime that is moistened by water and injected into the reactor. Here the moisture coats the surface of the recycled particles in a thin film and then the water evaporates, as opposed to evaporating an entire droplet of water containing lime slurry as in the SDA. The water content of the slurry droplet or liquid film evaporates and SO_2 is absorbed and neutralized simultaneously. All of the dry and semi-dry FGD technologies require a particulate matter control device downstream of the reactor. Therefore, these technologies are often referred to in this report with a /FF following the absorber designation. The reaction products of the semi-dry FGD processes, including the SDA, CDS and FDA, are mixed with flyash when captured, and thus not do not generally have an aftermarket value.

The most common chemical reagents used in FGD processes are quicklime (calcium oxide, CaO), hydrated lime (calcium hydroxide, $Ca(OH)_2$) and limestone (predominantly calcium carbonate, $CaCO_3$). As a general rule of thumb, wet FGD processes can be assumed to utilize limestone and semi-dry FGD, including SDA, CDS and FDA systems, use lime. There are wet FGD processes that utilize lime, but these are generally used in situations where limestone is not readily available and these incur greater operating costs as a result. Dry and semi-dry FGD systems exclusively utilize lime because of its greater reactivity under typical dry and semi-dry operating conditions.

The wet FGD process was exclusively used for FGD retrofits for compliance with Phase I of the Acid Rain Program. The semi-dry process is a common SO_2 control measure identified in the review of recent new coal-fired boiler BACT determinations from the EPA's RACT/BACT/LAER

Clearinghouse (RBLC). The FDA and CDS technologies are more recent developments in semi-dry FGD technology.

3.2.2.1 WET FLUE GAS DESULFURIZATION

Wet FGD technology utilizing lime or limestone as the reagent and employing forced oxidation to produce gypsum (calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$) as the byproduct, is commonly applied to coal-fired boilers. Wet FGD utilizes either an open spray tower, or a spray tower with a perforated plate contactor to expose flue gas to the neutralizing slurry. Absorbed SO_2 is converted to calcium sulfite and then oxidized to calcium sulfate dihydrate (gypsum) which is filtered from the scrubber solution and either disposed of in a permitted disposal facility, or possibly sold for either wallboard or cement production. Historically wet FGD systems have operated with an SO_2 control efficiency anywhere from 70% to in excess of 95%. For the purposes of this study, wet FGD performance was evaluated at 95% SO_2 control as representative of presumptive BART requirements. Further technical characteristics associated with wet FGD are described in Appendix B.

Based on the ability of a wet FGD system to achieve 95% percent SO_2 removal efficiencies and commercial availability and applicability, wet FGD systems were found to be an acceptable BART alternative for SO_2 emission control.

3.2.2.2 SEMI-DRY FLUE GAS DESULFURIZATION

As an alternative to wet FGD technology, the control of SO_2 emissions can be accomplished using semi-dry FGD technology. The most common semi-dry FGD system is the lime Spray Dryer Absorber (SDA) using a fabric filter for downstream particulate collection.

There are several variations of the semi-dry process in use today. This section addresses the spray dryer FGD process. Two other variations, the Flash Dryer Absorber and Circulating Dry Scrubber are addressed in following sections. They primarily differ by the type of reactor vessel used, the method in which water and lime are introduced into the reactor and the degree of solids recycling. Technical characteristics associated with the SDA are described in Appendix B.

No variation of semi-dry FGD systems has clearly demonstrated the ability to achieve SO_2 removal levels similar to wet FGD systems in the U.S. Table B-1, in Appendix B, lists many of the recent lime spray dryer system installations in the U.S. The information in Table B-1 was obtained from the RACT/BACT/LAER Clearing House. Two units were recently permitted with SO_2 emission rates representing removal efficiencies of 94.5% and 95%. However, Burns & McDonnell recently completed a study of the emission reduction performance of existing, electric utility, semi-dry FGD systems.[3] Information utilized for the evaluation was derived from EIA coal quality data and EPA SO_2 stack emissions and heat input data. The evaluation determined that the highest SO_2 removal efficiency maintained on a continuous basis was just above 90%. No unit was able to maintain an efficiency of 95%. For the purpose of this BART determination, semi-dry FGD is considered a viable alternative, but the upper bound on SO_2 removal efficiency was set at 90% for application based on a review of the historic performance of this technology.

3.2.2.3 FLASH DRYER ABSORBER FLUE GAS DESULFURIZATION

The Flash Dryer Absorber (FDA) is a further development of the semi-dry FGD process. The approach is similar to the SDA in that the flue gas is only partially saturated during the process and thus corrosion problems are either reduced or eliminated. Like the SDA, the FDA mixes lime, water and recycled PM for enhanced surface area. Unlike the SDA, the FDA recycles a very high fraction of the captured PM and the flue gas flows vertically upward in the FDA. A second difference for the FDA is that it utilizes quicklime, instead of hydrated lime as a reagent. Additional technical characteristics associated with FDA are described in Appendix B.

The FDA is a relatively recent modification of the semi-dry FGD concept and as such, has not established a significant field record at this time. In their paper on FDA technology in 2002[4], Alstom cited a 280 MW plant in China with an 85% SO_2 removal efficiency. In its review of a recent Alstom proposal for a project involving an FDA downstream of a CFB boiler with limestone injection, Burns & McDonnell noted that the FDA mass balance included in the bid package indicated approximately 78% of the overall SO_2 removal occurred in the boiler. The FDA/FF combination on that project was guaranteed to achieve 75% SO_2 removal, but started with a significantly lower inlet SO_2 concentration that directly affects removal efficiency. Contrary to the lower emission rates presented in this section, the FDA has been shown to be similar in SO_2 removal performance to the SDA and thus was determined to be a feasible SO_2 control alternative for LOS.

3.2.2.4 CIRCULATING DRY SCRUBBER FLUE GAS DESULFURIZATION

In the circulating dry scrubbing process, the flue gas is introduced into the bottom of a reactor vessel at high velocity through a venturi nozzle, and mixed with water, hydrated lime, recycled flyash and FGD reaction products. A CDS absorber vessel for either LOS unit would be a smaller diameter than the SDA discussed previously in this report. Particles that are entrained in the flue gas leaving the top of the reactor are collected in an ESP or fabric filter downstream of the CDS absorber. A large portion of the collected particles is recycled to the reactor to sustain the bed and improve lime utilization. CDS absorbers have been installed with both fabric filters and ESPs for particulate control. Additional technical characteristics associated with CDS are described in Appendix B.

For the purpose of this analysis, the CDS technology is evaluated with a maximum SO_2 removal efficiency of 93% with a reagent utilization ratio approximately 10% greater than that of a similar SDA. The CDS was considered a feasible SO_2 control technology for the purpose of this study.

3.2.2.5 POWERSPAN ELECTRO-CATALYTIC OXIDATION (ECO™) TECHNOLOGY

The Powerspan Electro-Catalytic Oxidation (ECO™) system is a multipollutant control technology designed to control emissions of NO_X, SO_2, fine particulate, mercury and certain Hazardous Air Pollutants (HAPs). The ECO™ process has two main process vessels; a barrier discharge reactor and a multi-level wet scrubber. Additional technical characteristics associated with the ECO™ process are described in Appendix B.

Powerspan claims a routine SO_2 removal efficiency of 98% with inlet concentrations up to approximately 2,000 ppm and testing at a pilot plant has demonstrated performance, reliability and economics. However, no full size commercial scale ECO™ systems have been installed or are operating at the time of this report. The ECO system was determined not to be a feasible BART alternative because it is not commercially available.

3.2.3 RESULTS OF FEASIBILITY ANALYSIS

The evaluations of the identified BART alternatives following the feasibility analysis are summarized in Table 3.2-1.

TABLE 3.2-1 – BART SO_2 Control Feasibility Analysis Results

Control Technology	In service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable To Leland Olds Station
Fuel Switching	Yes	Yes	Yes	Yes
Coal Cleaning	No	Yes	Yes	No
Wet FGD	Yes	Yes	Yes	Yes
Lime Spray Dryer	Yes	Yes	Yes	Yes
Circulating Dry Scrubber	Yes	Yes	Yes	Yes
Flash Dryer Absorber	Yes	No	Yes	Yes
Powerspan ECO™	No	No	No	Yes

3.3 EVALUATE TECHNICALLY FEASIBILE SO_2 CONTROL OPTIONS BY EFFECTIVENESS

The third step in the BART analysis procedure is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the BART analysis, the control efficiency was reviewed and presented as part of the technical description for each technology. The evaluations of the remaining BART alternatives following the feasibility analysis are summarized in Table 3.3-1. The alternatives are ranked in descending order according to their effectiveness in SO_2 control.

TABLE 3.3-1 – SO_2 Control Technologies Identified for BART Analysis

Control Technology	Control Efficiency
Wet Limestone Flue Gas Desulfurization	95%
Circulating Dry Scrubber (CDS)	93%
Spray Dryer Absorber (SDA)	90%
Flash Dryer Absorber (FDA)	90%
Fuel Switching	$\leq$77%

3.4 EVALUATION OF IMPACTS FOR FEASIBLE SO_2 CONTROLS – UNIT 1

Step four in the BART analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) lists four factors to be considered in the impact analysis.

- The costs of compliance;

- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four impacts required by the BART Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the BART determination for LOS. In addition, as described in Section 1.1.6, the visibility impairment impact of each alternative was evaluated as part of the impact analysis.

3.4.1 COST ESTIMATES

Cost estimates for the wet and semi-dry (including SDA and fabric filter) SO_2 control technologies were completed utilizing the Coal Utility Environmental Cost (CUECost) computer model (Version 1.0) available from the U.S. Environmental Protection Agency. The CUECost model is a spreadsheet-based computer model that was specifically developed to estimate the cost of air pollution control technologies for utility power plants within +/- 30 percent accuracy. The EPA released the version of the model used for this study in February 2000. The model is available for download from the U.S. EPA website at www.epa.gov/ttn/catc/products.

The user must specify the design parameters for the air pollution control technologies in CUECost. Unit costs for consumables, labor, and other variables can be modified by the user to fit the specific situation under evaluation. Because these models are in spreadsheet form, the calculation procedures and assumptions can be readily determined and adjusted by the experienced user as necessary to fit the unique requirements of the evaluation being conducted. The program itself is also somewhat user adjustable to compensate for local conditions. The CUECost default case is a generic facility located in Pennsylvania. Burns & McDonnell has adjusted the CUECost spreadsheets as described in the following sections to account for known facility and local conditions. In addition, Burns & McDonnell has added the Balance of Plant (BOP) costs not included in CUECost to the base estimate to provide a more complete cost estimate.

Operating information utilized as input into the model for the purpose of cost estimating is listed in Tables 1.2-1 and 1.2-2. Economic information utilized as input into the model is given in Table 1.2-3. Economic information was provided in 2004 by BEPC in 2004 dollars. The model was run with

2004 designated as the cost basis year because equipment cost estimating in the model is based on the Chemical Engineering Cost Index and the composite 2004 index is the latest version available. Following completion of the estimating on a 2004 cost basis year, all costs were escalated to a 2005 basis year utilizing the inflation rates designated in Table 1.2-3.

The default General Facilities factor in CUECost is 10% of the direct costs. Because LOS is located in North Dakota where weather protection requirements are much greater than the default state of Pennsylvania, the General Facilities factor was increased to 15% to account for this additional cost.

The electrical subcontract in the BOP cost estimates includes the electrical equipment, materials and labor for engineering, procurement and installation of all electrical distribution system components for each alternative as required. The electrical estimate is based on recent experience with the LOS plant and local costs developed during a recent electrical upgrade project at LOS.

The foundation subcontract cost estimate for each alternative includes 80-foot deep piles and the necessary design and installation provisions for the high water table at the LOS plant site. The number of piles and the amount of concrete and steel required were developed from previous experience completing foundation designs for similar sized air pollution control equipment. The additional foundation subcontract was required because the generic capital cost information provided by CUECost is based on typical spread footing type foundations and does not include these extra provisions required for installation at LOS.

Capital costs for the additional alternatives were estimated from various literature sources and Burns & McDonnell's in-house experience and resources. Information from such sources was adjusted for known local conditions and BOP costs were added separately.

The indirect costs are estimates of additional costs expected to be incurred during a complete project. Engineering costs are estimated as a percentage of total direct costs and are representative of the cost for architectural/engineering services such as system design, specification production, contract evaluations and negotiations, contract administration and construction field services. The contingency is also a percent of the total direct costs and accounts for miscellaneous scope items not covered by the direct cost estimate. Finally, the BEPC indirect costs are an estimation of BEPC internal costs that would be incurred for the implementation of each alternative.

3.4.1.1 WET FGD CAPITAL COST ESTIMATE

The capital cost estimate for the wet FGD system includes the SO_2 control system, major support facilities and BOP costs. The SO_2 control system cost is representative of a typical furnish and erect contract by a wet FGD system supplier. The wet FGD system cost estimated by CUECost is broken down into the major subsystems of reagent preparation, SO_2 absorption tower, dewatering systems, flue gas handling systems (booster fans and ductwork) and support systems. BOP costs include a wet stack, make-up water treatment plant, electrical subcontract, foundations subcontract and repair/upgrade of the existing railroad tracks for limestone delivery. The results of the capital cost estimate are given in Table 3.4-1.

CUECost includes a cost estimate for a wet stack, but based upon Burns & McDonnell's recent experience with wet stack construction costs, this estimate was deleted from the CUECost results and a revised estimate by Burns & McDonnell was included in the BOP costs. The new stack estimate includes an alloy C-276 liner for the wet stack. The new wet stack was assumed to be 500' in height instead of the current 350' height of the existing LOS Unit 1 dry stack to prevent plume capture in building wakes.

The BOP costs include make-up water treatment equipment costs for pumps, piping, filters, and a clarifier. An estimated building cost for the makeup water treatment system is included in the Foundations Subcontract estimate.

Also included in the Foundations Subcontract cost estimate are roofed, two-walled enclosures for limestone and gypsum temporary storage to provide for weather protection.

An evaporation pond for disposal of periodic scrubber blowdown was included in the capital cost estimate.

Railroad delivery of limestone, utilizing the west spur crossing the main plant entrance road was assumed for the cost estimate. The railroad track estimate includes the cost of upgrading approximately 1,500 feet of railroad track to provide for limestone delivery to the LOS Unit 1 limestone railcar unloading station. The estimate also includes refurbishment of approximately 400 feet of track past the railcar unloading position for flexibility in car positioning.

TABLE 3.4-1 – Capital Cost Estimate for LOS Unit 1 Wet FGD System

DIRECT COSTS	**Estimated Cost ($2005)**	**General Facilities Markup (15%)**	**Total Direct Cost**
Reagent Prep System	$14,050,000	$2,110,000	$16,160,000
SO_2 Absorption System	$21,110,000	$3,170,000	$24,280,000
Flue Gas Handling System	$7,710,000	$1,160,000	$8,860,000
ByProduct Handling System	$1,740,000	$260,000	$2,000,000
Support Equipment	$2,210,000	$330,000	$2,540,000
		FGD Total Direct Cost =	**$53,840,000**
BOP COSTS			
Wet Stack	$7,490,000	NA	$7,490,000
Water Treatment Equipment	$840,000	NA	$840,000
Evaporation Pond	$930,000	NA	$930,000
Electrical Subcontract	$6,900,000	NA	$6,900,000
Ductwork	$3,430,000	NA	$3,430,000
Foundations Subcontract	$1,890,000	NA	$1,890,000
Railroad Upgrade/Repair	$300,000	NA	$300,000
		BOP Total Direct Cost =	**$21,780,000**
		Total Direct Cost =	**$75,620,000**
INDIRECT COSTS			
		Contingency (20% of DC)	$15,120,000
		A/E Engineering and Construction Management (10% of DC)	$7,430,000
		Allowance For Funds During Construction (AFDC 6%)	$4,540,000
BEPC INDIRECTS			
		Project Development (1% of DC)	$760,000
	Spare Parts & Plant Equipment		
		Rolling Stock	$500,000
		Initial Inventory Spare Parts (1.5% of DC)	$1,130,000
	Construction Startup and Support		
		O&M Staff Training (0.5% of DC)	$380,000
		Construction All-Risk Insurance (1.5% of DC)	$1,130,000
		Contingency (15% of BEPC Indirects)	$470,000
		Indirect Cost Subtotal	$31,600,000
		Total Capital Cost	**$107,220,000**

The total estimated capital cost estimate for a complete, stand-alone wet FGD system utilizing limestone reagent and forced oxidation is $107,220,000, or $487/kW for Unit 1.

3.4.1.2 CIRCULATING DRY SCRUBBER CAPITAL COST ESTIMATE

The Circulating Dry Scrubber (CDS) FGD technology is a relatively recent innovation in the United States, but has been used previously in Europe. Cost information on the CDS system is not as widely available as the more common wet and semi-dry systems. Capital costs for the CDS system were based on CUECost estimates for the SDA semi-dry FGD system with modifications to reflect the design and operational differences. Several literature sources[5, 6] and Burns & McDonnell in-house information were utilized in making these modifications. The CDS cost estimate is presented in a line item format with individual items adjusted to reflect differences between the CDS and SDA. The capital cost estimate is presented in Table 3.4-2.

The CDS absorber vessel is similar to the SDA, but smaller in diameter to provide for a greater gas velocity to make fluidized bed operation possible. The cost of the CDS absorber vessel was estimated at 80% of the cost of the SDA absorber vessel.

Because the CDS recirculates a much greater fraction of the flyash and absorber reaction products (80-95% vs. 30%) than the SDA, the byproduct handling system cost for the SDA was increased by 100% for the CDS estimate to account for the greater system capacity requirements.

The estimated cost for ancillary support equipment was also based on the SDA estimate from CUECost. The CUECost estimate for these systems for the SDA was increased by 10% to reflect the additional reagent usage and higher recycle flow rate.

The CUECost estimate for SDA flue gas handling systems was increased by 15% to account for the additional booster fan capacity required to accommodate the greater pressure drop of the CDS. Ductwork costs were assumed not to change due to the CDS configuration versus the SDA.

TABLE 3.4-2 – Capital Cost Estimate for LOS Unit 1 CDS FGD System

DIRECT COSTS	**Estimated Cost ($2005)**	**General Facilities Markup (15%)**	**Total Direct Cost**
CDS System			
Reagent Prep System	$12,830,000	$1,920,000	$14,750,000
SO_2 Absorption System	$9,140,000	$1,370,000	$10,510,000
Flue Gas Handling System	$7,000,000	$1,050,000	$8,040,000
ByProduct Handling System	$3,620,000	$540,000	$4,160,000
Support Equipment	$2,940,000	$440,000	$3,380,000
		CDS Total Direct Cost =	**$40,840,000**
Fabric Filter			
Fabric Filter Housing	$8,840,000	$1,330,000	$10,160,000
Bags	$1,290,000	$190,000	$1,480,000
Ash Handling System	$6,620,000	$990,000	$7,610,000
Instruments & Controls	$300,000	$40,000	$340,000
		Fabric Filter Total Direct Cost =	**$19,590,000**
BOP Costs			
Water Treatment Facility	$700,000	NA	$700,000
Electrical Subcontract	$6,900,000	NA	$6,900,000
Ductwork	$3,430,000	NA	$3,430,000
Foundations Subcontract	$1,790,000	NA	$1,790,000
Railroad Upgrade/Repair	$300,000	NA	$300,000
		BOP Total Direct Cost =	**$13,120,000**
		Total Direct Cost =	**$73,560,000**

INDIRECT COSTS	
Contingency (20% of DC)	$14,710,000
A/E Engineering and Construction Management (10% of DC)	$7,660,000
Allowance For Funds During Construction (AFDC 6%)	$4,600,000
BEPC INDIRECTS	
Project Development (1% of DC)	$740,000
Spare Parts & Plant Equipment	
Rolling Stock	$500,000
Initial Inventory Spare Parts (1.5% of DC)	$1,100,000
Plant Furnishings (0.5% of DC)	$370,000
Construction Startup and Support	
O&M Staff Training (0.5% of DC)	$370,000
Construction All-Risk Insurance (1.5% of DC)	$1,100,000
Contingency (15% of BEPC Indirects)	$570,000
Indirect Cost Subtotal	$31,230,000
Total Capital Cost	**$104,790,000**

Because the CDS recirculates a much greater fraction of flyash and absorber reaction products than the SDA, the estimated cost for the ash handling system was increased 25% over the CUECost estimate for the SDA. In the same manner, the estimated ash handling system and instrumentation and control costs were increased to reflect additional capacity requirements.

A new stack was not included in the BOP capital cost estimate. It was assumed that the CDS facility would be located on the west side of the plant near Unit 1 and that the existing stack could be reused. Included in the Foundations Subcontract cost estimate is a silo for temporary storage of waste products prior to transport to the permitted waste disposal facility.

Railroad delivery of lime, utilizing the west spur crossing the main plant entrance road was assumed for the cost estimate. The railroad track estimate includes the cost of upgrading approximately 1,500 feet of railroad track to provide for lime delivery to the LOS Unit 1 railcar unloading station. The estimate includes refurbishment of approximately 400 feet of track past the railcar unloading position for flexibility in car positioning.

The total estimated capital cost estimate for a complete, stand-alone CDS with Fabric Filter for SO_2 control for LOS Unit 1, utilizing hydrated lime as a reagent is $104,790,000, or $476/kW.

3.4.1.3 SEMI-DRY FGD CAPITAL COST ESTIMATE

Estimated direct costs for the semi-dry FGD system include the SDA, fabric filter, major support facilities and BOP costs. The SO_2 control system cost is representative of a typical furnish and erect contract by a lime SDA/FF system supplier. The SDA/FF system costs estimated by CUECost are broken down into the major subsystems of reagent preparation, spray dryer absorber, waste handling systems, flue gas handling systems (booster fans and ductwork) and support systems. A fabric filter is included in the estimate for the capture of entrained absorption products. BOP costs include an electrical subcontract, foundations subcontract, water treatment equipment and repair/upgrade of the existing railroad tracks for lime delivery. The results of the capital cost estimate are given in Table 3.4-3.

A new stack was not included in the capital cost estimate. It was assumed for the purpose of the estimate that the existing stack would be reused as the flue gas is not near saturation.

Included in the Foundations Subcontract cost estimate is a silo for temporary waste product storage.

TABLE 3.4-3 – Capital Cost Estimate for LOS Unit 1 Semi-Dry FGD System

DIRECT COSTS	Estimated Cost ($2005)	General Facilities Markup (15%)	Total Direct Cost
SDA System			
Reagent Prep System	$9,410,000	$1,410,000	$10,820,000
SO_2 Absorption System	$10,990,000	$1,650,000	$12,640,000
Flue Gas Handling System	$6,360,000	$950,000	$7,310,000
ByProduct Handling System	$1,770,000	$270,000	$2,040,000
Support Equipment	$2,670,000	$400,000	$3,070,000
	SDA Total Direct Cost =		**$35,880,000**
Fabric Filter			
Fabric Filter Housing	$8,840,000	$1,330,000	$10,160,000
Bags	$1,290,000	$190,000	$1,480,000
Ash Handling System	$3,560,000	$530,000	$4,100,000
Instruments & Controls	$300,000	$40,000	$340,000
	Fabric Filter Total Direct Cost =		**$16,080,000**
BOP Costs			
Water Treatment Equipment	$380,000	NA	$380,000
Electrical Subcontract	$6,900,000	NA	$6,900,000
Ductwork	$1,790,000	NA	$1,790,000
Foundations Subcontract	$3,430,000	NA	$3,430,000
Railroad Upgrade/Repair	$300,000	NA	$300,000
	BOP Total Direct Cost =		**$12,800,000**
	Total Direct Cost =		**$64,760,000**
INDIRECT COSTS			
Contingency (20% of DC)			$12,950,000
A/E Engineering and Construction Management (10% of DC)			$6,320,000
Allowance For Funds During Construction (AFDC 6%)			$3,790,000
BEPC INDIRECTS			
Project Development (1% of DC)			$650,000
Spare Parts & Plant Equipment			
Rolling Stock			$500,000
Initial Inventory Spare Parts (1.5% of DC)			$970,000
Construction Startup and Support			
O&M Staff Training (0.5% of DC)			$320,000
Construction All-Risk Insurance (1.5% of DC)			$970,000
Contingency (15% of BEPC Indirects)			$510,000
Indirect Cost Subtotal			$27,240,000
Total Capital Cost			**$92,000,000**

Railroad delivery of lime, utilizing the west spur crossing the main plant entrance road was assumed for the cost estimate. The railroad track estimate includes the cost of upgrading approximately 1,500 feet of railroad track to provide for lime delivery to the LOS Unit 1 railcar unloading station.

The estimate includes refurbishment of approximately 400 feet of track past the railcar unloading position for flexibility in car positioning.

The total estimated capital cost estimate for a complete, stand-alone SDA/FF FGD system on LOS Unit 1, utilizing hydrated lime as a reagent is $92,000,000, or $418/kW.

3.4.1.4 FLASH DRYER ABSORBER CAPITAL COST ESTIMATE

The Flash Dryer Absorber (FDA) is a relatively recent development of the semi-dry FGD process. Because few FDA's have been placed in service at this time, cost breakdown information is difficult to find for them. The FDA cost estimate presented here is primarily based on in-house pricing information from Burns & McDonnell for an FDA/FF application to LOS Unit 1. The cost estimate includes the FDA reactor, the hydrator/mixer, the solids recycling system, and the Fabric Filter, with local waste solids handling systems. Additional cost information, for equipment and systems not included in the indicative pricing, were taken from the CUECost SDA cost estimate with individual line items adjusted to reflect modifications based on known differences in individual system capacities and capabilities. The results of the capital cost estimate for the FDA and Fabric Filter, along with BOP requirements, is provided in Table 3.4-4.

The estimated cost for the reagent preparation system for the FDA was taken as the CUECost estimate for a semi-dry system, including the estimated cost of a lime hydrator.

Estimated water treatment plant costs for the FDA system were decreased 45% from those of the wet FGD to reflect the lower makeup water requirements estimated for the FDA system.

The cost of the electrical subcontract for the FDA system was estimated to be equivalent to that of the semi-dry system due to the similarities in equipment requirements. Where system capacities changed significantly, such as ash handling systems, the number and capacity of electrical subsystems will undoubtedly change. However, sufficient information was not available to differentiate between the SDA and FDA electrical subsystem costs.

TABLE 3.4-4 – Capital Cost Estimate for LOS Unit 1 FDA with Fabric Filter

DIRECT COSTS	Estimated Cost ($2005)	General Facilities Markup (15%)	Total Direct Cost
FDA System			
Reagent Prep System	$9,410,000	$1,410,000	$10,820,000
SO_2 Absorption System	$6,250,000	$310,000	$6,560,000
Flue Gas Handling System	$5,900,000	$890,000	$6,790,000
ByProduct Handling System	$1,470,000	$221,000	$1,691,000
Support Equipment	$2,400,000	$360,000	$2,760,000
		FDA Total Direct Cost =	**$28,620,000**
Fabric Filter			
Fabric Filter Housing	$10,630,000	$1,870,000	$12,500,000
Bags	$1,615,000	$285,000	$1,900,000
Instruments & Controls	$4,477,000	$790,000	$5,267,000
Ash Handling Systems	$2,270,000	$340,000	$2,610,000
		Fabric Filter Total Direct Cost =	**$22,300,000**
BOP Costs			
Water Treatment Plant	$570,000	NA	$570,000
Electrical Subcontract	$5,520,000	NA	$5,520,000
Ductwork	$3,430,000	NA	$3,430,000
Foundations Subcontract	$1,890,000	NA	$1,890,000
Railroad Upgrade/Repair	$300,000	NA	$300,000
		BOP Total Direct Cost =	**$11,140,000**
		Total Direct Cost =	**$62,060,000**
INDIRECT COSTS			
Contingency (20% of DC)			$12,520,000
A/E Engineering and Construction Management (10% of DC)			$5,620,000
Allowance For Funds During Construction (AFDC 6%)			$3,370,000
BEPC Indirects			
Project Development (1% of DC)			$630,000
Spare Parts & Plant Equipment			
Rolling Stock			$500,000
Initial Inventory Spare Parts (1.5% of DC)			$940,000
Construction Startup and Support			
O&M Staff Training (0.5% of DC)			$310,000
Construction All-Risk Insurance (1.5% of DC)			$940,000
Contingency (15% of BEPC Indirects)			$500,000
Indirect Cost Subtotal			$26,360,000
Total Capital Cost			**$88,980,000**

An estimate was not provided for a new stack for Unit 1. For the purposes of this study, it was assumed that the existing Unit 1 stack would be reused.

The estimated cost of the foundation subcontract (including pilings and weather enclosures) was left unchanged from that of the SDA primarily because it has been estimated that the reduced foundation requirements of the reactor are offset by the increased foundation requirements of the fabric filter. Similarly, for the basis of this estimate, it was assumed that any reduction in absorber enclosure requirements was offset by additional costs for enlargement of the fabric filter casing(s).

The estimated cost of the railroad upgrade/repair to allow for lime delivery was left unchanged from the SDA estimate because the slight change in reagent usage would not affect the cost of the modifications required to allow for rail delivery.

The total estimated capital cost for the installation of and FDA system on LOS Unit 1 is $88,980,000 or $404/kW.

3.4.1.5 FUEL SWITCHING CAPITAL COST ESTIMATE

The potential for switching to PRB fuel for LOS Unit 1 was investigated by BEPC and an internal report was generated in 1997[1]. This report examined the results of a test burn with a PRB coal similar to the current PRB coal used in the current blended fuel. From the 1997 report, a switch to 100% PRB usage in LOS Unit 1 would impact the operating and maintenance costs, but significant capital expenditures for modification of the coal handling system were not identified. The results of the cost estimate for the fuel switching alternative are given in Table 3.4-5. One significant problem that was identified was the unloading time of the coal delivery trains. Current rail car parking capacity is limited and with the current rail system configuration part of the coal train would have to be parked on the main line while unloading. The potential solutions to this particular problem are not analyzed in the report, though it is mentioned that it is possible the railroad operator can adjust to this condition. A cost estimate for potential rail line modifications was not included in this report because this question was not resolved during the short test period.

The cost of a flue gas conditioning system was included to maintain ESP performance for this alternative. The capital cost estimate for the flue gas conditioning system includes a dry sulfur unloading station, dry sulfur storage hopper, transfer conveyance from storage hopper to sulfur melter, sulfur metering pump skid with MCC and variable speed drives, SO_3 production skid and injection probes with metering ports.

TABLE 3.4-5 – Capital Cost Estimate for Fuel Switching with Flue Gas Conditioning

DIRECT COSTS		**Estimated Cost ($2005)**
Injection System		$969,000
Unloading Station		(Included Above)
Storage Hopper		(Included Above)
Transfer Conveyor		(Included Above)
Metering Pump Skid		(Included Above)
SO_3 Production Skid		(Included Above)
Injection Probes		(Included Above)
	Total Direct Cost =	**$969,000**
INDIRECT COSTS	Contingency (20% of DC)	$194,000
	A/E Engineering and Construction Management (10% of DC)	$97,000
	Allowance for Funds During Construction (AFDC 6%)	$58,000
BEPC INDIRECTS	Project Development (1% of DC)	$9,700
	Spare Parts & Plant Equipment	
	Initial Inventory Spare Parts (1.5% of DC)	$14,500
	Construction Startup and Support	
	O&M Staff Training (0.5% of DC)	$4,800
	Construction All-Risk Insurance (1.5% of DC)	$14,500
	Contingency (15% of BEPC Indirects)	$5,000
	Indirect Cost Subtotal	$398,000
	Total Capital Cost	**$1,367,000**

Additional capital investments may be required for a switch to PRB fuel, including construction of fuel barns and the installation of additional conveyors, but those costs were not identified as part of this study. The estimated total capital investment for fuel switching alternative for LOS Unit 1, including flue gas conditioning, is estimated to be $1,367,000 or $6.21/kW

3.4.1.6 WET FGD O&M COST ESTIMATE

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). These costs were developed as part of the CUECost model and include operating labor, administrative and support labor and maintenance. Table 3.4-6 summarizes the O&M cost estimates for the wet FGD system.

The fixed costs include operating labor, administrative and support labor and the maintenance material and labor costs. The maintenance material and labor cost was estimated as approximately 3% of the wet FGD system direct capital cost in Table 3.4-1. Administrative and support labor cost was estimated as 12% of the maintenance material and labor cost plus 30 percent of the operating labor costs. Previous studies and guidelines for FGD O&M costs by EPRI and others are in line with these percentages.

TABLE 3.4-6 – O&M Cost Estimate for LOS Unit 1 Wet FGD System

Fixed Costs	
Operating Labor	$1,460,000
Admin and Support labor	$670,000
Maintenance Material and Labor	$1,950,000
Total Fixed O&M Costs =	$4,090,000
Variable Costs	
Limestone Reagent	$1,760,000
Byproduct Disposal	$630,000
Water	$270,000
Auxiliary Power	$1,600,000
Total Variable O&M Costs =	$4,260,000
Total Annual O&M Costs	**$8,350,000**
Net Annual O&M Cost ($/MWh)	**$4.81**

The operating labor cost is based on a total of 15 additional personnel, including two operators per shift (one in the control room and one on roving duty) with two truck drivers at 40 hours per week for hauling of FGD wastes and two laborers on day shift and one on roving assignment. In addition, four maintenance staff working one shift per day, five days per week are included in the maintenance cost estimate.

Variable costs include reagent, makeup water, FGD byproduct disposal and auxiliary power costs. The estimated annual costs for these consumables are based on consumption rates modeled by the CUECost model and the unit cost information provided by BEPC and described in Table 1.2-3 Economic Design Criteria. A cost of $5.50 per ton for hauling the FGD wastes was included for waste disposal. No additional cost for landfilling at the permitted solid waste facility was included. The total estimated annual O&M cost for application of wet FGD to LOS Unit 1 is $8,350,000 or $4.81/kW.

3.4.1.7 CIRCULATING DRY SCRUBBER O&M COST ESTIMATE

Estimated O&M costs for the CDS/FF alternative were developed from the CUECost estimate of the O&M costs for the SDA/FF alternative. The operating labor was increased by 8% over that of the SDA as indicated in a recent study by Sargent & Lundy[5] comparing the two alternative technologies. Administration and Support and maintenance and material costs were similarly increased 8% based upon the same reference. The CDS reagent usage was also increased 17% (effective stoichiometric ratio of 2.1) above that for the SDA based upon the same findings. Waste disposal costs were increased 5% over those of the SDA, as estimated by CUECost, to reflect the increased reagent wastage. The power requirement for the CDS was increased 15% over that estimated by CUECost for the SDA based upon Sargent & Lundy's findings[5]. The estimated annual O&M costs for application of the CDS/FF alternative at LOS Unit 1 are given in Table 3.4-7.

TABLE 3.4-7 – O&M Cost Estimate for LOS Unit 1 CDS/FF System

Fixed Costs	
Operating Labor	$1,280,000
Admin and Support labor	$400,000
Maintenance Material and Labor	$1,460,000
Total Fixed O&M Costs =	$3,140,000
Variable Costs	
Lime Reagent	$4,470,000
Byproduct Disposal	$820,000
Water	$110,000
Auxiliary Power	$1,160,000
Total Variable O&M Costs =	$6,560,000
Total Annual O&M Costs	**$9,700,000**
Net Annual O&M Cost ($/MWh)	**$5.59**

3.4.1.8 SEMI-DRY FGD O&M COST ESTIMATE

The O&M cost estimate for the SDA/FF alternative was taken directly from CUECost. Lime usage was set at 1.80 lbmol of lime (CaO) per lbmol of SO_2 removed. A ratio of 5.5 lb of recycled solids per pound of lime added and a 35% solids slurry were also set as design conditions in CUECost. A total of 11" w.g. pressure drop across the combined SDA/FF system was also utilized as a design condition. The Fabric Filter was sized for a gas-to-cloth ratio of 3.5 ACFM/Ft^2. A three year bag life was assumed. The results of the SDA/FF O&M cost estimate are summarized in Table 3.4-8.

TABLE 3.4-8 – O&M Cost Estimate for LOS Unit 1 SDA/FF System

Fixed Costs	
Operating Labor	$1,150,000
Admin and Support labor	$360,000
Maintenance Material and Labor	$1,350,000
Total Fixed O&M Costs =	$2,860,000
Variable Costs	
Lime Reagent	$4,180,000
Byproduct Disposal	$780,000
Water	$110,000
Auxiliary Power	$1,010,000
Total Variable O&M Costs =	$6,080,000
Total Annual O&M Costs	**$8,940,000**
Net Annual O&M Cost ($/MWh)	**$5.15**

3.4.1.9 FLASH DRYER ABSORBER O&M COST ESTIMATE

The FDA/FF O&M costs were estimated from a combination of the CUECost estimate for the SDA/FF system and vendor supplied materials usage information for the FDA/FF. The operating labor, administration and support for the FDA/FF were taken directly from the SDA/FF estimate because the FDA/FF system operation is no more technically complex than the SDA/FF. Maintenance costs were estimated as 90% of the SDA/FF maintenance cost estimated by CUECost. Reagent usage and waste solids generation rates were estimated by a system vendor for the current fuel blend, increased for the additional sulfur content of the design fuel and the costs determined from the economic information in Table 1.2-3. Auxiliary power costs for the SDA/FF system were increased 10% for the FDA/FF usage. The results of the FDA/FF O&M cost estimate are given in Table 3.4-9.

TABLE 3.4-9 – O&M Cost Estimate for LOS Unit 1 FDA/FF System

Fixed Costs	
Operating Labor	$1,220,000
Admin and Support labor	$480,000
Maintenance Material and Labor	$1,000,000
Total Fixed O&M Costs =	$2,700,000
Variable Costs	
Lime Reagent	$5,070,000
Byproduct Disposal	$830,000
Water	$120,000
Auxiliary Power	$1,110,000
Total Variable O&M Costs =	$7,120,000
Total Annual O&M Costs	**$9,820,000**
Net Annual O&M Cost ($/MWh)	**$5.66**

3.4.1.10 FUEL SWITCHING O&M COST ESTIMATE

In the 1997 report[1] on the PRB test burn, BEPC reported several operational advantages to the use of PRB in LOS Unit 1. These included reduced station service (from 7.6 to 7.2%), reduced sulfur emissions and reduced ash quantities. The test report specifically mentions that although some features of PRB firing were documented, the test duration was extremely short and many potential long term impacts were neither investigated nor documented. Additional O&M cost might result from unknown impacts caused by a fuel switch. For the purpose of estimating impacts of a switch to 100% PRB fuel on the operating and maintenance costs of LOS Unit 1, the changes in fuel cost, station service costs and ash disposal were estimated based on the report contents and are summarized in Table 3.4-10.

The change in fuel cost calculated to result from a switch to 100% PRB was based upon the design heat input to LOS Unit 1, taking into account a 2.1% increase in boiler efficiency (at full generation). The station service benefit was calculated as the net decrease in station service based on operating costs given in Table 1.2-3. Because PRB has a significantly lower ash content, a credit for reduction in both bottom ash and flyash disposal costs is also included. The annual additional O&M cost of switching LOS Unit 1 to PRB is estimated to be $5,510,000 or $2.86/MWh.

TABLE 3.4-10 – O&M Cost Estimate for LOS Unit 1 Fuel Switching

Fuel Cost Change	$6,002,000
Reduced Station Service	-$292,900
Change in Ash Disposal Cost	-$355,100
Annual Flue Gas Conditioning Maintenance	$13,000
Flue Gas Conditioning Reagent	$143,000
Total Annual Change to O&M Cost	**$5,510,000**
Total Annual Change to O&M Cost ($/MWh)	**$2.86**

3.4.1.11 LEVELIZED TOTAL ANNUAL COST

The Levelized Total Annual Cost (LTAC) for all alternatives were calculated based on economic conditions given in Table 1.2-3 and a 20 year project life. The LTAC was calculated for each alternative utilizing the estimated costs in Tables 3.4-1 through 3.4-10 and the economic conditions described in Section 1 of this report. Estimated capital costs were split evenly over a two year construction period for all alternatives. A system startup date of December 17, 2013 was used based upon the projected timing of Regional Haze Rule implementation given by NDDH. O&M costs were included through the end of the calendar year 2034. No salvage value was assumed at the end of the service life for any of the alternatives. The LTAC for all BART alternatives remaining under consideration are presented in Table 3.4-11.

TABLE 3.4-11 – Levelized Total Annual Costs of Unit 1 BART SO_2 Control Alternatives(1)

BART Alternative	Control Efficiency	Annual Emission Reduction from Historical Case (tpy)(2)	Annual Emission Reduction from Future PTE Case (tpy)(3)	Installed Capital Cost ($2005)	Annual O&M Cost ($2005)	Levelized Total Annual Cost ($2005)(4)
Wet FGD	95%	17,019	37,453	$107,220,000	$8,350,000	$19,310,000
CDS/FF	93%	16,327	36,664	$104,790,000	$9,700,000	$20,720,000
SDA/FF	90%	15,289	35,482	$92,000,000	$8,940,000	$18,700,000
FDA/FF	90%	15,289	35,482	$88,980,000	$9,820,000	$19,480,000
Fuel Switching	77%	10,792	30,475	$1,367,000	$5,510,000	$6,690,000

(1) - All Costs in 2005 dollars.

(2) - Annual emission reduction is uncontrolled Historic case emissions minus controlled Future PTE case emissions.

(3) - Annual emission reduction is uncontrolled Future PTE case emissions minus controlled Future PTE case emissions.

(4) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

The annual tons of SO_2 reduction in this study are calculated for two cases. One case is the difference between the uncontrolled emissions from the Historical case (firing the baseline fuel at the historical heat input) and the controlled emissions for the Future PTE case at the nameplate heat input and a capacity factor of 1.0. The second case is the difference between the uncontrolled emissions and the controlled emissions for the Future PTE case.

Figure 3.4-1 is a plot of the Levelized Total Annual Cost for each technology alternative versus the annual removal in tons (Future PTE basis) for each BART alternative shown in Table 3.4-11. A similar graphic analysis is not presented for the Historic Case due to the similarity of the results. The purpose of Figure 3.4-1 is to identify the Dominant Controls Curve which is the rightmost boundary of the control cost envelope. The Dominant Controls Curve is the best fit line through the points forming the rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual removal tonnage for the various BART alternatives. Points distinctly above, or to the left of, this curve are inferior control alternatives on a cost effectiveness basis. Of the technically feasible BART alternatives considered for LOS Unit 1, data points for the CDS, the SDA and the FDA all lie distinctly above the least cost boundary of the control cost envelope. The reason for this

FIGURE 3.4-1 – LOS Unit 1 SO_2 Least Cost Envelope for Future PTE Case

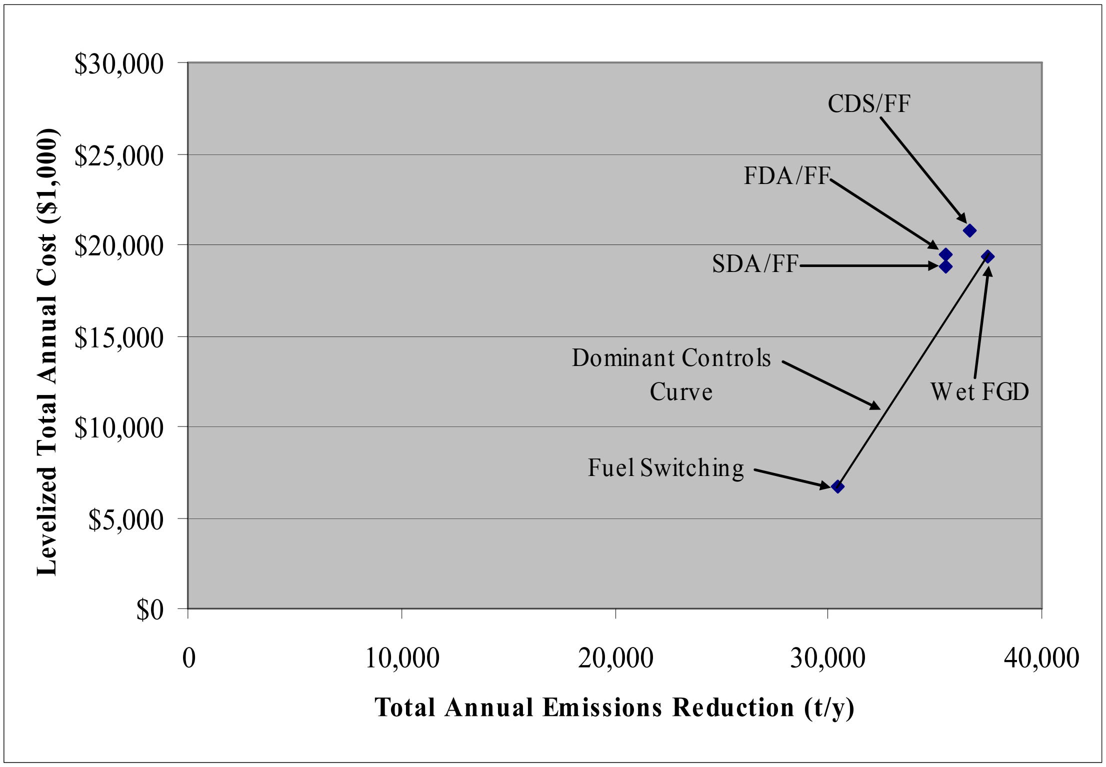

TABLE 3.4-12 – Unit Control Costs of Unit 1 BART SO_2 Control Alternatives

BART Alternative	Control Efficiency	Levelized Total Annual Cost ($2005)(1)	Annual Emission Reduction from Historical Case (tpy)	Historical Case Unit Control Cost ($/ton)	Annual Emission Reduction from Future PTE Case (tpy)	Future PTE Case Unit Control Cost ($/ton)
Wet FGD	95%	$19,310,000	17,019	$1,135	37,453	$516
CDS/FF	93%	$20,720,000	16,327	$1,269	36,664	$565
SDA/FF	90%	$18,700,000	15,289	$1,223	35,482	$527
FDA/FF	90%	$19,480,000	15,289	$1,274	35,482	$549
Fuel Switch	77%	$6,690,000	10,792	$620	30,475	$220

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

is clear from Table 3.4-12 where the unit control costs for the SO_2 control alternatives are listed. In a top down analysis each of the SO_2 control technologies represented by a data point above the Dominant Control Curve could be excluded from further analysis on a cost effectiveness basis. However, because the accuracy of the estimate (± 30%) is greater than the variance of the estimated LTACs (±11%) and the Unit Control Costs (± 12%) for all post combustion control alternatives, none of the alternatives were excluded from further analysis on a cost basis.

The next step in the cost effectiveness analysis for the remaining BART alternatives is to review the incremental cost effectiveness between a given alternative and those above and below it on the Dominant Controls Curve. Table 3.4-13 contains a repetition of the cost and control information from Table 3.4-11 and the incremental cost effectiveness for each dominant control alternative.

TABLE 3.4-13 – Incremental Cost Effectiveness of Unit 1 BART SO_2 Control Alternatives On the Dominant Controls Curve

BART Alternative	Levelized Total Annual Cost(1)	Annual Emission Reduction from Historic Case (tpy)	Incremental Cost Effectiveness for Historic Case ($/ton)	Annual Emission Reduction from Future PTE Case (tpy)	Incremental Cost Effectiveness for Future PTE Case ($/ton)
Wet FGD	$19,310,000	17,019	$2,267	37,453	$2,023
Fuel Switching	$6,690,000	10,792	NA	30,475	NA

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

In the BART Determination guidelines, EPA does not provide definition, or even discussion of reasonable, or unreasonable, Unit Control Costs. Similarly, EPA does not address reasonable or unreasonable ranges for the incremental cost effectiveness. The incremental cost effectiveness is a marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the dominant control cost curve) between successively less effective alternatives. The incremental cost effectiveness for wet FGD versus fuel switching in Table 3.4-13 is within the range of reasonable costs used in other regulatory analyses and thus does not indicate that wet FGD is prohibitively expensive relative to the fuel switching alternative.

The cost analysis portion of the BART determination for LOS Unit 1 has shown that none of the Unit Control Costs for the dominant alternatives are exceedingly expensive on a Unit Control Cost basis. However, three of the BART alternatives were established as being potentially inferior to alternatives forming the Dominant Controls Curve. None of these alternatives were excluded from further analysis due to the similarity of the estimated cost impacts compared to the estimate accuracy. From a top-down economic analysis viewpoint, wet FGD appears to be the most cost effective evaluated SO_2 control alternative for LOS Unit 1. However, because the capital costs of all of these technologies are subject to market conditions at the time of purchase, such as; alloy pricing, major equipment lead times (i.e., slurry pumps, booster fans, etc.) the relative closeness of the estimated capital costs is a good indicator that the cost ranking of these alternatives might even be reversed at the time of actual purchase.

At the conclusion of the cost impact analysis, the decision was made to delete the FDA/FF alternative from further consideration as it duplicated the control efficiency of the SDA/FF alternative, but at a higher price. This deletion is not anticipated to prejudice study results because of the relative closeness of the costs of the post combustion control alternatives. It is not intended to imply that the FDA/FF is excluded from consideration as an actual technology for BART compliance, only that this alternative is excluded from the remainder of this analysis as a duplicate alternative. When Basin Electric Power Cooperative initiates procurement of SO_2 control equipment, there is no reason to exclude the FDA/FF alternative from the bidding process. The purpose of the BART analysis is to identify the emission level that constitutes BART, not to restrict the source to a specific control technology.

3.4.2 ENERGY IMPACTS

The energy impacts of each alternative, in terms of both estimated kW of energy usage and the percent of total generation, are given in Table 3.4-14. The fuel switching option actually has a negative energy demand due to the decrease in plant services primarily resulting from the decrease in the Net Plant Heat Rate of approximately 300 Btu/kW.[1]

The primary energy impacts of the wet FGD alternative consists of the additional electrical load resulting from pumps, blowers, booster fans, ball mills for limestone grinding and vacuum pumps for byproduct slurry dewatering. The largest energy users for the semi-dry and dry alternatives are pumps, blowers, atomizers and booster fans. Building HVAC and interior and exterior lighting loads are also included, but the major energy consumption is due to the primary systems described above.

TABLE 3.4-14 – Energy Requirements of Unit 1 BART SO_2 Control Alternatives

BART Alternative	Energy Demand (kW)	Percent of Nominal Generation
Wet FGD	4,814	2.2%
CDS/FF	3,500	1.6%
SDA/FF	3,043	1.4%
Fuel Switching	-880	-0.4%

3.4.3 NON-AIR QUALITY ENVIRONMENTAL IMPACTS

Non-air quality environmental impacts of the installation and operation of the various BART alternatives include hazardous waste generation, solid and aqueous waste streams, and salable products that could result from the implementation of various BART alternatives. One general exception is the fuel switching alternative which would actually result in the reduction of ash quantities and might even produce salable flyash. The cost reduction for reduced ash disposal was included in the O&M cost estimate for fuel switching, but no credit was taken for potential future ash sales.

Captured mercury in the solid waste stream from any post combustion alternative would be present as a trace contaminant in the solid waste, not affecting disposal options as long as the waste passes the Toxic Characteristic Leaching Procedure (TCLP), which FGD system wastes have historically.

A wet FGD system for LOS Unit 1 is estimated to produce approximately 14.9 tons per hour of solid waste. The waste stream would be composed of gypsum solids and inerts at approximately 15% moisture. Over the course of a year, the total solid waste quantity is estimated to be approximately

130,500 tons of gypsum solids which would be landfilled in the current permitted solid waste disposal facility near the plant.

The annual quantity of aqueous waste that would be produced by a wet FGD system is difficult to quantify because the blowdown rate from a wet FGD system is primarily a function of the dissolved chloride levels in the absorber reaction tank. Most of the chloride reaching the scrubber is in the form of hydrochloric acid which is readily absorbed and neutralized. Hydrochloric acid removal rates in a typical wet FGD system typically exceed 95%. CUECost estimates 41 lb/hr of hydrochloric acid in the flue gas stream which is assumed to be completely removed by the absorber system. The waste solids stream leaving the wet FGD system contains approximately 15% water which would contain $CaCl_2$ which would not require blowdown for disposal. Assuming the chloride to be present in the blowdown stream as $CaCl_2$ and assuming an average chloride concentration of 9,000 parts per million, one can calculate approximately 41 pounds per hour of chloride would leave the plant in the entrained moisture in the solid waste. No blowdown specifically for chloride disposal would be required under these conditions. For the purpose of this analysis, it was assumed that an irregular blowdown stream would be required and would be sent to a dedicated evaporation pond on site for disposal.

During preparation for the visibility analysis a review of the cost impact analysis results was conducted and fuel switching (77%) was identified as a significantly inferior alternative compared to the post combustion SO_2 control alternatives (90-95%) and it was decided that fuel switching should be excluded from further consideration in the study. Further explanation is provided in the next section.

3.4.4 VISIBLITY IMPACTS

The final impact analysis conducted was to assess the visibility impairment impact reduction for each proposed BART alternative. Pre-control Historic emission rates and post-control emission rates for the Future PTE case were modeled for visibility impairment impacts. CALPUFF was used to model the long-range transport and interaction of SO_2, NO_X and PM to estimate the visibility impairment impact in deciViews (dV). The reduction in visibility impairment impact due to each control scenario was then calculated as the difference between the visibility impairment impact for each control scenario and the pre-control visibility impairment impact. Per the BART Guidelines and the modeling protocol provided by NDDH, the pre-control modeling case was the maximum 24 hour emission rate for each pollutant for the years 2000-2002, inclusive. The post-control emission rates for each pollutant were developed from the Future PTE case. These results were then compared to assess the relative visibility impairment reduction for each BART alternative.

The BART guidelines state that the comparison should be made at the 98th percentile level (70 FR 39170). However, NDDH directed that the comparison should be made at the 90th percentile to be consistent with the Western Regional Air Partnership (WRAP) protocol. Therefore, the visibility impairment impact reduction presented for each control scenario in this section is based on the 90th percentile value.

CALPUFF modeling was conducted separately for the application of each SO_2 control technology to the Future PTE case. The modeling results, expressed as the change in visibility impairment impact in deciViews (ΔdV), is the change in visibility impairment impact in the affected Class 1 area as a result of the emission reduction attributed to the implementation of each BART alternative on LOS Unit 1. The visibility impairment impact reduction (Δ dV) for each BART alternative is given in Table 3.4-15 for each affected Class 1 Area.

The visibility impairment impact reduction for each modeled BART alternative is given in column three of Table 3.4-15. This value is the average visibility impairment impact reduction over the three modeled years (2000-2002) for each affected Class 1 area. For all modeled conditions, the visibility impairment reduction for any BART alternative varied from approximately 0.2 to 0.5dV. The Lostwood National Wildlife Refuge (Lostwood NWR) shows the greatest average visibility impairment impact reduction, regardless of the BART alternative modeled, thus indicating that this area will gain the greatest benefit from SO_2 BART implementation of all the Class 1 Areas included in the modeling. The Teddy Roosevelt National Park, Elkhorn site (TRNP-Elkhorn) is shown to gain the least visibility impairment impact reduction, regardless of the BART alternative. A review of Table 3.4-15 finds the visibility impairment impacts for BART alternative vary by year and area. The observed variations between Class 1 Areas are primarily a result of different directions and distances from the plant as well as variability in the meteorological data for each area and each year.

In addition to the average ΔdV values, three other types of data are presented in Table 3.4-15, the number of days in each of the affected Class 1 Areas the visibility impairment impact, after implementation of a BART alternative, exceeded 0.5 dV, the number of days the impact exceeded 1.0

dV and the maximum number of consecutive days the impact exceeded 0.5 dV. The 0.5 dV value is the lowest visibility impairment impact that is considered discernible by the human eye and the EPA

TABLE 3.4-15 – Visibility Impairment Impacts - Unit 1

Class 1 Area	BART Alternative Control Efficiency(1)	Visibility Impairment Reduction (ΔdV)	Days Exceeding 0.5 dV in 2000	Days Exceeding 0.5 dV in 2001	Days Exceeding 0.5 dV in 2002	Days Exceeding 1.0 dV in 2000	Days Exceeding 1.0 dV in 2001	Days Exceeding 1.0 dV in 2002	Consecutive Days Exceeding 0.5 dV 2000	Consecutive Days Exceeding 0.5 dV 2001	Consecutive Days Exceeding 0.5 dV 2002
TRNP South	95%	0.337	3	1	13	0	0	3	1	1	2
	93%	0.335	3	4	15	2	0	3	1	2	2
	90%	0.316	4	4	15	2	0	3	1	2	2
TRNP North	95%	0.369	4	4	10	1	0	3	1	1	3
	93%	0.347	7	4	12	2	1	4	1	1	3
	90%	0.332	8	7	13	2	1	4	1	2	3

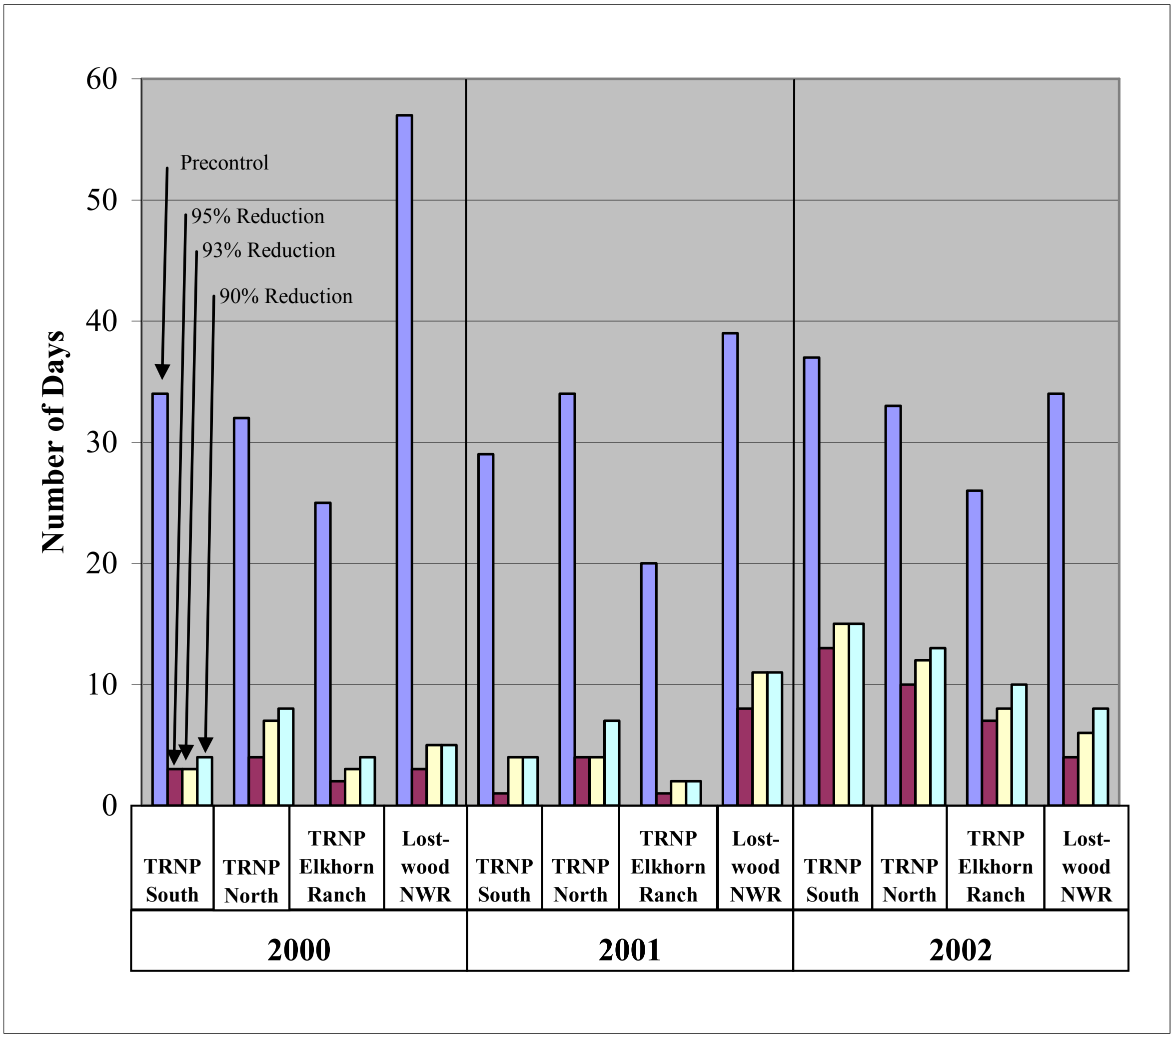
	93%	0.221	3	2	8	1	0	2	1	1	2
	90%	0.207	4	2	10	2	0	3	1	1	2
Lostwood NWR	95%	0.519	3	8	4	1	2	0	1	2	1
	93%	0.489	5	11	6	1	4	1	1	2	1
	90%	0.467	5	11	8	1	5	2	1	2	1

(1) - A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

set this threshold in the screening analysis, as the point above which a source is considered to be contributing to visibility impairment (70 FR 39120). The 1.0 dV threshold was established in the final rule as the threshold during the screening analysis at which a state should consider a source to be a cause of visibility impairment (70 FR 39120). The visibility impairment impact analysis consists of examining the magnitude of impact reduction for each alternative as well as the number of exceedances described above.

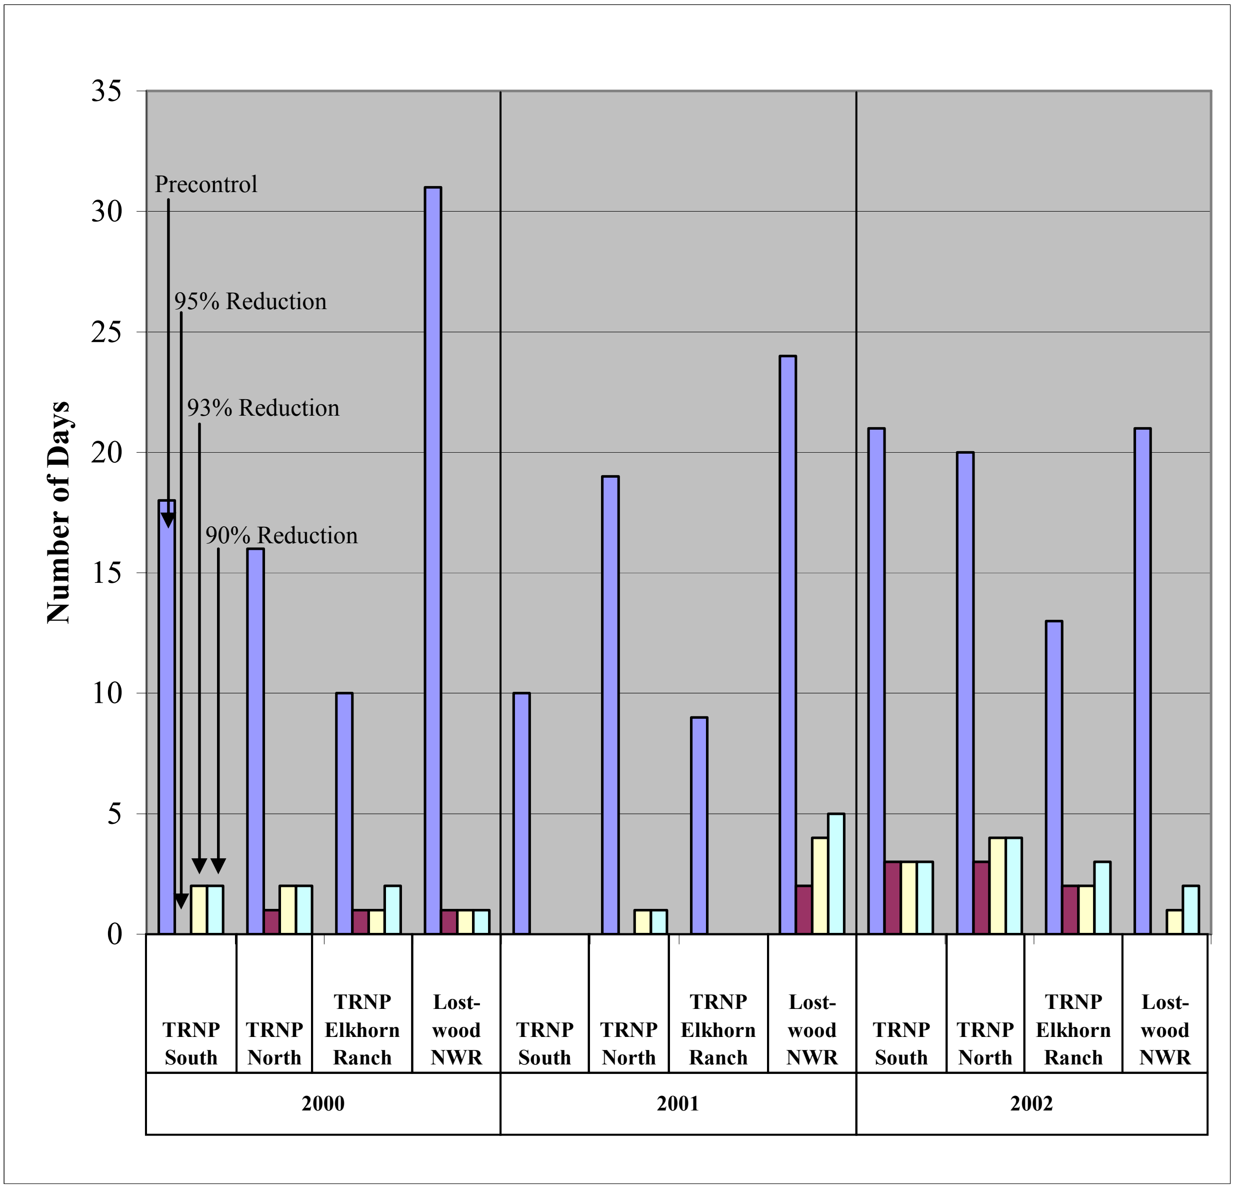
In the model year 2000, the worst impact in terms of days exceeding 0.5 dV occurs at TRNP-North, during 2001 at the Lostwood NWR and during 2002 at TRNP-South, regardless of the BART alternative under consideration. A graphic representation of these impacts is presented in Figure 3.4-2. A comparison of the number of exceedance days for the pre-control and post-control scenarios

FIGURE 3.4-2 – Number of Days Exceeding 0.5 dV for Pre- and Post-Control



shown in Figure 3.4-2 reinforces the earlier observation that the Lostwood NWR gains the most improvement in terms of visibility impairment reduction, regardless of the modeled BART alternative. A graphic representation of the number of days exceeding 1.0 dV is presented in Figure 3.4-3. During the years 2000 and 2002, the greatest number of days where visibility impairment impact

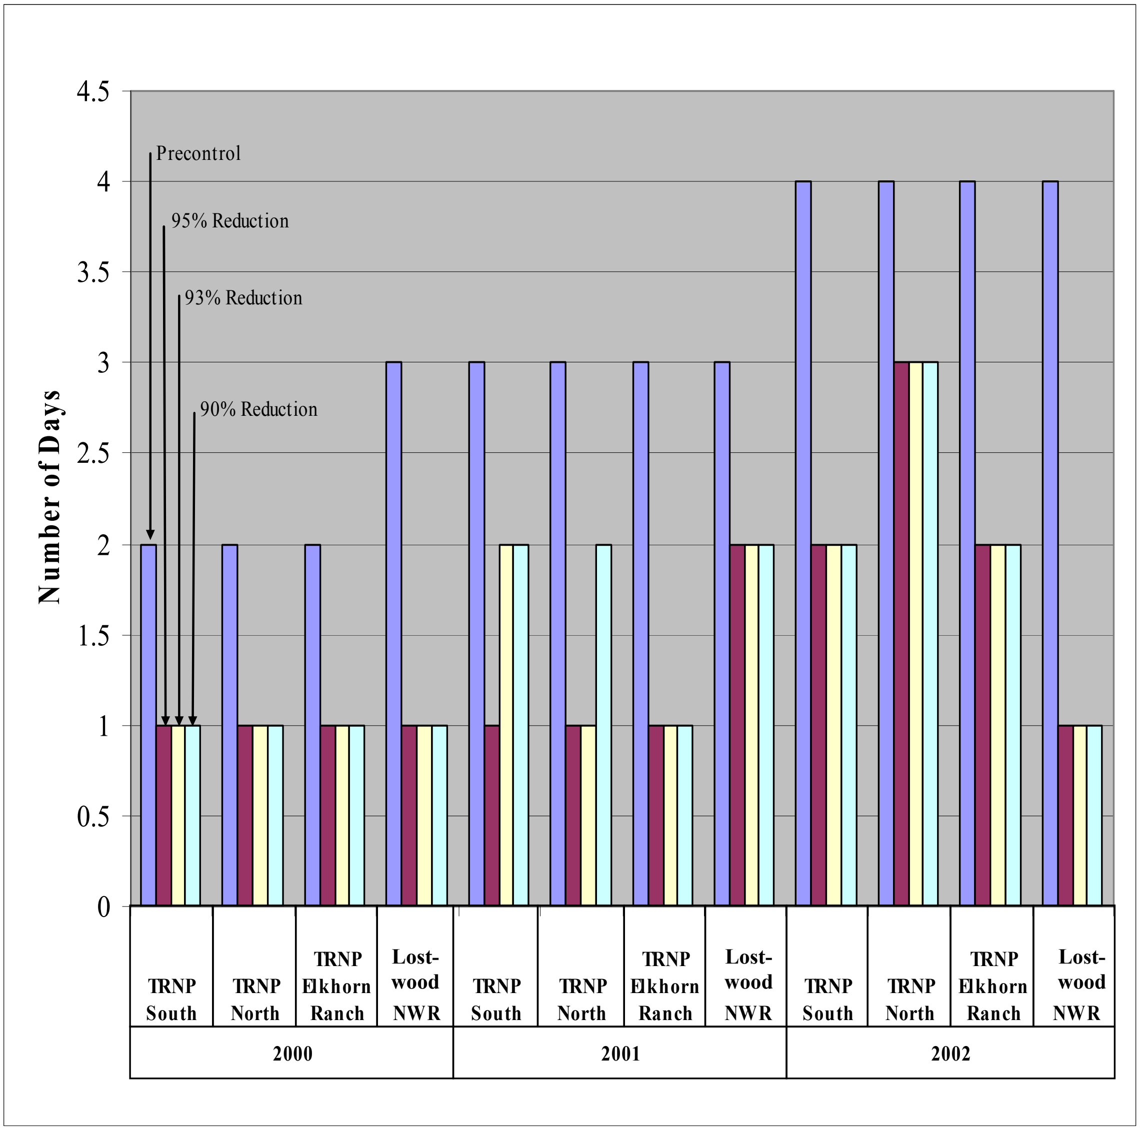
FIGURE 3.4-3 – Number of Days Exceeding 1.0 dV for Pre- and Post-Control



exceeds 1.0 dV, occurs in TRNP-North, but in the Lostwood NWR in 2001. In 2001 both TRNP South and TRNP Elkhorn Ranch have zero days of visibility impairment exceeding 1.0 dV according to the modeling results.

Figure 3.4-4 is a graphic presentation of the maximum number of consecutive days where the visibility impairment impact exceeds 0.5 dV for the modeled Class 1 Areas. Both pre-control and post-control conditions are presented for the three years 2000-2002, inclusive. In 2000, the number

FIGURE 3.4-4 – Maximum Consecutive Days Exceeding 0.5 dV for Pre- and Post Controls



of consecutive days exceeding 0.5 dV of impact is the same for all areas for both the uncontrolled and controlled scenarios. In 2001 TRNP-South and Lostwood NWR both experience the same number of consecutive days of visibility impairment greater than 0.5 dV for the 90% and 93% control cases, but at the 95% control level, the Lostwood NWR is predicted to experience two consecutive days versus one day for all other areas. In 2002 the TRNP-North area is predicted to experience three consecutive days of visibility impairment greater than 0.5 dV and in general, all modeled areas are predicted to experience more consecutive days of visibility impairment greater than 0.5 dV than in either of the two previous years.

The total number of days where the visibility impairment impact exceeded 0.5 dV over the entire modeling period (2000-2002) is greatest for TRNP-North. TRNP-South is predicted to have experienced the least number of days with a visibility impairment impact greater than 0.5 dV over the modeling period. Similarly, the total number of days where the impact exceeded 1.0 dV is greatest for TRNP-North over the modeled time period and least for the TRNP Elkhorn Ranch area. The maximum number of consecutive days with impacts greater than 0.5 dV also occurs in TRNP-North and the TRNP-Elkhorn Ranch and Lostwood NWR areas have the least number of consecutive days.

Compared to the baseline case the visibility impairment reduction predicted for each BART alternative by the visibility modeling, as shown in Figures 3.4-2 though 3.4-4, will result in a significant decrease in visibility impairment in all of the Class 1 areas. Even the least effective BART alternative under analysis will, under the worst modeled meteorological conditions, reduce the number of days with greater than 0.5dV of impact by over half. Days with visibility impairment greater than 1.0 dV will decrease by over 75% under those same worst case model meteorological conditions. Figure 3.4-4 clearly shows that averaged over all model years and Class 1 areas, the number of consecutive days with greater than 0.5 dV will be reduced by approximately half, regardless of the BART alternative under consideration.

The visibility impairment impact reduction results for each BART SO_2 removal alternative are summarized in Table 3.4-16. The second column contains the reduction in visibility impairment impact relative to the uncontrolled Future PTE case emissions. Column four shows the marginal visibility impairment impact improvement for the 93% and 95% SO_2 removal alternatives relative to a lowest removal efficiency condition of 90%. As can be seen in column four, the marginal visibility impairment impact reduction for any of the Class 1 areas is less than ten percent of the minimum change discernible by the human eye, as stated in the BART Guidelines (70 FR 39119, Footnote 28).

Therefore, it is reasonable to conclude from this table that in terms of discernible visibility impairment impact, there is no difference between any of the remaining SO_2 removal alternatives for LOS Unit 1.

TABLE 3.4-16 – Marginal Visibility Impairment Impact Reduction

BART Alternative	BART Alternative and Percent Reduction	Visibility Impairment Reduction (Δ dV)(1)	Marginal Visibility Impairment Reduction (Δ dV)(2)
TRNP-S	95%	0.337	0.021
	93%	0.335	0.019
	90%	0.316	Base
TRNP-N	95%	0.369	0.037
	93%	0.347	0.015
	90%	0.332	Base
TRNP-Elkhorn Ranch	95%	0.233	0.026
	93%	0.221	0.014
	90%	0.207	Base
Lostwood NWR	95%	0.519	0.052
	93%	0.489	0.022
	90%	0.467	Base

(1) - Average modeled visibility impairment impact over three model years. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - Marginal visibility impairment impact improvement relative to the base impact at 90% removal.

3.4.5 IMPACT SUMMARY

As stated in Section 3.4, this report has examined the listed impacts of each BART alternative as part of the BART determination process. Table 3.4-17 summarizes the various impacts discussed in Sections 3.4.1 through 3.4.4. The cost of compliance analysis examined the capital cost of the technology that is central to each feasible BART alternative and the Balance of Plant costs necessary to implement the alternative. In addition, the cost analysis examined the operating and maintenance costs associated with each alternative. These costs were then combined into the Levelized Total Annual Cost (LTAC) for a comparative assessment of the overall cost of each alternative. Finally, as part of the top down analysis, a Dominant Control Curve was plotted and the Unit Control Costs were determined for each alternative. As discussed in Section 3.4.4, the cost impact analysis was basically inconclusive as the difference between the minimum and maximum estimated LTAC was approximately one third of the estimate accuracy and thus no strong conclusion was indicated. The visibility impairment impact analysis examined the visibility impairment impact reduction attributable to each alternative and determined that the marginal change in visibility impairment impact between any two feasible BART alternatives was less than ten percent of the minimum change in visibility impairment discernible by the human eye. So, similar to the cost analysis, the visibility impairment impact analysis reached no definitive conclusion.

The energy impact was also evaluated for each alternative and some differentiation between alternatives was identified. The energy demand for the 90% SO_2 control alternative (SDA/FF) was approximately 60% of the energy demand for the most stringent SO_2 control alternative at 95% SO_2 control (WFGD). All three BART alternatives listed in Table 3.4-17 produce solid waste streams in similar quantities. The WFGD alternative is expected to also produce an intermittent liquid blowdown stream that would be disposed of in a permitted evaporation pond on site.

TABLE 3.4-17 – LOS Unit 1 Impacts Summary for SO_2 Control Alternatives

BART SO_2 Control Alternative	Annual Emissions Reduction (tpy)	Levelized Total Annual Cost(1)	Unit Control Cost ($/ton)	Visibility Impairment Impact Reduction		Energy Impact (kW)	Non Air Quality Impacts
				Area	ΔdV(2)		
95%	37,453	$19,310,000	$516	TRNP-S	0.337	4,800	Solid and Liquid Waste Streams
				TRNP-N	0.369		
				TRNP-Elk	0.233		
				LW-NWR	0.519		
93%	36,664	$20,720,000	$565	TRNP-S	0.335	3,500	Solid Wastes
				TRNP-N	0.347		
				TRNP-Elk	0.221		
				LW-NWR	0.489		
90%	35,482	$18,700,000	$527	TRNP-S	0.316	3,040	Solid Wastes
				TRNP-N	0.332		
				TRNP-Elk	0.207		
				LW-NWR	0.467		

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

(2) - Change in visibility impairment impact between uncontrolled Historical emissions and controlled Future PTE emissions.

3.5 EVALUATION OF IMPACTS FOR FEASIBLE SO_2 CONTROLS – UNIT 2

Step four in the BART analysis procedure is the impact analysis. The BART determination guidelines (70 FR 39166) list four factors to be considered in the impact analysis. This BART Determination will consider the following four factors in the impact analysis:

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four factors considered in the impact analysis are discussed in the following sections. The factor for the remaining useful life of the source is incorporated as part of the cost of compliance. In addition, as described in Section 1.1.6, the visibility impairment impacts are to be evaluated as part of the analysis. Thus, visibility impairment is included as part of the impacts analysis.

3.5.1 COST ESTIMATES

The procedure used to obtain cost estimates for LOS Unit 2 SO_2 control technologies is the same general procedure described in Section 3.4.1 for LOS Unit 1. Any exceptions to this procedure are described in the following sections for each individual control alternative.

3.5.1.1 WET FGD CAPITAL COST ESTIMATE

The capital cost estimate for the wet FGD system includes the SO_2 control system, major support facilities and BOP costs. The SO_2 control system cost is representative of a typical furnish and erect contract by a wet FGD system supplier. The wet FGD system cost estimated by CUECost is broken down into the major subsystems of reagent preparation, SO_2 absorption tower, dewatering systems, flue gas handling systems (booster fans and ductwork) and support systems. BOP costs include a wet stack, make-up water treatment plant, electrical subcontract, foundations subcontract and repair/upgrade of the existing railroad tracks for limestone delivery. The results of the capital cost estimate are given in Table 3.5-1.

CUECost includes a cost estimate for a wet stack, but based upon Burns & McDonnell's recent experience with wet stack construction costs, this estimate was deleted from the CUECost results and

TABLE 3.5-1 – Capital Cost Estimate for LOS Unit 2 Wet FGD System

DIRECT COSTS	Estimated Cost ($2005)	General Facilities Markup (15%)	Total Direct Cost
Reagent Prep System	$15,300,000	$2,300,000	$17,600,000
SO_2 Absorption System	$32,180,000	$4,830,000	$37,010,000
Flue Gas Handling System	$12,170,000	$1,830,000	$14,000,000
ByProduct Handling System	$2,190,000	$330,000	$2,520,000
Support Equipment	$2,650,000	$400,000	$3,050,000
	FGD Total Direct Cost =		**$74,180,000**
BOP COSTS			
Wet Stack	$10,660,000	NA	$10,660,000
Water Treatment Equipment	$1,300,000	NA	$1,300,000
Evaporation Pond	$1,850,000	NA	$1,850,000
Electrical Subcontract	$6,900,000	NA	$6,900,000
Foundations Subcontract	$2,390,000	NA	$2,390,000
Relocate Pipe Rack	$390,000	NA	$390,000
Extend Ductwork	$5,720,000	NA	$5,720,000
Railroad Upgrade/Repair	$130,000	NA	$130,000
	BOP Total Direct Cost =		**$29,330,000**
	Total Direct Cost =		**$103,490,000**
INDIRECT COSTS			
Contingency (20% of DC)			$20,700,000
A/E Engineering and Construction Management (10% of DC)			$9,910,000
BEPC INDIRECTS			
Project Development (1% of DC)			$1,034,900
Spare Parts & Plant Equipment			
Rolling Stock			$1,000,000
Initial Inventory Spare Parts (1.5% of DC)			$1,550,000
Plant Furnishings (0.5% of DC)			$520,000
Construction Startup and Support			
O&M Staff Training (0.5% of DC)			$520,000
Construction All-Risk Insurance (1.5% of DC)			$1,550,000
Allowance For Funds During Construction (AFDC 6%)			$6,210,000
Contingency (15% of BEPC Indirects)			$690,000
Indirect Cost Subtotal			$44,120,000
Total Capital Cost			**$147,600,000**

a revised estimate by Burns & McDonnell was included in the BOP costs. The new stack estimate includes an alloy C-276 liner for the wet stack. The new wet stack was assumed to be 500' in height.

The BOP costs include make-up water treatment equipment costs for pumps, piping, filters, and a clarifier. An estimated building cost for the makeup water treatment system is included in the Foundations Subcontract estimate.

Also included in the Foundations Subcontract cost estimate are roofed, two-walled enclosures for limestone and gypsum temporary storage to provide for weather protection.

An evaporation pond for disposal of blowdown, for chloride control, was included in the capital cost estimate. Railroad delivery of limestone, utilizing the west spur crossing the main plant entrance road was assumed for the cost estimate. The railroad track estimate includes the cost of upgrading of approximately 1,500 feet of railroad track to provide for limestone delivery to the LOS Unit 2 limestone railcar unloading station. The estimate also includes refurbishment of approximately 400 feet of track past the railcar unloading position for flexibility in car positioning.

The total estimated capital cost for a complete, stand-alone wet FGD system utilizing limestone reagent and forced oxidation is $147,600,000, or $335/kW for LOS Unit 2.

3.5.1.2 CIRCULATING DRY SCRUBBER CAPITAL COST ESTIMATE

The Circulating Dry Scrubber (CDS) FGD technology is a relatively recent innovation in the United States, but has been used previously in Europe. Cost information on the CDS system is not as widely available as the more common wet and semi-dry systems. Capital costs for the CDS system were based on CUECost estimates for the SDA semi-dry FGD system with modifications to reflect the design and operational differences. Several literature sources[5, 6] and Burns & McDonnell in-house information were utilized in making these modifications. The CDS cost estimate is presented in a line item format with individual items adjusted to reflect differences between the CDS and SDA. The capital cost estimate is presented in Table 3.5-2.

The CDS absorber vessel is similar to the SDA, but smaller in diameter to provide for a greater gas velocity to make fluidized bed operation possible. The cost of the CDS absorber vessel was estimated at 80% of the cost of the SDA absorber vessel.

TABLE 3.5-2 – Capital Cost Estimate for LOS Unit 2 CDS FGD System

DIRECT COSTS	Estimated Cost ($2005)	General Facilities Markup (15%)	Total Direct Cost
CDS System			
Reagent Prep System	$16,210,000	$2,430,000	$18,640,000
SO_2 Absorption System	$16,990,000	$2,550,000	$19,540,000
Flue Gas Handling System	$11,340,000	$1,700,000	$13,050,000
ByProduct Handling System	$3,620,000	$540,000	$4,160,000
Support Equipment	$3,600,000	$540,000	$4,140,000
		CDS Total Direct Cost =	**$59,530,000**
Fabric Filter			
Fabric Filter Housing	$14,880,000	$2,230,000	$17,110,000
Bags	$2,690,000	$400,000	$3,090,000
Ash Handling System	$10,990,000	$1,650,000	$12,640,000
Instruments & Controls	$510,000	$80,000	$580,000
		Fabric Filter Total Direct Cost =	**$33,420,000**
BOP Costs			
Dry Stack	$8,530,000	NA	$8,530,000
Water Treatment Equipment	$1,220,000	NA	$1,220,000
Electrical Subcontract	$6,900,000	NA	$6,900,000
Foundations Subcontract	$2,050,000	NA	$2,050,000
Relocate Pipe Rack	$360,000	NA	$360,000
Extend Ductwork	$5,720,000	NA	$5,720,000
Railroad Upgrade/Repair	$130,000	NA	$130,000
		BOP Total Direct Cost =	**$24,900,000**
		Total Direct Cost =	**$117,850,000**
INDIRECT COSTS			
		Contingency (20% of DC)	$23,570,000
		A/E Engineering and Construction Management (10% of DC)	$11,080,000
BEPC INDIRECTS			
		Project Development (1% of DC)	$1,180,000
	Spare Parts & Plant Equipment		
		Rolling Stock	$1,000,000
		Initial Inventory Spare Parts (1.5% of DC)	$1,770,000
		Plant Furnishings (0.5% of DC)	$590,000
	Construction Startup and Support		
		O&M Staff Training (0.5% of DC)	$590,000
		Construction All-Risk Insurance (1.5% of DC)	$1,770,000
		Allowance For Funds During Construction (AFDC 6%)	$7,070,000
		Contingency (15% of BEPC Indirects)	$770,000
		Indirect Cost Subtotal	$50,090,000
		Total Capital Cost	**$167,900,000**

Because the CDS recirculates a much greater fraction of the flyash and absorber reaction products (80-95% vs. 30%) than the SDA, the byproduct handling system cost for the SDA was increased by 100% for the CDS estimate to account for the greater system capacity requirements.

The estimated cost for ancillary support equipment was also based on the SDA estimate from CUECost. The CUECost estimate for these systems for the SDA was increased by 10% to reflect the additional reagent usage and higher recycle flow rate.

The CUECost estimate for SDA flue gas handling systems was increased by 10% to account for the additional booster fan capacity required to accommodate the greater pressure drop of the CDS. Ductwork costs were assumed not to change due to the CDS configuration versus the SDA.

Because the CDS recirculates a much greater fraction of flyash and absorber reaction products than the SDA, the estimated cost for the ash handling system was increased 86% over the CUECost estimate for the SDA.

A new dry stack was included in the BOP capital cost estimate. It was assumed that the CDS facility would be in a new location and returning the ductwork to the existing stack would be cost prohibitive.

Included in the Foundations Subcontract cost estimate is a silo for temporary storage of waste products prior to transport to the permitted waste disposal facility.

Railroad delivery of lime, utilizing the west spur crossing the main plant entrance road was assumed for the cost estimate. The railroad track estimate includes the cost of upgrading approximately 1,500 feet of railroad track to provide for lime delivery to the LOS Unit 2 railcar unloading station. The estimate includes refurbishment of approximately 400 feet of track past the railcar unloading position for flexibility in car positioning.

The total estimated capital cost estimate for a complete, stand-alone CDS with Fabric Filter for SO_2 control for LOS Unit 2, utilizing hydrated lime as a reagent is \$167,900,000, or \$382/kW.

3.5.1.3 SEMI-DRY FGD CAPITAL COST ESTIMATE

Estimated direct costs for the semi-dry FGD system include the SDA, fabric filter, major support facilities and BOP costs. The SO_2 control system cost is representative of a typical furnish and erect contract by a lime SDA/FF system supplier and is presented in Table 3.5-3. The SDA/FF system costs estimated by CUECost are broken down into the major subsystems of reagent preparation, spray dryer absorber, waste handling systems, flue gas handling systems (booster fans and ductwork) and support systems. A fabric filter is included in the estimate for the capture of entrained absorption products. BOP costs include an electrical subcontract, foundations subcontract, water treatment equipment and repair/upgrade of the existing railroad tracks for lime delivery.

A new dry stack was included in the BOP capital cost estimate. It was assumed that the CDS facility would be in a new location and returning the ductwork to the existing stack would be cost prohibitive.

Included in the Foundations Subcontract cost estimate is a silo for temporary waste product storage.

Railroad delivery of lime, utilizing the west spur crossing the main plant entrance road was assumed for the cost estimate. The railroad track estimate includes the cost of upgrading approximately 1,500 feet of railroad track to provide for lime delivery to the LOS Unit 2 railcar unloading station. The estimate includes refurbishment of approximately 400 feet of track past the railcar unloading position for flexibility in car positioning.

The total estimated capital cost estimate for a complete, stand-alone lime SDA FGD system with a fabric filter, utilizing lime as a reagent is $155,700,000, or $354/kW for LOS Unit 2.

TABLE 3.5-3 – Capital Cost Estimate for LOS Unit 2 Semi-Dry FGD System

DIRECT COSTS	Estimated Cost ($2005)	General Facilities Markup (15%)	Total Direct Cost
Semi-Dry FGD System			
Reagent Prep System	$13,080,000	$1,960,000	$15,040,000
SO_2 Absorption System	$20,740,000	$3,110,000	$23,850,000
Flue Gas Handling System	$10,310,000	$1,550,000	$11,860,000
ByProduct Handling System	$1,770,000	$270,000	$2,040,000

Total Capital Cost			**$155,700,000**

3.5.1.4 FLASH DRYER ABSORBER CAPITAL COST ESTIMATE

The Flash Dryer Absorber (FDA) is a relatively recent development of the semi-dry FGD process. The same methodology used for estimating the FDA capital costs for Unit 1 in Section 3.4.1.4 is used for Unit 2 with exceptions provided below. The results of the capital cost estimate for the FDA and Fabric Filter, along with BOP requirements, is provided in Table 3.5-4.

An estimate is provided for a new stack for Unit 2. For the purposes of this study, it was assumed that reusing the existing Unit 2 stack would be cost prohibitive.

The total estimated capital cost for the installation of and FDA/FF system on LOS Unit 2 is $147,000,000 or $334/kW.

TABLE 3.5-4 – Capital Cost Estimate for LOS Unit 2 FDA with Fabric Filter

Total Capital Cost			**$147,000,000**

3.5.1.5 FUEL SWITCHING CAPITAL COST ESTIMATE

The potential for switching to PRB fuel for LOS Unit 2 was investigated by BEPC and an internal report was generated in 1997[1]. This report examined the test burn of a PRB coal similar to the current PRB coal used in the current blended fuel. From the 1997 report, a switch to 100% PRB usage at LOS Unit 2 would impact the operating and maintenance costs, but significant capital expenditures for modification of the coal handling system were not identified. The results of the cost estimate for the fuel switching alternative are given in Table 3.5-5. One significant problem that was identified was the unloading time of the coal delivery trains. Current rail car parking capacity is limited and with the current rail system configuration part of the coal train would have to be parked on the main line while unloading. The potential solutions to this particular problem are not analyzed in the report, though it is mentioned that it is possible the railroad operator can adjust to this condition. A cost estimate for potential rail line modifications was not included in this report because this question could not be resolved during the short test period.

The cost of a flue gas conditioning system was included to maintain ESP performance for this alternative. The capital cost estimate for the flue gas conditioning system includes the dry sulfur unloading station, dry sulfur storage hopper, transfer conveyance from storage hopper to sulfur melter, sulfur metering pump skid with MCC and variable speed drives, SO_3 production skid and injection probes with metering ports.

Additional capital investments may be required for a switch to PRB fuel, including construction of fuel barns and the installation of additional conveyors, but those costs were not identified as part of this study. The total capital investment for the fuel switching alternative, including flue gas conditioning, is estimated to be $1,247,000 or $2.83/kW for LOS Unit 2.

TABLE 3.5-5 – Capital Cost Estimate for Fuel Switching with Flue Gas Conditioning

Direct Costs	**Estimated Cost ($2005)**
Injection System	$884,000
Unloading Station	(Included Above)
Storage Hopper	(Included Above)
Transfer Conveyor	(Included Above)
Metering Pump Skid	(Included Above)
SO_3 Production Skid	(Included Above)
Injection Probes	(Included Above)
Total Direct Cost	**$835,000**
INDIRECT COSTS Contingency (20% of DC)	$177,000
A/E Engineering and Construction Management (10% of DC)	$88,000
Allowance for Funds During Construction (AFDC 6%)	$53,000
BEPC INDIRECTS Project Development (1% of DC)	$9,000
Spare Parts & Plant Equipment	
Initial Inventory Spare Parts (1.5% of DC)	$13,000
Construction Startup and Support	
O&M Staff Training (0.5% of DC)	$4,000
Construction All-Risk Insurance (1.5% of DC)	$13,000
Contingency (15% of BEPC Indirects)	$6,000
Indirect Cost Subtotal	$363,000
Total Capital Cost	**$1,247,000**

3.5.1.6 WET FGD O&M COST ESTIMATE

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). These costs were developed as part of the CUECost model and include operating labor, administrative and support labor and maintenance. Table 3.5-6 summarizes the O&M cost estimates for the wet FGD system.

The fixed costs include operating labor, administrative and support labor and the maintenance material and labor costs. The maintenance material and labor cost was estimated as approximately 3% of the wet FGD system direct capital cost in Table 3.5-1. Administrative and support labor cost was estimated as 12% of the maintenance material and labor cost plus 30% of the operating labor costs. Previous studies and guidelines for FGD O&M costs by EPRI and others are in line with these percentages.

TABLE 3.5-6 – O&M Cost Estimate for LOS Unit 2 Wet FGD System

Fixed Costs	
Operating Labor	$2,330,000
Admin and Support labor	$1,020,000
Maintenance Material and Labor	$2,680,000
Total Fixed O&M Cost =	$6,030,000
Variable Costs	
Limestone Reagent	$3,340,000
Byproduct Disposal	$1,190,000
Water	$550,000
Auxiliary Power	$3,100,000
Total Variable O&M Cost =	$8,180,000
Total Annual O&M Cost =	**$14,210,000**
Net Annual O&M Cost ($/MWh)	**$4.34**

The operating labor cost is based on a total of 19 additional personnel, including two operators per shift (one in the control room and one on roving duty) with two truck drivers at 40 hours per week for hauling of FGD wastes and three laborers on day and second shifts and one on roving assignment. In addition, four maintenance staff working one shift per day, five days per week, plus two for weekend duty are included in the maintenance cost estimate.

Variable costs include reagent, makeup water, FGD byproduct disposal and auxiliary power costs. The estimated annual costs for these consumables are based on consumption rates modeled by the CUECost model and the unit cost information provided by BEPC and described in Table 1.2-3 Economic Design Criteria. A cost of $5.50 per ton for hauling the FGD wastes was included for waste disposal. No additional cost for landfilling at the permitted solid waste facility was included. The LOS Unit 2 estimated annual O&M costs are $14,210,000 or $4.34/MWh.

3.5.1.7 CIRCULATING DRY SCRUBBER O&M COST ESTIMATE

Estimated O&M costs for the CDS/FF alternative were developed from the CUECost estimate of the O&M costs for the SDA/FF alternative. The operating labor was increased by 8% over that of the SDA as indicated in a recent study by Sargent & Lundy[5] comparing the two alternative technologies. The CDS reagent usage was also increased 7% above that for the SDA. Waste disposal costs were increased 5% over those of the SDA, as estimated by CUECost, to reflect the increased reagent wastage. The power requirement for the CDS was increased 18% over that estimated by CUECost for the SDA based upon Sargent & Lundy's findings[5]. The estimated annual O&M costs for application of the CDS/FF alternative at LOS Unit 2 are given in Table 3.5-7.

TABLE 3.5-7 – O&M Cost Estimate for LOS Unit 2 CDS/FF System

Fixed Costs	
Operating Labor	$1,860,000
Admin and Support labor	$740,000
Maintenance Material and Labor	$2,440,000
Total Fixed O&M Cost =	$5,040,000
Variable Costs	
Lime Reagent	$8,740,000
Byproduct Disposal	$1,460,000
Water	$230,000
Auxiliary Power	$2,430,000
Total Variable O&M Cost =	$12,870,000
Total Annual O&M Costs	**$17,910,000**
Net Annual O&M Cost ($/MWh)	**$5.16**

3.5.1.8 SEMI-DRY FGD O&M COST ESTIMATE

The O&M cost estimate for the SDA/FF alternative was taken directly from CUECost. Lime usage was set at 1.80 lbmol of lime (CaO) per lbmol of SO_2 removed. A ratio of 5.5 lb of recycled solids per pound of lime added and a 35% solids slurry were also set as design conditions in CUECost. A total of 11" w.g. pressure drop across the combined SDA/FF system was also utilized as a design condition. The Fabric Filter was sized for a gas-to-cloth ratio of 3.5 ACFM/Ft^2. A three year bag life was assumed. The results of the SDA/FF O&M cost estimate are summarized in Table 3.5-8.

TABLE 3.5-8 – O&M Cost Estimate for LOS Unit 2 SDA/FF System

Fixed Costs	
Operating Labor	$1,670,000
Admin and Support labor	$770,000
Maintenance Material and Labor	$2,260,000
Total Fixed O&M Cost =	$4,700,000
Variable Costs	
Lime Reagent	$8,170,000
Byproduct Disposal	$1,390,000
Water	$230,000
Auxiliary Power	$2,050,000
Total Variable O&M Cost =	$11,850,000
Total Annual O&M Costs	**$16,550,000**
Net Annual O&M Cost ($/MWh)	**$4.77**

3.5.1.9 FLASH DRYER ABSORBER O&M COST ESTIMATE

The FDA/FF O&M costs were estimated from a combination of the CUECost estimate for the SDA/FF system and vendor materials. The operating labor for the FDA/FF were taken directly from the SDA/FF estimate because the FDA/FF system operation is no more technically complex than the SDA/FF. Maintenance costs were estimated as 90% of the SDA/FF maintenance cost estimated by CUECost. Reagent usage and waste solids generation rates were taken from information supplied by Alstom for the current fuel blend, increased for the additional sulfur content of the design fuel and the costs determined from the economic information in Table 1.2-3. Auxiliary power costs for the SDA/FF system were increased 10% for the FDA/FF usage. The results of the FDA/FF O&M cost estimate are given in Table 3.5-9.

TABLE 3.5-9 – O&M Cost Estimate for LOS Unit 2 FDA/FF System

Fixed Costs	
Operating Labor	$1,670,000
Admin and Support labor	$710,000
Maintenance Material and Labor	$2,090,000
Total Fixed O&M Cost =	$4,470,000
Variable Costs	
Lime Reagent	$8,450,000
Byproduct Disposal	$1,540,000
Water	$180,000
Auxiliary Power	$2,160,000
Total Variable O&M Cost =	$12,320,000
Total Annual O&M Costs	**$16,800,000**
Net Annual O&M Cost ($/MWh)	**$4.84**

3.5.1.10 FUEL SWITCHING O&M COST ESTIMATE

In the 1997 report[1] on the PRB test burn, BEPC reported several operational advantages to the use of PRB in LOS Unit 2. These included reduced station service (from 7.6 to 7.2%), reduced sulfur emissions and reduced ash quantities. The test report specifically mentions that although some features of PRB firing were documented, the test duration was extremely short and many potential long term impacts were neither investigated nor documented. Additional O&M cost might result from unknown impacts caused by a fuel switch. For the purpose of estimating impacts of a switch to 100% PRB fuel on the operating and maintenance costs of LOS Unit 2, the changes in fuel cost, station service costs and ash disposal were estimated based on the report contents and are summarized in Table 3.5-10.

The change in fuel cost calculated to result from a switch to 100% PRB was based upon the design heat input to LOS Unit 2, taking into account a 2.1% increase in boiler efficiency (at full generation). The station service benefit was calculated as the net decrease in station service based on operating costs given in Table 1.2-3. Because PRB has a significantly lower ash content, a credit for reduction in both bottom ash and flyash disposal costs is also included. The annual additional O&M cost of switching LOS Unit 2 to PRB is estimated to be $11,213,000 or $2.91/MWh.

TABLE 3.5-10 – O&M Cost Estimate for LOS Unit 2 Fuel Switching

Fuel Cost Change Reduced Station Service Change in Ash Disposal Cost	$11,743,000 -$292,900 -$449,100
Flue Gas Conditioning Reagent	$200,000
Flue Gas Conditioning Equipment Maintenance	$12,000
Total Annual Change to O&M Cost	**$11,213,000**
Total Annual Change to O&M Cost ($/MWh)	**$2.91**

3.5.1.11 LEVELIZED TOTAL ANNUAL COST

The Levelized Total Annual Cost (LTAC) for all alternatives were calculated based on economic conditions given in Table 1.2-3 and a 20 year project life. The LTAC was calculated for each alternative utilizing the estimated costs in Tables 3.5-1 through 3.5-10 and the economic conditions described in Section 1 of this report. Estimated capital costs were split evenly over a two year construction period for all alternatives. A system startup date of December 17, 2013 was used based upon the projected timing of Regional Haze Rule implementation given by NDDH. O&M costs were included through the end of the calendar year 2034. No salvage value was assumed at the end of the service life for any of the alternatives. The LTAC for each alternative are presented below in Table 3.5-11.

The annual tons of SO_2 reduction in this study are calculated for two cases. One case is the difference between the uncontrolled Historical emissions and the controlled emissions for the Future PTE case. The second case is the difference between uncontrolled emissions and controlled emissions for the Future PTE case.

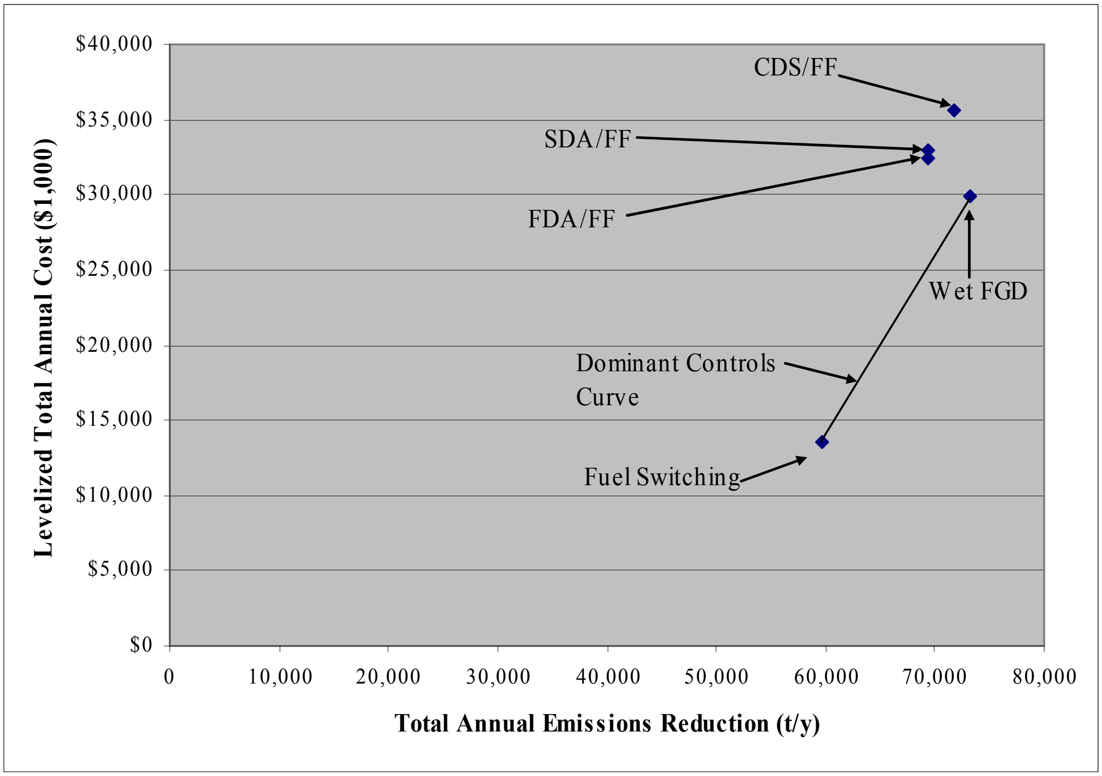
TABLE 3.5-11 – Levelized Total Annual Costs of Unit 2 BART SO_2 Control Alternatives(1)

BART Alternative	Control Efficiency	Annual Emission Reduction from Historical Case (tpy)(2)	Annual Emission Reduction from Future PTE Case (tpy)(3)	Installed Capital Cost ($2005)	Annual O&M Cost ($2005)	Levelized Total Annual Cost ($2005)(4)
Wet FGD	95%	35,568	73,272	$147,600,000	$14,210,000	$29,840,000
CDS/FF	93%	34,025	71,729	$167,900,000	$17,910,000	$35,580,000
SDA/FF	90%	31,711	69,415	$155,700,000	$16,550,000	$32,890,000
FDA/FF	90%	31,711	69,415	$147,000,000	$16,800,000	$32,430,000
Fuel Switch	77%	21,685	59,620	$1,247,000	$11,213,000	$13,490,000

(1) - All Costs in 2005 dollars.
(2) - Annual emission reduction is uncontrolled Historical emissions minus controlled Future PTE emissions.
(3) - Annual emission reduction is uncontrolled emissions minus controlled emissions for Future PTE case.
(4) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

Figure 3.5-1 is a plot of the Levelized Total Annual Cost versus the annual removal in tons (Future PTE case basis) for each BART alternative shown in Table 3.5-11. A similar graphic analysis was not presented for the Historic case due to the similarity to the Future PTE case analysis. The purpose

FIGURE 3.5-1 – LOS Unit 2 SO_2 Least Cost Envelope for Future PTE Case



of Figure 3.5-1 is to identify the Dominant Controls Curve which is the rightmost boundary of the control cost envelope. The Dominant Controls Curve is the best fit line through the points forming the rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual removal tonnage for the various BART alternatives. Points distinctly above or to the left of this curve are inferior control alternatives on a cost effectiveness basis. Of the technically feasible BART alternatives considered for LOS Unit 2, data points for the CDS, the SDA and the FDA all lie distinctly above the least cost boundary of the control cost envelope. The reason for this is clear from Table 3.5-12 where the unit control costs for all of the BART alternatives are listed. In a top down analysis each of the SO_2 control technologies represented by a data point above the Dominant Control Curve could be excluded from further analysis on a cost effectiveness basis.

TABLE 3.5-12 – Unit Control Costs of Unit 2 BART SO_2 Control Alternatives

BART Alternative	Control Efficiency	Levelized Total Annual Cost ($2005)[1]	Annual Emission Reduction from Historical Case (tpy)	Historical Case Unit Control Cost ($/ton)	Annual Emission Reduction from Future PTE Case (tpy)	Future PTE Case Unit Control Cost ($/ton)
Wet FGD	95%	$29,840,000	35,568	$839	73,272	$407
CDS/FF	93%	$35,580,000	34,025	$1,046	71,729	$496
SDA/FF	90%	$32,890,000	31,711	$1,037	69,415	$474
FDA/FF	90%	$32,430,000	31,711	$1,023	69,415	$467
Fuel Switch	77%	$13,490,000	21,685	$622	59,620	$226

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

The next step in the cost effectiveness analysis for the remaining BART alternatives is to review the incremental cost effectiveness between a given alternative and those above or below it on the Dominant Controls Curve. Table 3.5-13 contains a repetition of the cost and control information from Table 3.5-11 and the incremental cost effectiveness between each dominant control alternative.

TABLE 3.5-13 – Incremental Cost Effectiveness of Unit 2 BART SO_2 Control Alternatives

BART Alternative	Levelized Total Annual Cost ($2005)(1)	Annual Emission Reduction from Historical Case (tpy)	Incremental Cost Effectiveness for Baseline Case ($/t)	Annual Emission Reduction from Future PTE Case (tpy)	Incremental Cost Effectiveness for Future PTE Case ($/t)
Wet FGD	$29,840,000	35,568	$1,380	73,272	$1,406
Fuel Switching	$13,490,000	21,685	NA	59,620	NA

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

In the BART Determination guidelines, EPA does not provide definition, or even discussion of reasonable, or unreasonable, Unit Control Costs. Similarly, EPA does not address reasonable or unreasonable ranges for the incremental cost effectiveness. The incremental cost effectiveness is a marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the Dominant Control Cost curve) between successively less effective alternatives. The incremental cost effectiveness for wet FGD versus fuel switching in Table 3.5-13 is within the range of reasonable costs used in other regulatory analyses and thus does not indicate that wet FGD is prohibitively expensive.

The cost analysis portion of the BART determination for LOS Unit 2 has shown that none of the Unit Control Costs for the dominant alternatives are exceedingly expensive on a Unit Control Cost basis. However, three of the BART alternatives were established as being inferior based upon the Dominant Controls Curve. Unlike the Unit 1 SO_2 BART analysis, the range of the estimated LTACs (± 20%) for Unit 2 post combustion controls approaches much closer to the estimate accuracy (± 30%). Similarly, the range for the post combustion control alternative Unit Control Costs (± 25%) is much closer to the estimate accuracy. For this reason, the Unit 2 cost impact analysis results were interpreted to indicate that further analysis for the recommended SO_2 BART for LOS Unit 2 should be limited to alternatives on the Dominant Control Curve.

Considering the results of the cost impact analysis for LOS Unit 2, fuel switching (77%) was identified as a significantly inferior alternative to presumptive BART. Further, the remaining alternative, wet FGD, achieving 95% SO_2 emission reduction equals presumptive BART and was the recommended alternative at the end of the cost impact analysis. Therefore, Basin Electric Power Cooperative decided that fuel switching should be excluded from further consideration in the study.

This decision leaves wet FGD as the sole SO_2 control alternative for LOS Unit 2 and meets the recommended presumptive BART for units of its size.

3.5.2 ENERGY IMPACTS

The energy impacts of wet FGD, both in terms of estimated kW of energy usage and the percent of total generation, are given in Table 3.5-14. The primary energy impacts of the wet FGD alternative consists of the additional electrical load resulting from pumps, blowers, booster fans, ball mills for limestone grinding and vacuum pumps for byproduct slurry dewatering. Building HVAC and interior and exterior lighting loads are also included, but the major energy consumption is due to the primary systems described above.

TABLE 3.5-14 – Energy Requirements of Unit 2 BART SO_2 Control Alternatives

BART Alternative	Energy Demand (kW)	Percent of Nominal Generation
Wet FGD	9,315	2.1%

3.5.3 NON-AIR QUALITY ENVIRONMENTAL IMPACTS

Non-air quality environmental impacts of the installation and operation of the various BART alternatives include hazardous waste generation, solid and aqueous waste streams, and salable products that could result from the implementation of various BART alternatives.

The captured mercury in the solid waste stream from a wet FGD system is a trace contaminant in the solid waste, not affecting disposal options as long as the waste passes the Toxic Characteristic Leaching Procedure (TCLP), which most FGD system wastes do. Therefore, this potential non-air quality environmental impact was not considered to warrant attention during this analysis.

The wet FGD system for LOS Unit 2 is estimated to produce approximately 28.3 tons per hour of solid wastes. The waste stream would be composed of gypsum solids and inerts at approximately 10% - 15% moisture. Over the course of a year, the total solid waste quantity is estimated to be approximately 248,000 tons of gypsum solids which would be landfilled in the current permitted solid waste disposal facility near the plant.

The annual quantity of aqueous waste that would be produced by the wet FGD system is difficult to quantify because the blowdown rate from a wet FGD system is primarily a function of the dissolved chloride levels in the absorber and recycle tank. Most of the chloride reaching the scrubber is in the form of hydrochloric acid which is readily absorbed and neutralized. Hydrochloric acid removal rates in a typical wet FGD system typically exceed 95%. CUECost estimates 80 lb/hr of hydrochloric acid in the flue gas stream which is assumed to be completely removed by the absorber system. The waste solids stream leaving the wet FGD system contains approximately 15% water which would contain $CaCl_2$ which would not require blowdown for disposal. Assuming the chloride to be present in the blowdown stream as $CaCl_2$ and assuming an average chloride concentration of 9,500 parts per million, one can calculate approximately 80 pounds an hour of chloride would leave the plant in the gypsum wastes. No blowdown specifically for chloride disposal would be required. For the purpose of this analysis, it was assumed that an irregular blowdown stream would be sent to a dedicated evaporation pond on site for disposal.

3.5.4 VISIBILITY IMPACTS

The final impact analysis conducted was to assess the visibility impairment impact reduction for the presumptive BART control level. Visibility impairment impacts due to pre-control historical emissions and post-control (future PTE) emission levels were modeled. CALPUFF was used to model long-range transport of SO_2, NO_X and PM to estimate the visibility impairment impact in deciViews (dV). The reduction in visibility impairment impact due to presumptive SO_2 BART (95% control) was then calculated as the difference between the visibility impairment impact for wet FGD and the pre-control visibility impairment impact.

The BART guidelines state that the comparison should be made at the 98th percentile level (70 FR 39170). However, NDDH directed that the comparison should be made at the 90th percentile. Therefore, the visibility impairment impact reduction presented for each control scenario in this section is based on the 90th percentile value.

CALPUFF modeling was conducted for the application of presumptive BART. The modeling results, expressed as the change in visibility impairment impact, in deciViews (ΔdV) is the change in visibility impairment impact in the affected Class 1 area as a result of the implementation of wet FGD on LOS Unit 2. The visibility improvement for the modeled case is given in Table 3.5-15 for each Class 1 Area. In addition to the average ΔdV values, three other types of data are presented in this table, the number of days exceeding 0.5 dV, the number of days exceeding 1.0 dV and the maximum number of consecutive days exceeding 0.5 dV after implementation of presumptive BART. The 0.5 dV value is the lowest visibility impairment impact that is considered discernible by the human eye and the EPA set this threshold as the point where a given source is considered a "contributing source" (70 FR 39120). The 1.0 dV threshold was established in the final rule as the threshold at which a state should consider a source to be a cause of visibility impairment (70 FR 39120). Therefore, the number of occurrences of each of these impacts is part of the visibility impairment impact analysis. The final criteria, the maximum number of consecutive days in which the visibility impairment impact exceeds 0.5 dV is also tabulated as this is a further measure of the extent of visibility impairment attributable to a given source.

The visibility impairment impact reduction attributable to the application of presumptive BART is given in column 2 of Table 3.5-15. This value is the 90th percentile visibility impairment impact reduction over each modeled year (2000-2002) for each affected Class 1 area. Column 3 of the table lists the three year average impact for each Class 1 Area. The Lostwood National Wildlife Refuge (Lostwood NWR) shows the greatest average visibility impairment impact reduction, thus indicating that this area will gain the greatest benefit from BART implementation of all the Class 1 Areas included in the modeling. The Teddy Roosevelt National Park, Elkhorn site (TRNP-Elkhorn) is shown to gain the least visibility impairment impact reduction from presumptive BART implementation.

A review of Table 3.5-15 finds that the visibility impairment impacts for presumptive BART vary with area and year of modeled results. The greatest number of days exceeding 0.5 dV in column 4 of Table 3.5-15 is shown graphically in Figure 3.5-2 for clarity. Both precontrol and postcontrol modeling results are presented to demonstrate the impact reduction achieved by presumptive BART implementation. The worst impact in terms of days exceeding 0.5 dV after BART implementation

TABLE 3.5-15 – Visibility Impairment Impacts – Unit 2

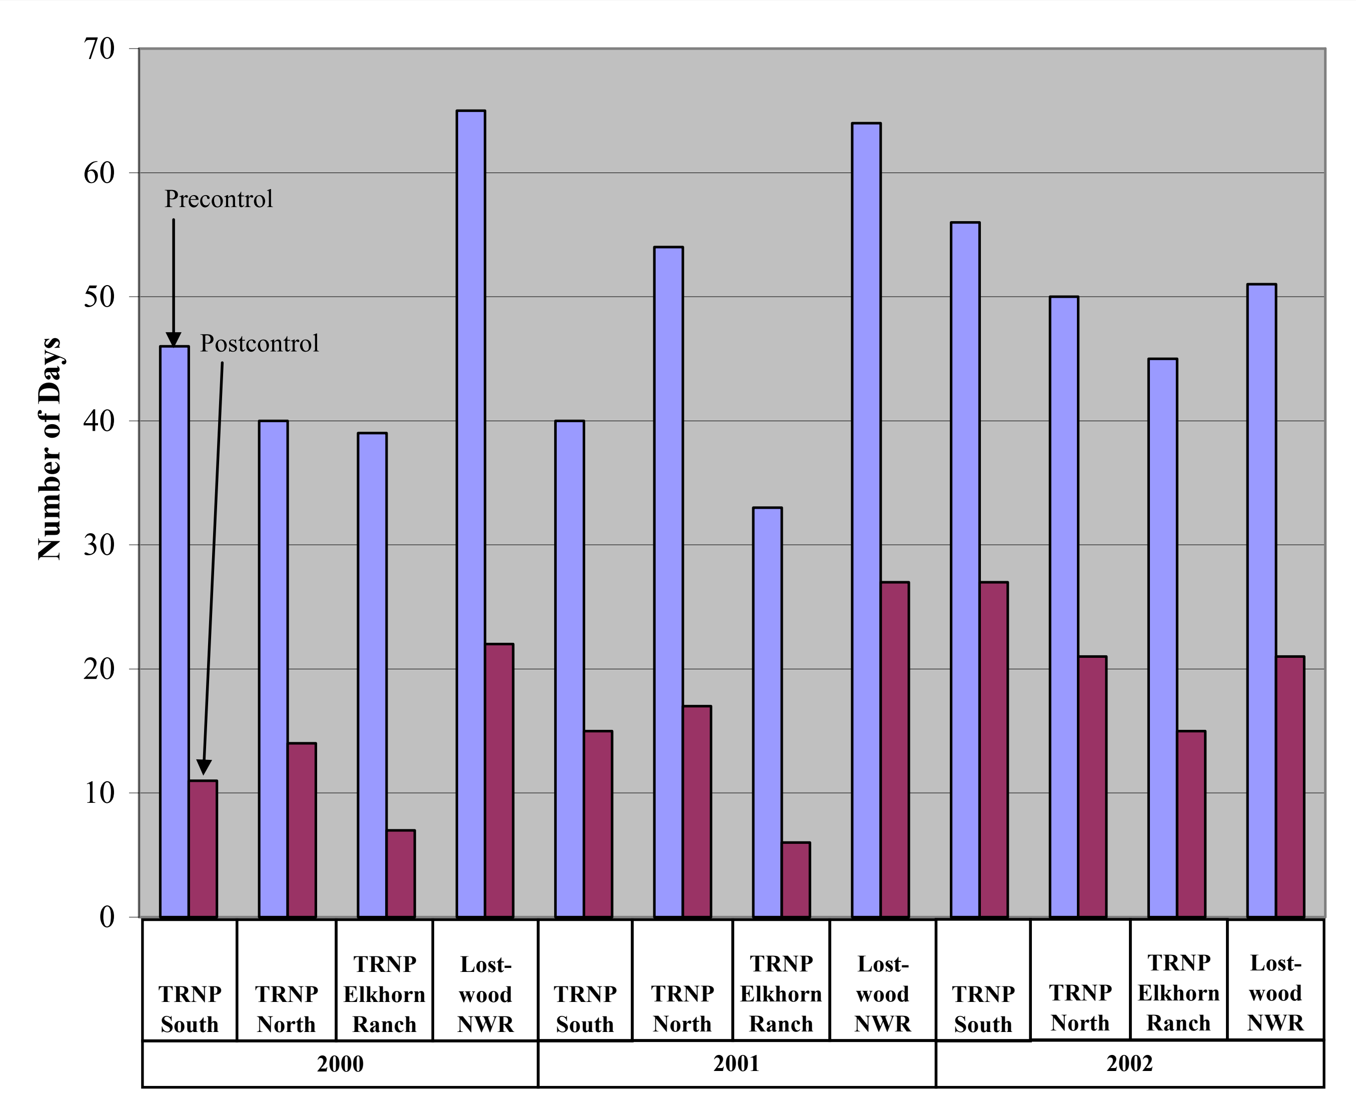
Year And Class 1 Area	Visibility Impairment Reduction (ΔdV)$^{(1),(2)}$	Three Year Average Visibility Impairment Reduction (Δ dV)	Days$^{(2)}$ Exceeding 0.5 dV	Days$^{(2)}$ Exceeding 1.0 dV	Consecutive Days$^{(2)}$ Exceeding 0.5 dV
2000					
TRNP South	0.496	0.586	11	4	2
TRNP North	0.535	0.578	14	6	1
TRNP Elkhorn	0.411	0.415	7	2	1
Lostwood NWR	0.802	0.694	22	6	2
2001					
TRNP South	0.438	0.586	15	2	2
TRNP North	0.646	0.578	17	5	2
TRNP Elkhorn	0.358	0.415	6	1	2
Lostwood NWR	0.693	0.694	27	12	3
2002					
TRNP South	0.825	0.586	27	15	3
TRNP North	0.549	0.578	21	14	3
TRNP Elkhorn	0.475	0.415	15	8	2
Lostwood NWR	0.587	0.694	21	5	3

(1) - 90th percentile visibility impairment impact reduction. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - All values in this table are for combination case of WFGD for SO_2 control and Advanced SOFA for NO_X control.

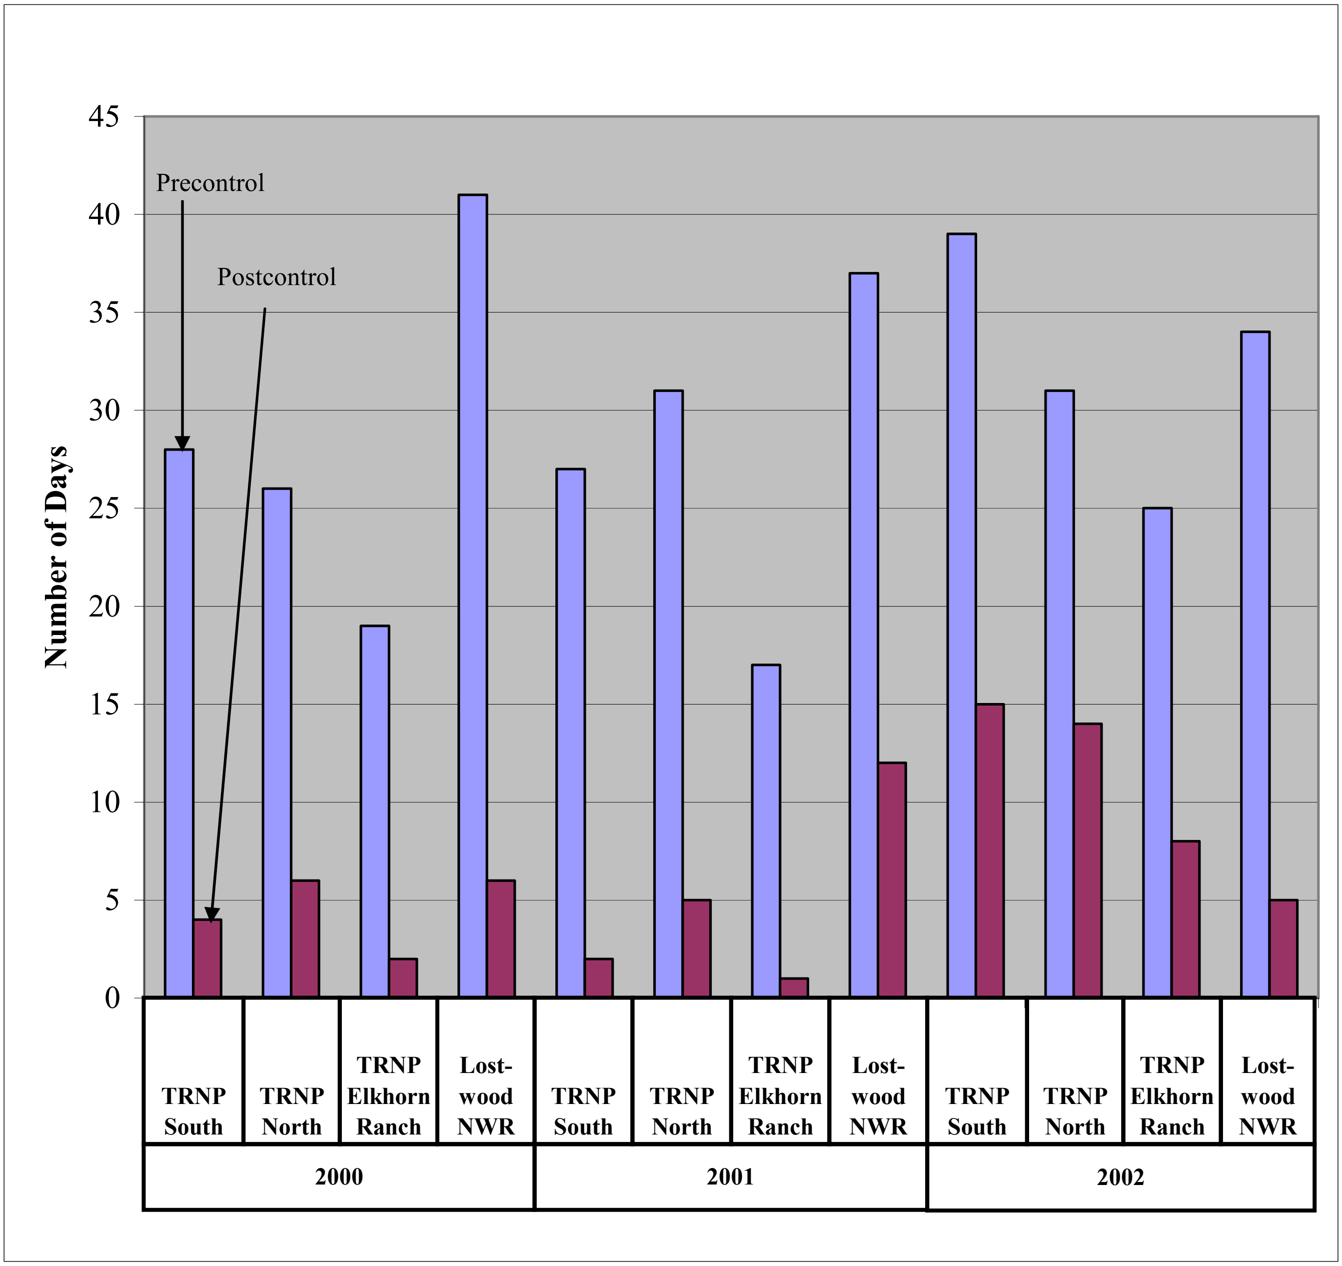
occurs at Lostwood NWR for model years 2000 and 2001. However, in 2002, the greatest number occurs at TRNP South. The TRNP Elkhorn Ranch site consistently exhibits the least number of days exceeding 0.5 dV after BART implementation.

FIGURE 3.5-2 – Number of Days Exceeding 0.5 dV for Pre- and Post-Control



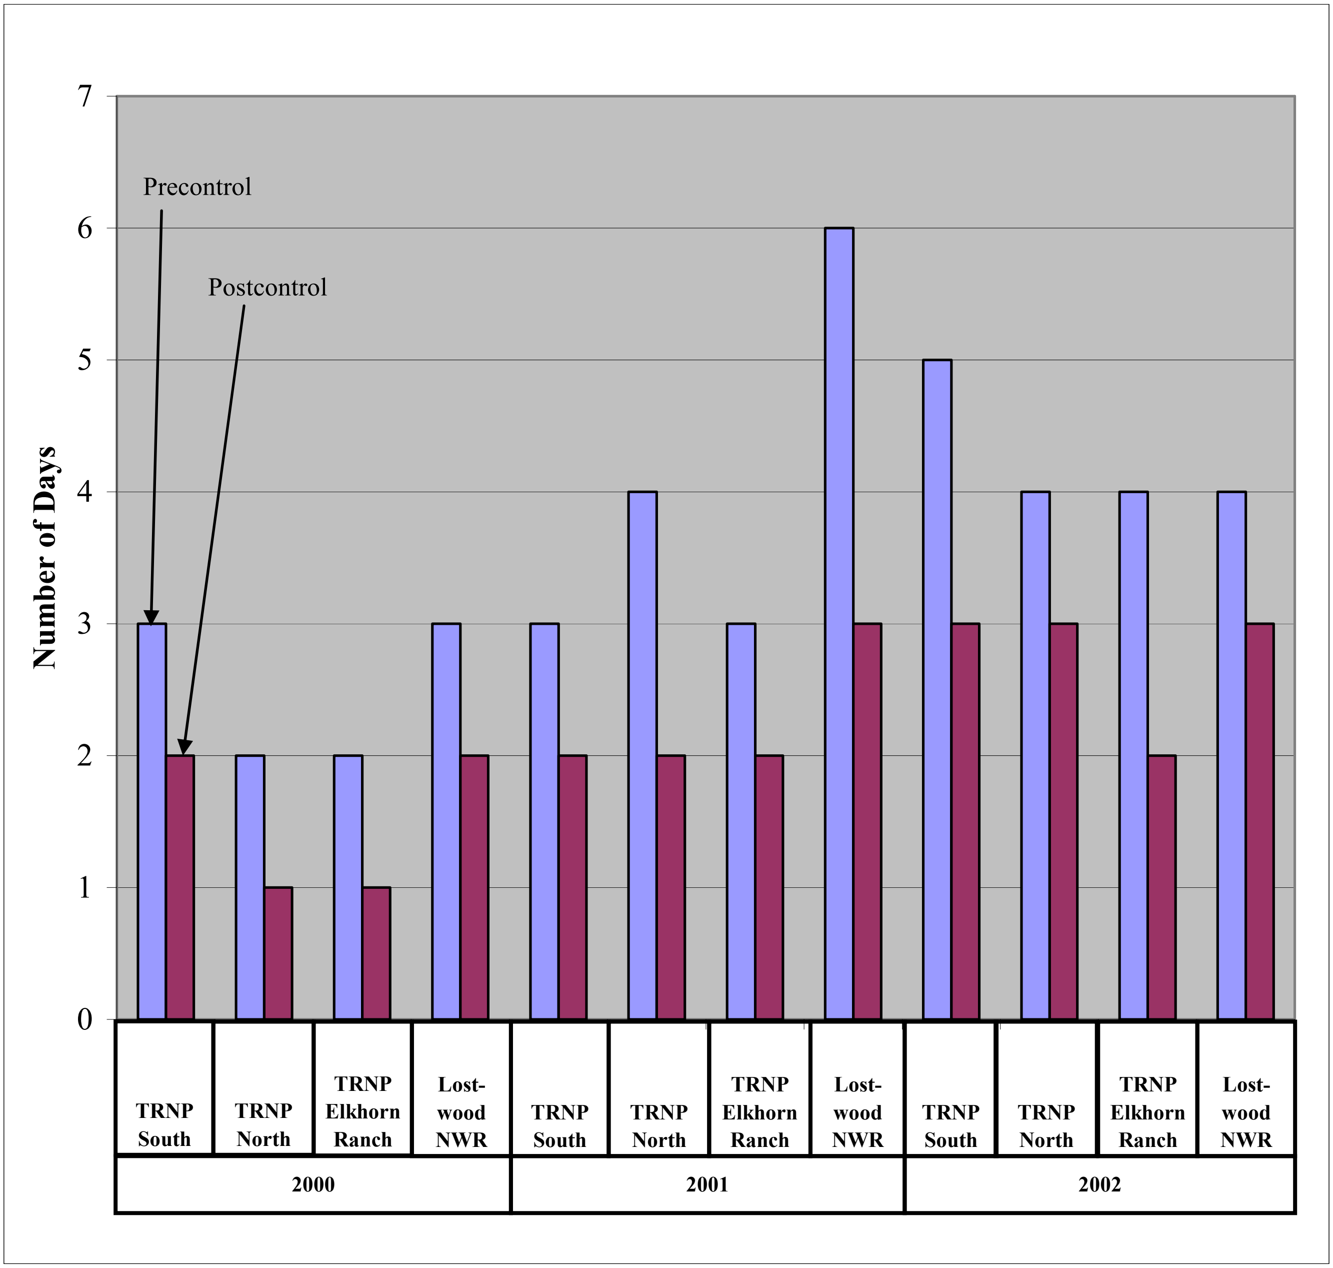
The number of days in a year where the modeled visibility impairment impact exceeded 1.0 dV are listed in column five of Table 3.5-15 and shown graphically in Figure 3.5-3. Both pre-control and post-control modeling results are presented to demonstrate the impact reduction achieved by presumptive BART implementation. The greatest number of days with at least 1.0 dV of impact occurs in both TRNP-North and Lostwood NWR in 2000, in Lostwood NWR in 2001 and TRNP-South in 2002. The least number of days with at least 1.0 dV of impact occurs in TRNP Elkhorn Ranch in 2000 and 2001 and in Lostwood NWR in 2002. This trend is similar to the one observed for the number of post BART implementation days with an impact exceeding 0.5 dV.

FIGURE 3.5-3 – Number of Days Exceeding 1.0 dV for Pre- and Post-Control



The greatest number of consecutive days exceeding 0.5 dV of impact is listed in column six of Table 3.5-15 and shown graphically in Figure 3.5-4. Both precontrol and postcontrol modeling results are presented to demonstrate the impact reduction achieved by presumptive BART implementation. The model year 2000 results are the same for TRNP-North and TRNP Elkhorn Ranch with only one day

FIGURE 3.5-4 – Maximum Consecutive Days Exceeding 0.5 dV for Pre- and Post-Control



occurrences. TRNP-South and Lostwood NWR tie for the highest number of consecutive days at two per year in 2000. The greatest number of consecutive days in 2001 occurs in Lostwood NWR at three days and two days per year for all TRNP sites. In 2002 the model predicts that TRNP-South, TRNP-North and Lostwood NWR would all experience the three consecutive days while the TRNP Elkhorn Ranch site would have only experienced two consecutive days that same year.

The total number of days where the visibility impairment impact exceeded 0.5 dV over the entire modeling period (2000-2002) is greatest for Lostwood NWR. Similarly, the total number of days where the impact exceeded 1.0 dV is greatest for TRNP-North over the model period and the maximum number of consecutive days with impacts greater than 0.5 dV is slightly greater for Lostwood NWR overall. The model results predict that the TRNP Elkhorn Ranch site would have experienced the least overall post BART implementation visibility impacts on all modeled sites.

A review of Table 3.5-15 and Figures 3.5-2 through 3.5-4 clearly demonstrates a significant visibility impairment reduction due to the implementation of presumptive BART (95% SO_2 control), regardless of model year and Class 1 area.

3.5.5 IMPACT SUMMARY

Section 3.5 of this report has analyzed the impacts of BART alternatives for LOS Unit 2. Table 3.5-16 summarizes the results of this analysis. At the conclusion of the cost impact analysis, it was determined that only two of the BART alternatives, wet FGD and fuel switching, were cost effective. The other three alternatives, CDS/FF, SDA/FF and FDA/FF were excluded from further analysis on a cost impact basis. Neither the Unit Control Costs for wet FGD and fuel switching, nor the marginal Unit Control Cost for wet FGD relative to fuel switching were unreasonable. Thus, it was determined that fuel switching at 77% control was clearly inferior to wet FGD as a BART alternative and fuel switching was also excluded from further analysis at the end of the cost analysis. Visibility impact analysis results were presented for the wet FGD alternative in Section 3.5.4. The impact analysis results for wet FGD are summarized in Table 3.5-16.

TABLE 3.5-16 – LOS Unit 2 Impacts Summary for SO_2 Control Alternatives

BART Alternative and Control Efficiency (%)	Annual Emissions Reduction (tpy)	Levelized Total Annual Control Cost ($2005)(1)	Unit Control Cost ($/tons)	Visibility Impairment Impact Reduction		Visibility Impairment Reduction Unit Cost ($/dV)	Energy Impact (kW)	Non Air Quality Impacts
				Class 1 Area	ΔdV(2)			
WFGD 95	73,272	$29,840,000	$407	TRNP-S	0.586	$50,920,000	9,315	Solid and Liquid Wastes
				TRNP-N	0.577	$51,720,000		
				TRNP-Elkhorn	0.415	$71,900,000		
				Lostwood NWR	0.694	$43,000,000		

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

(2) - Average three year change in visibility impairment impact between uncontrolled and controlled emissions for the Future PTE case with both WFGD and ASOFA.

4.0 PARTICULATE MATTER BART EVALUATION

The primary source of particulate matter (PM) associated with a coal-fired boiler is the ash from combustion of the coal. There is also unburned carbon present in the flue gas, which is the result of incomplete combustion that adds to the PM emissions. In this section, steps 1 through 5 of the BART determination for Leland Olds Station (LOS) Units 1 and 2 are described for PM. All PM control technologies are first identified. A technical description of the processes and their capabilities are then reviewed to determine availability and feasibility. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to nominal PM control capability. The impacts analysis then reviews the estimated cost, energy, and non-air quality impacts for each technology. The impact of the remaining useful life of the source was reviewed as part of the cost analysis. In the final step of the analysis, the remaining technologies were assessed for their potential visibility impairment impact reduction capability via visibility modeling results. The results of the complete analyses are tabulated and possible BART control options are listed.

The quantity of uncontrolled PM emissions is a strong function of the type of boiler utilized. Different boiler types generate different splits between bottom ash, which is collected in the bottom of the boiler, and fly ash, which is entrained in the flue gas and becomes boiler particulate matter emissions. Unit 1 is a wall-fired, dry-bottom, pulverized coal boiler with a bottom ash/fly ash split of 30/70 respectively. Unit 2 is a cyclone-fired unit burning crushed coal, with a bottom ash/fly ash split of 70/30 respectively. The design parameters, including coal analysis, unit type, unit size, etc., used in this analysis are displayed in Tables 1.2-1 and 1.2-2.

The BART guidelines published in the Federal Register on July 6, 2005 (70 FR 39104) do not specify presumptive BART levels for particulate matter (PM) emissions. The guidelines suggest the use of PM_{10} as the indicator for all $PM_{2.5}$, because $PM_{2.5}$ emissions are encompassed within the PM_{10} emissions fraction. (70 FR 39160) For modeling purposes, both the BART guidelines and the NDDH protocol specify that a distinction between coarse (PM_{10} minus $PM_{2.5}$) or fine ($PM_{2.5}$) PM be used to determine visibility impacts. The distinction between course and fine particulate was made during CALPUFF visibility modeling.

The BART guidelines indicate that one of the evaluated emission limits must be at least as stringent as the New Source Performance Standard (NSPS) requirement for the source (70 FR 39164). The PM emission limit under NSPS that most closely relates to LOS is 0.1 lb/mmBtu. Therefore, for the purpose of this report, at least one of the evaluated control technologies achieves a PM emission level of 0.1 lb/mmBtu.

4.0.1 FILTERABLE AND CONDENSABLE PARTICULATE MATTER

Particulate matter emissions are composed of filterable and condensable particles. The filterable particles are characterized using EPA standard reference methods (i.e., Method 5, 17, 201, or 201A) and are commonly referred to as the front-half of the particulate sample train. The reference method used for characterization is dependent upon the size of the particle, the temperature of the flue gas, and is usually specified in the applicable permit. Solid particles are captured using a heated filter while the majority of condensable particles are not collected as they are in the gaseous form until after the flue gas has passed through the filter.

As flue gas moves through the different processes associated with each unit, condensable particulate matter (condensable PM) may react with atmospheric or flue gas constituents and then either condense into a droplet, coalesce into a solid particle, or form a solid particle as more volatile components evaporate. Condensable PM is characterized using EPA standard reference Method 202 which is commonly referred to as the back-half of the particulate sampling train. Using Method 202, the flue gas passes through a heated filter to remove filterable PM and condensable flue gas constituents are condensed by bubbling them through water at 20^{o}C. The water is evaporated and the remaining residue is weighed to determine condensable PM emissions. However, Method 202 has an inherent flaw because the means by which condensable particulate is collected differs from how particulate condenses in the stack. Method 202 can provide inaccurate measurements due to the creation of PM artifacts in the sampling water that would not normally condense in the stack plume (e.g., SO_2 and NH_3 compounds). For a fixed operating condition, Method 202 can provide inconsistent emission rate measurements and can result in high emission rates. Thus, there is considerable uncertainty surrounding emissions measured with Method 202 for the purpose of compliance demonstration.

Condensable PM may include both organic and inorganic constituents. Organic constituents in the flue gas can exist as a vapor at stack temperatures and a liquid or solid at ambient temperatures. Control technologies designed to minimize the formation of condensable organic emissions are the same technologies that are used to minimize carbon monoxide (CO) and volatile organic compound (VOC) emissions. A review of the RBLC database shows that good combustion practices are universally used to control CO/VOC emissions for similar units. Both LOS units already practice good combustion practices while maintaining combustion efficiency in the boiler and controlling NO_X emissions. Because good combustion practices are already in use at both units, the organic portion of condensable PM is not addressed further in this report.

Sulfuric acid (H_2SO_4) mist is the most widely recognized form of inorganic condensable PM emitted by combustion sources. Other inorganic condensable PM constituents may include to a lesser extent other acid gases, ammonium sulfate ($(NH_4)_2SO_4$), and unidentified inorganic species. Control technologies designed to reduce sulfuric acid mist will also reduce the other inorganic constituents. H_2SO_4 is typically generated in the flue gas when sulfur trioxide (SO_3) reacts with water. SO_3 is a by-product created during the combustion of fuels containing sulfur and is formed when sulfur dioxide (SO_2) in the flue gas is oxidized. Limited data is available on the quantity of SO_2 that will be converted to SO_3 in a lignite fired unit. Estimates of the conversion range from 0.2 to 1.0 percent.

Combustion controls commonly used to control NO_X (e.g., staged combustion and separated overfire air) provide a co-benefit of sulfuric acid mist control by limiting the oxygen available in the boiler and reducing formation of SO_3 in the boiler. The H_2SO_4 vapor will adsorb on the fly ash as the flue gas cools under appropriate temperature and moisture conditions. Consequently, when those conditions exist, H_2SO_4 mist is removed from the gas stream by particulate control equipment. Control technologies designed to remove SO_2 will also achieve SO_3 removal and reduce emissions of H_2SO_4. Typical SO_3 removal associated a wet FGD process is 40 to 60 percent and higher for semi-dry FGD processes. The Southern Company estimates a 50% reduction in H_2SO_4 emissions for use of wet FGD.[1] Thus, control technologies used to control NO_X through combustion controls, SO_2 through a FGD process and filterable PM through a device to be analyzed in this section of the report are also able to provide H_2SO_4 control.

Under Section 313 of the Emergency Planning and Community Right-to-Know Act (EPCRA), industrial facilities such as LOS must submit information to the State about the annual release of certain chemicals. Three of the main constituents of inorganic condensable PM are included in the chemicals that must be reported. Sulfuric acid mist, hydrogen chloride and hydrogen fluoride are the reported constituents that make up the majority of inorganic condensable PM emissions. During the period from 2000 to 2004 under EPCRA, utilizing the Southern Company estimating procedures, LOS reported a maximum annual condensable particulate release of 0.0029 lb/mmBtu and 0.0025 lb/mmBtu for Unit 1 and Unit 2 respectively. For the same time period LOS reported in their Annual

Emission Inventory report, the average front half particulate emission of 0.027 and 0.032 lb/mmBtu for Unit 1 and Unit 2 respectively. Therefore the total PM Emissions including PM_{10}, $PM_{2.5}$, HCL, HF and H_2SO_4 were approximately 0.030 and 0.034 lb/mmBtu respectively.

Based upon a review of the RACT/BACT/LAER database, the emission limit associated with the current Best Available Control Technology (BACT) for PM from new EGUs, including condensable PM, is approximately 0.03 lb/mmBtu. Because condensable PM is controlled through technologies that will be in place for NO_X, SO_2 and PM, the actual release of the main constituents of inorganic condensable PM are expected to be reduced by a minimum of 50% from the installation of SO_2 controls on each unit.

Recommended BART for condensable PM is the co-benefit of NO_X control through combustion controls, SO_2 control through a FGD process and filterable PM control through a device to be analyzed in this section of the report and is not addressed further. Therefore this BART analysis investigates control methods to reduce filterable PM emissions only.

4.1 IDENTIFICATION OF AVAILABLE RETROFIT PM CONTROL TECHNOLOGIES

The initial step of the BART determination is the identification of available retrofit PM control technologies. In order to produce a list of control technologies and their estimated capabilities, sources such as the RACT/BACT/LAER Clearinghouse (RBLC) were used. The results of the investigation determined that the removal of PM from flue gas is accomplished using post combustion technology. The two most common post combustion technologies used to control PM emissions include fabric filters (FF) and electrostatic precipitators (ESPs). The existing LOS configurations contain ESPs with each control technology rated at 99.1% control. Table 4.1-1 contains the results of the available PM control technologies.

TABLE 4.1-1 – PM Control Technologies Identified for BART Analysis

Control Technology	Approximate Control Efficiency
Fuel Switching with Flue Gas Conditioning w/ ESP	99.1%
Fabric Filter or Baghouse	99.7%
COHPAC Baghouse	99.7%
New Electrostatic Precipitator	99.7%
Existing Unit 1 Electrostatic Precipitator	99.5%
Existing Unit 2 Electrostatic Precipitators	99.1%

4.2 TECHNICAL DESCRIPTION AND FEASIBLITY ANALYSIS

The second step in the BART analysis procedure is a technical feasibility analysis of the options identified in Step 1. This analysis is presented below for each identified option.

4.2.1 FUEL SWITCHING WITH FLUE GAS CONDITIONING

Fuel switching along with flue gas conditioning is a viable method of reducing particulate matter emissions in certain situations. Often, coal combustion facilities are constructed to take maximum advantage of the particular combustion characteristics of a specific fuel. In the case of LOS, the boilers were designed and constructed specifically for firing North Dakota lignite, which is a low Btu content, high ash, high moisture, and medium sulfur content fuel. For this analysis, fuel switching would consist of changing from North Dakota lignite to Powder River Basin (PRB) coal. Technical characteristics associated with fuel switching are described in Appendix C1.

Fly ash conditioning methods installed upstream of an ESP usually involve the injection of a chemical into the flue gas stream to reduce the electrical resistivity of the fly ash. The PRB coal being evaluated with this option contains low concentrations of sulfur (0.43%) while the ash has a relatively high concentration of calcium oxide (24.6%). The low sulfur content and the high alkaline ash both contribute to high resistivity. The low sulfur content limits the amount of sulfur trioxide that is formed while the calcium oxide will preferentially react with the acid and form a non-conducting ash. Therefore, this analysis assumed that flue gas conditioning would be required as part of any fuel switching option.

The most common types of flue gas conditioning systems for this application include humidification of the flue gas, sulfur trioxide injection, ammonia injection, or a combination of these conditioning methods. Because most, if not all, of the humidification process used for flue gas conditioning on

PRB coal have been replaced with another type of conditioning system, humidification was not evaluated in this analysis. Considering the size of the ESPs installed on both LOS units, it was assumed that sulfur trioxide injection alone could effectively reduce the resistivity of the ash and ammonia injection was not evaluated in this analysis.

Switching to a fuel such as PRB and adding a flue gas conditioning system to achieve lower PM emission rates would achieve approximately 50% reduction in PM emissions prior to particulate controls. Assuming that the control efficiency of the existing ESPs when firing PRB coal can be restored by adding a flue gas conditioning system, fuel switching was considered a viable option for PM control.

4.2.2 FABRIC FILTER (FF)

A fabric filter or baghouse removes particulate by passing flue gas through filter bags. A pulse-jet fabric filter (PJFF), a common type of fabric filter, consists of isolatable compartments and a tube sheet which separates the particulate laden flue gas from the clean flue gas. The flue gas passes through the PJFF by flowing from the outside of the bag to the inside up the center of the bag through the hole in the tube sheet and out the PJFF. Fly ash particles are collected on the outside of the bags and the cleaned gas stream passes through the bag to the outlet of the fabric filter. Each filter bag alternates between relatively long periods of filtering and short periods of cleaning. During the cleaning period, fly ash that has accumulated on the bags is removed by pulses of air and falls into a hopper for disposal. Additional technical characteristics associated with fabric filters are described in Appendix C1.

Fabric filters have been proven to control PM with removal efficiency in excess of 99%. It is anticipated that the use of fabric filters on LOS could achieve a filterable PM emission rate of approximately 0.015 lb/mmBtu. Therefore, the use of a fabric filter is a technically feasible option.

4.2.3 COHPAC

A COmpact Hybrid PArticulate Collector (COHPAC) is a high air-to-cloth ratio pulse jet fabric filter located downstream of an existing ESP. The COHPAC acts as a polishing device for control of particulate emissions. The difference between a COHPAC and the fabric filter described above is that a COHPAC is installed after an ESP. The ESP prior to the COHPAC will remove the majority of the fly ash. This allows the COHPAC to have a higher air-to-cloth ratio than a typical fabric filter. The air-to-cloth ratio for a COHPAC unit is typically greater than or equal to 6 ACFM/ft^2 while the air-to-cloth ratio for a typical pulse jet fabric filter is approximately 3.5 to 4.0 ACFM/ft^2.

The advantages and disadvantages of a COHPAC are similar to those mentioned for a fabric filter above; however, there are a few differences worth mentioning. Because the COHPAC has a higher air-to-cloth ratio, it is smaller and less costly than a conventional PJFF. However, the operation of the COHPAC is dependent upon continued operation and maintenance of the ESP.

COHPAC units have been proven to control PM removal efficiencies in excess of 99%. It is anticipated that for LOS Unit 1 or Unit 2, an installed COHPAC could achieve a filterable PM emission rate of 0.015 lb/mmBtu. Therefore, the use of a COHPAC is a technically feasible option.

4.2.4 ELECTROSTATIC PRECIPITATOR (ESP)

ESPs are commonly used as the primary filterable PM control device on coal fired units. The ESP discharge electrodes generate a high voltage electrical field that gives the particulate matter an electric charge (positive or negative). The charged particles will then be collected on a collection plate. Technical characteristics associated with ESPs are described in Appendix C1.

ESPs have proven to control PM in excess of 99%. It is anticipated that a new ESP installed for either unit at LOS could achieve a PM emission rate of approximately 0.015 lb/mmBtu. Therefore, the use of a new electrostatic precipitator is a technically feasible option.

Unit 1 at LOS has an existing ESP that is an older design which achieves lower removal efficiency than a new ESP. The existing ESPs can achieve a filterable PM emission rate of 0.1 lb/mmBtu. Therefore, the existing ESP is a technically feasible option.

Unit 2 at LOS has two parallel existing ESPs that are of an older design which achieves slightly lower removal efficiency than a new ESP. The existing ESPs can achieve a combined filterable PM emission rate of 0.1 lb/mmBtu. Therefore, the existing ESPs are a technically feasible option.

The results of the feasibility analysis for the available BART alternatives following the feasibility analysis are summarized in Table 4.2-1. Every alternative was identified as commercially available, in service on the same or similar services and technically applicable to LOS Units 1 & 2 in a retrofit situation.

TABLE 4.2-1 – BART PM Control Feasibility Analysis Results

Control Technology	In Service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable to Leland Olds Station
Fabric Filter	Yes	Yes	Yes	Yes
COHPAC	Yes	Yes	Yes	Yes
Fuel Switching with Flue Gas Conditioning	Yes	Yes	Yes	Yes
New ESP	Yes	Yes	Yes	Yes
Existing ESPs	Yes	NA	NA	Yes

4.3 RANK OF TECHNICALLY FEASIBLE PM CONTROL OPTIONS BY EFFECTIVENESS

The third step in the BART analysis procedure is to rank the technically feasible alternatives. The BART alternatives remaining in consideration following the feasibility analysis are listed in Table 4.3-1, ranked according to their effectiveness in PM control.

TABLE 4.3-1 – PM Control Technologies Identified for BART Analysis

Control Technology	PM Emission Capability (lb/mmBtu)
COHPAC	0.015
Fabric Filter	0.015
New ESP	0.015
Fuel Switching with Flue Gas Conditioning	0.054
Existing Unit 1 ESP	0.10
Existing Unit 2 ESP	0.10

4.4 EVALUATION OF IMPACTS FOR FEASIBLE PM CONTROLS – UNIT 1

Step four in the BART analysis procedure is the impact analysis. The BART determination guidelines (70 FR 39166) list four factors to be considered in the impact analysis. This BART Determination will consider the following four factors in the impact analysis:

- The costs of compliance;
- Energy impacts;

- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four factors considered in the impact analysis are discussed in the following sections. The factor for the remaining useful life of the source is incorporated as part of the cost of compliance. In addition, as described in Section 1.1.6, the visibility impairment impacts are to be evaluated as part of the analysis. Thus, visibility impairment is included as part of the impacts analysis.

4.4.1 COST OF COMPLIANCE

Cost estimates for all of the Unit 1 particulate control technologies except fuel switching with flue gas conditioning were conducted utilizing the Coal Utility Environmental Cost (CUECost) computer model (Version 1.0) available from the U.S. Environmental Protection Agency. A description of the CUECost model is in Section 3.4.1 of this report. Operating information utilized as input into the model for the purpose of estimating the cost of the particulate control technologies is listed in Table 1.2-1 and 1.2-2. Economic information utilized as input into the model is given in Table 1.2-3. Economic information was provided in 2004 by BEPC in 2004 dollars. The model was run with 2004 designated as the cost basis year because equipment cost estimating in the model is based on the Chemical Engineering Cost Index and the composite 2004 index is the latest version available. Following completion of the estimating with a 2004 cost basis year, all costs were escalated to a 2005 basis year utilizing the inflation rates designated in Table 1.2-3. Burns & McDonnell added estimated Balance of Plant (BOP) costs not included in the CUECost output to the base estimate to provide a more complete cost estimate.

The cost estimate for fuel switching with flue gas conditioning was obtained from vendor quotes. The estimate in this report only includes capital costs for the flue gas conditioning system and does not include any capital costs for fuel switching. As mentioned in Section 3.4.1 of this report, potential rail line modifications may be required to fully implement the fuel switching alternative, but no capital expenditures were included in the report for these modifications. Therefore, all of the costs associated with fuel switching were assumed to be operating and maintenance costs, which are discussed in the Operating and Maintenance Costs section.

4.4.1.1 CAPITAL COSTS

The capital cost estimate is comprised of direct costs and indirect costs. The direct costs for each technology except the flue gas conditioning system include the particulate control system, ash handling system, booster fan, instrument and controls, and balance of plant costs. The particulate control system cost is representative of a typical furnish and erect contract cost by a fabric filter or ESP system supplier. The particulate control system cost estimated by CUECost is broken down into the major subsystems consisting of fabric filter or ESP, ash handling system, booster fan, and instrumentation and controls. It should be noted that a booster fan would not be required for a new ESP as the existing ID fan is sufficient. BOP costs include the electrical subcontract.

The electrical subcontract estimate includes the electrical equipment, materials and labor for engineering, procurement and installation of all electrical distribution system components. The electrical estimate is based on recent experience with the LOS plant and local costs developed during a recent electrical upgrade project at LOS.

The capital cost estimate for the flue gas conditioning system includes the dry sulfur unloading station, dry sulfur storage hopper, transfer conveyance from storage hopper to sulfur melter, sulfur metering pump skid with MCC & variable speed drives, SO_3 production skid, and injection probes with metering ports. The existing ESP would be utilized with this option.

The indirect costs are estimates of additional costs expected to be incurred during fabrication, construction, startup and commissioning. Engineering costs are estimated as a percentage of total direct costs and are representative of the cost for architectural/engineering services such as system design, specification production, contract evaluations and negotiations, contract administration and construction field services. The contingency is estimated as a percent of the total direct costs and accounts for miscellaneous scope items not covered by the direct cost estimate. Finally, the BEPC indirect costs are an estimation of the internal costs that would be incurred by BEPC for a project. The results of the capital cost estimate are given in Table 4.4-1, Table 4.4-2, Table 4.4-3, and Table 4.4-4. The option to utilize the existing ESP does not require any capital expenditure so it is not shown.

TABLE 4.4-1 – Capital Cost Estimate for LOS Unit 1 Fabric Filter

Direct Costs	Estimated Cost ($2005)	General Facilities Markup (15%)	Total Direct Cost
Fabric Filter	$10,810,000	$1,620,000	$12,440,000
Bags	$1,640,000	$250,000	$1,880,000
Ash Handling System	$1,200,000	$180,000	$1,380,000
Booster Fan	$1,390,000	$210,000	$1,600,000
Instruments & Controls	$290,000	$40,000	$330,000

Total Capital Cost	**$1,370,000**

4.4.1.2 OPERATING AND MAINTENANCE COSTS

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). These costs except for fuel switching with flue gas conditioning were developed as part of the CUECost model and include operating labor, administrative and support labor and maintenance.

The fixed costs include maintenance costs. The maintenance cost was estimated as approximately 1.35% of the sum of the total direct cost.

The annual variable cost for the fabric filter and COHPAC is the auxiliary power costs plus the cost of 1/3 of a total bag replacement. The 1/3 is derived from the estimated three year bag filter life. The variable costs for the existing ESP consist solely of the auxiliary power cost.

The annual variable cost for the fuel switching with flue gas conditioning consists of the fuel cost change, reduced station service, change in ash disposal cost and reagent cost for the flue gas conditioning system. Section 3.4.1.11 of this report contains a description of the variable annual O&M costs associated with fuel switching.

The fixed and variable costs of the existing ESP were also included in the evaluation. The existing ESP would no longer function if a fabric filter or new ESP were installed. Therefore, the O&M costs associated with the existing ESP are shown as negative costs for those alternatives that would result in the replacement of the ESP. However, if a COHPAC unit or fuel switching with flue gas conditioning were utilized, the O&M costs of the existing ESP would not constitute a new cost and thus would not appear in those cost estimates.

The annual O&M cost estimate for each of the particulate control alternatives is summarized in Table 4.4-5.

TABLE 4.4-5 – Annual O&M Cost Estimates for Unit 1 PM Control Alternatives

	FF	NEW ESP	COHPAC	Fuel Switching with Flue Gas Conditioning
Fixed Costs				
Maintenance Costs	$262,000	$279,000	$160,000	$13,000
Existing ESP Maintenance Costs	($91,000)	($91,000)	$0	$0
Total Fixed O&M Costs	**$171,000**	**$188,000**	**$160,000**	**$13,000**
Variable Costs				
Bag Replacement	$279,000	NA	$147,000	NA
Auxiliary Power	$565,000	$180,000	$520,000	(included below)
Auxiliary Power (Existing ESP)	($179,000)	($179,000)	$179,000	$0
Auxiliary Power & Reagent				$109,000
Fuel Cost Change				$4,796,000
Reduced Station Service				($292,900)
Change in Ash Disposal Cost				($369,100)
Total Variable O&M Costs	**$665,000**	**$1,000**	**$846,000**	**$4,243,000**
Total Annual O&M Costs	**$836,000**	**$189,000**	**$1,006,000**	**$4,256,000**
Net Annual O&M Costs ($/MWh)	**$0.43**	**$0.098**	**$0.52**	**$2.20**

4.4.1.3 LEVELIZED TOTAL ANNUAL COST RESULTS

In order to effectively compare the cost of installing, operating and maintaining each of the particulate control systems capital and O&M costs need to be evaluated on a levelized basis. The levelized costs and associated PM emissions are shown in Table 4.4-6.

TABLE 4.4-6 – Levelized Total Annual Costs of Unit 1 BART PM Control Alternatives

	Emissions		Economic Impacts			
PM Control Alternative	**Emission Rate (lb/mmBtu)**	**Emission Reduction[1] (tons/yr)**	**Installed Capital Cost ($2005)**	**Annual O & M Cost ($2005)**	**Levelized Total Annual Cost ($2005/yr)**	**Unit Control Cost ($/ton)**
FF	0.015	827	$25,840,000	$836,000	$3,260,000	$3,940
New ESP	0.015	827	$27,470,000	$189,000	$2,630,000	$3,180
COHPAC	0.015	827	$15,740,000	$1,006,000	$2,473,000	$2,990
Fuel Switch with Flue Gas Conditioning	0.054	448	$1,370,000	$4,256,000	$5,197,000	$11,600
Existing ESP	0.100	Baseline	Baseline	Baseline	Baseline	Baseline
[1] Annual emissions are based on Future PTE case.						
					Life, years	20
					Cost of Money, %	6%
					Capital Recovery Factor	0.08718

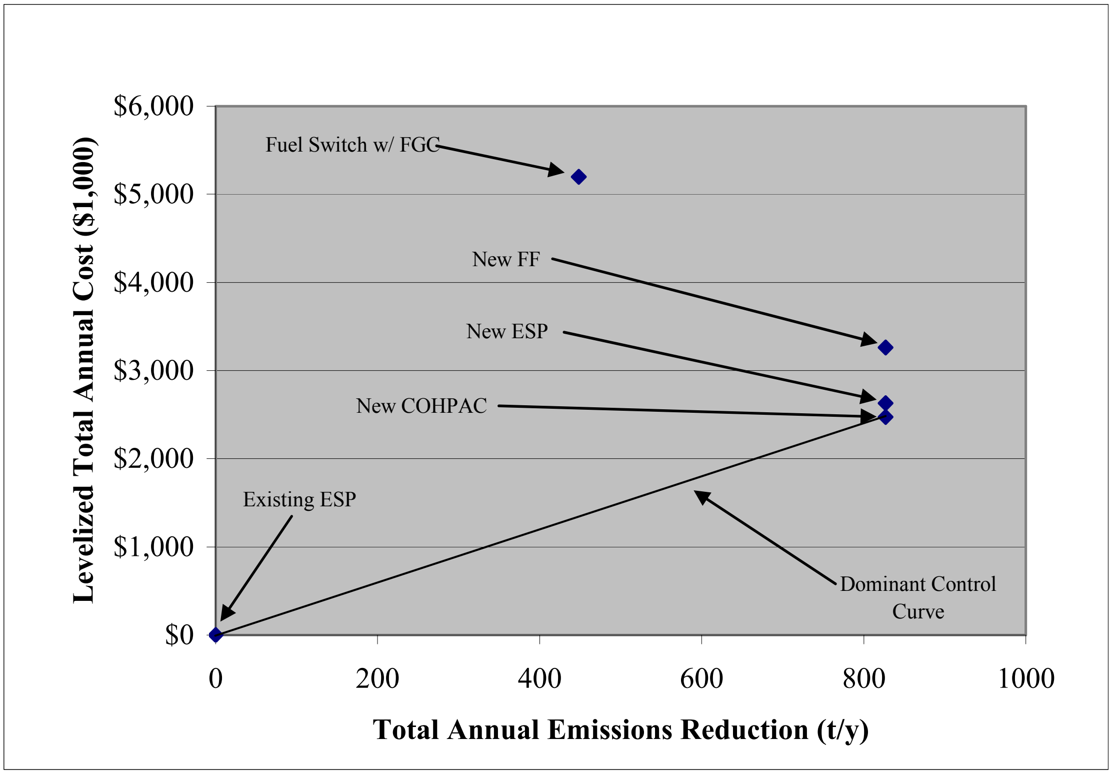
					Conversion Tax (New ESP), $	7,949
					Conversion Tax (COHPAC), $	7,516
					O &M Levelization Factor	1.19314

Figure 4.4-1 is a plot of the Levelized Total Annual Cost (LTAC) for each alternative versus the annual removal in tons. The purpose of Figure 4.4-1 is to identify the Dominant Controls Curve, which is the rightmost boundary of the control cost envelope. The Dominant Controls Curve is the best fit line through the points forming the rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual removal tonnage for the various BART alternatives. Points distinctly to the left of this curve are inferior control alternatives on a cost effectiveness basis. The existing ESP was chosen as the baseline for both LTAC and annual emissions. Therefore, the existing ESP is shown graphically as not having any emission reduction benefits or any added cost.

Of the technically feasible BART alternatives considered for LOS Unit 1 the data point for the fuel switching with flue gas conditioning lies distinctly above the least cost boundary of the control cost envelope. This chart also clearly shows that the new FF and new ESP alternatives are inferior to a COHPAC as all three of these options can achieve the same emissions reduction, but the FF and ESP both have greater LTAC. The reason for this is clear from Table 4.4-6 where the unit control costs for all of the BART alternatives are listed. Considering the small cost difference between new ESP and COHPAC and the accuracy of the cost estimates, both technologies should be considered equivalent. In a BART analysis each of the PM control technologies represented by a data point above the Dominant Control Curve could be excluded from further analysis on a cost efficiency basis. Therefore, the fuel switching with flue gas conditioning, FF and new ESP options are not considered cost effective PM control alternatives for LOS Unit 1 and could be excluded from further analysis.

FIGURE 4.4-1 – LOS Unit 1 Least Cost Envelope for PM Control Alternatives



The next step in the cost effectiveness analysis for the remaining BART alternatives is to review the incremental cost effectiveness between a given alternative and those above and below it on the Dominant Control Curve shown in Figure 4.4-1. The incremental cost effectiveness is the slope of a line between any two adjacent points on the Dominant Controls Curve as shown in Figure 4.4-1. Table 4.4-7 contains a repetition of the cost and control information from Table 4.4-6 and the incremental cost effectiveness between the successive set of alternatives.

TABLE 4.4-7 – Incremental Cost Effectiveness of Unit 1 BART PM Control Alternatives

Alternative	Levelized Total Annual Cost ($2005)(1)	Annual Reduction (tpy)	Incremental Cost Effectiveness ($/t)
COHPAC	$2,473,000	827	$2,990
Existing ESP	$0	0	ND(2)

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.
(2) - Not Defined - baseline condition.

In the BART Determination guidelines, EPA neither proposes hard definitions for reasonable, or unreasonable, Unit Control Costs nor for incremental cost effectiveness values. The incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the dominant control cost curve) between successive, dominant alternatives. While these findings do not eliminate any alternative, because there are no Unit Control Cost or incremental control cost criteria during a BART analysis, the findings do clearly define the more cost effective alternatives.

4.4.2 ENERGY AND NON-AIR QUALITY ENVIRONMENTAL IMPACTS

The energy requirement for an ESP is due to the pressure drop across the ESP, expressed as fan power, and the power required to operate the T/R sets and rappers. The power consumption of an ESP system is estimated to be approximately 590 kW. However, since there is an existing ESP installed on LOS Unit 1, it was assumed there would not be an additional energy impact with the installation of a new ESP as a similar level of power is currently being consumed by the existing ESP.

There are not any significant non-air quality environmental impacts associated with the existing ESP or a new ESP. One difference between the two options is that the new ESP will have a greater control efficiency and collect 827 more tons per year of fly ash that would be sent to the permitted disposal facility.

4.4.3 VISIBLITY IMPACTS

Visibility impacts for Historical pre-control and Future PTE post-control emission levels were modeled using CALPUFF. CALPUFF is used to model long-range transport of PM to determine the visibility impacts measured in deciViews (dV). Unlike emissions from NO_X and SO_2, PM emissions for LOS do not significantly contribute to visibility impacts in nearby Class 1 areas. As part of the CALPUFF output, every visibility impact is broken down into a percent contribution by each pollutant. This percentage was used to calculate the PM contribution to the modeled impact for each Class 1 area and then averaged over the three model years. When pre-control PM contributions were determined for the 90th percentile, the highest PM impact was 0.0097 dV for Unit 1 and occurred in Lostwood NWR.

Because this is the highest visibility impact attributed to PM emissions from Unit 1, any reduction in impact caused by the use of more effective controls would be only a percentage of this impact. To be conservative, this report analyzed a 100% reduction in visibility impairment impact for the visibility improvement comparison. In other words, although other control technologies would provide various levels of emission reduction and visibility impairment impact reduction, a reduction of 0.0097 dV was used as the best achievable impact reduction for the visibility comparison and assigned to each alternative. The assigned visibility improvement and estimated LTAC for each alternative are given in Table 4.4-8. The LTAC for each control technology was divided by the visibility impairment impact reduction in dV's to obtain a cost per dV of improvement relative to the existing ESP. These values are also tabulated in Table 4.4-8.

The highest modeled impact of 0.0097 dV is approximately 1.9 percent of the 0.5 dV impact that the BART guidelines define as contributing to visibility impairment. Achieving this slightly greater visibility improvement requires a significantly higher cost per dV when compared with other pollutants addressed in this study. Based upon these two factors, this analysis recommends that the existing ESP be maintained as the technology used for controlling particulate matter.

TABLE 4.4-8 – Visibility Improvement and Associated Costs

BART Alternative	Levelized Total Annual Cost ($2005)(1)	Visibility Impairment Impact Reduction (dV)	Cost per dV of Improvement ($/dV)
Fuel Switch w/ FGC	$5,197,000	0.0097	$535,800,000
New FF	$3,260,000	0.0097	$336,100,000
New ESP	$2,630,000	0.0097	$271,100,000
COHPAC	$2,473,000	0.0097	$254,900,000
Existing ESP	$0	0	ND(2)

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.
(2) - Not Defined - baseline condition.

Although condensable PM was removed from the BART analysis in Section 4.0.1, one additional aspect should be mentioned with regard to the effect of condensable PM on visibility in the nearest

Class 1 area. As discussed above, the modeled visibility impact for the filterable portion of PM was 0.0097 dV when modeled at the Permit Emission limit of 0.1 lb/MMBtu. Compared to a BART guideline that defines a contributing impact as more than 0.5 dV of visibility impairment impact, the filterable PM emission impact is insignificant. Current estimated emissions of condensable PM are approximately 11 percent of the amount of filterable PM emissions. Because condensable PM emission rates are significantly less than filterable PM emissions and the modeled visibility impairment impact attributable to filterable PM is insignificant even at the permit conditions, it is reasonable to assume that the visibility impairment impact attributable to condensable PM would also be insignificant. Thus, the elimination of condensable PM from this analysis is supported by the insignificant visibility impairment impact of filterable PM as determined by the visibility modeling included in this report.

4.4.4 IMPACT SUMMARY

The results of the impact analysis for PM control on LOS Unit 1 are presented below in Table 4.4-9. The cost of compliance analysis examined the capital cost of each alternative and any Balance of Plant costs necessary to implement the alternative. In addition, the cost analysis examined the operating and maintenance cost for each alternative. These costs were then combined into the Levelized Total Annual Cost for a comparative assessment of the total implementation cost of each alternative. As part of the top down analysis, a Dominant Control Curve was plotted and the Unit Control Cost for each alternative was evaluated. Two alternatives, the existing ESP and a COHPAC downstream of the existing ESP, were on the Dominant Controls Curve and identified as the more cost effective alternatives. Three of the alternatives, a new Fabric Filter, a new ESP and the COHPAC were evaluated at the same control level and the COHPAC, the more cost effective of the three, fell on the Dominant Control Curve. The estimated LTAC for these three alternatives varied by approximately 30% and thus the COHPAC was determined to be significantly more cost effective.

TABLE 4.4-9 – LOS Unit 1 Impacts Summary for PM Control Alternatives

PM Control Alternative	Emission Reduction (tpy)	Levelized Total Annual Cost ($2005)[1]	Unit Control Cost ($/t)	Maximum Visibility Impairment Impact Reduction (dV)	Unit Cost Effectiveness ($/dV)
Fabric Filter	827	$3,260,000	$3,942	0.0097	$443,900,000
New ESP	827	$2,630,000	$3,180	0.0097	$336,100,000
COHPAC	827	$2,473,000	$2,990	0.0097	$271,100,000
Fuel Switch w/ FGC	448	$5,197,000	11,600	0.0097	$254,900,000
Existing ESP	Baseline	$0	$0	0	ND[2]

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.
(2) - Not Defined - baseline condition.

The visibility impairment impact analysis evaluated the modeled impact of PM emission and determined that even if 100% of the visibility impairment impact attributed to PM emissions were eliminated, the change in visibility impairment would be significantly less than detectable by the human eye. As can be determined from the information summarized in Table 4.4-9, the cost of any PM_{10} BART alternative would be prohibitively high on both a unit cost and visibility impairment basis.

4.5 EVALUATION OF IMPACTS FOR FEASIBLE PM CONTROLS – UNIT 2

Step four in the BART analysis procedure is the impact analysis. The BART determination guidelines (70 FR 39166) list four factors to be considered in the impact analysis. This BART Determination will consider the following four factors in the impact analysis:

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four factors considered in the impact analysis are discussed in the following sections. The factor for the remaining useful life of the source is incorporated as part of the cost of compliance. In addition, as described in Section 1.1.6, the visibility impairment impacts are to be evaluated as part of the analysis. Thus, visibility impairment is included as part of the impacts analysis.

4.5.1 COST OF COMPLIANCE

Cost estimates for all of the Unit 2 particulate control technologies use the same general estimation procedure that was described for Unit 1 in Section 4.4.1. Any exceptions to this procedure are described in the following sections for each individual control alternative.

4.5.1.1 CAPITAL COSTS

The capital cost estimate is comprised of direct costs and indirect costs. The methodology used to estimate Unit 2 direct and indirect costs is the same as was described for Unit 1 in Section 4.4.1.1. The results of the capital cost estimate are given in Table 4.5-1, Table 4.5-2, Table 4.5-3, and Table 4.5-4. The option to utilize the existing ESP does not have any capital costs so it is not shown.

TABLE 4.5-1 – Capital Cost Estimate for LOS Unit 2 Fabric Filter

Direct Costs	**Estimated Cost ($2005)**	**General Facilities Markup (15%)**	**Total Direct Cost**
Fabric Filter	$18,520,000	$2,780,000	$21,300,000
Bags	$3,500,000	$520,000	$4,020,000
Ash Handling System	$1,090,000	$160,000	$1,250,000
Booster Fan	$2,220,000	$330,000	$2,550,000
Instruments & Controls	$480,000	$70,000	$550,000

Contingency (15% of BEPC Indirects)	$6,000
Indirect Cost Subtotal	$363,000
Total Capital Cost	**$1,247,000**

4.5.1.2 OPERATING AND MAINTENANCE COSTS

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). These costs except for fuel switching with flue gas conditioning were developed as part of the CUECost model and include operating labor, administrative and support labor and maintenance.

The fixed costs include maintenance costs. The maintenance cost was estimated as approximately 1.35% of the sum of the total direct cost.

The annual variable cost for the fabric filter and COHPAC is the auxiliary power costs plus the cost of 1/3 of the total bags. The 1/3 is determined by the bag life. It was assumed that the bag life for both of these systems is 3 years. The variable costs for the ESP consist solely of the auxiliary power costs.

The annual variable cost for the fuel switching with flue gas conditioning consist of the fuel cost change, reduced station service, and change in ash disposal cost. Section 3.4.1.11 of this report contains a description of the costs associated with fuel switching.

TABLE 4.5-5 – Annual O&M Cost Estimate for Unit 2 PM Control Alternatives

	NewFF	New ESP	New COHPAC	Fuel Switching with Flue Gas Conditioning
Fixed Costs				
Maintenance Costs	$435,000	$510,000	$255,000	$12,000
Existing ESP Maintenacne Costs	($91,000)	($91,000)	$0	$0
Total Fixed O&M Costs	**$344,000**	**$419,000**	**$255,000**	**$12,000**
Variable Costs				
Bag Replacement	$596,000	NA	$315,000	NA
Auxiliary Power	$1,197,000	$384,000	$1,101,000	(included below)
Auxiliary Power (Existing ESP)	($358,000)	($358,000)	$0	$0
Auxiliary Power & Reagent				$200,000
Fuel Cost Change				$9,383,000
Reduced Station Service				($292,000)
Change in Ash Disposal Cost				($467,200)
Total Variable O&M Costs	**$1,435,000**	**$26,000**	**$1,416,000**	**$8,835,000**
Total Annual O&M Costs	**$1,779,000**	**$445,000**	**$1,671,000**	**$8,835,000**
Net Annual O&M Cost ($/MWh)	**$0.54**	**$0.14**	**$0.51**	**$2.63**

The fixed and variable costs of the existing ESP were also included in the evaluation. The existing ESP would be abandoned if a fabric filter or a new ESP were installed; therefore, the O&M costs associated with the existing ESP are shown as negative costs. However, if a COHPAC unit or fuel switching with flue gas conditioning were utilized, the O&M costs of the existing ESP would remain.

The annual O&M cost estimate for each of the particulate control systems is summarized in Table 4.5-5.

4.5.1.3 LEVELIZED TOTAL ANNUAL COST RESULTS

In order to effectively compare the cost of installing, operating and maintaining each of the particulate control systems capital and O&M costs need to be evaluated on a levelized basis. The levelized costs and associated PM emissions are shown in Table 4.5-6.

TABLE 4.5-6 – Levelized Total Annual Costs of Unit 2 BART PM Control Alternatives

	Emissions		Economic Impacts			
PM Control Alternative	**Emission Rate (lb/mmBtu)**	**Emission Reduction[1] (tons/yr)**	**Installed Capital Cost ($2005)**	**Annual O & M Cost ($2005)**	**Levelized Total Annual Cost ($2005/yr)**	**Unit Control Cost ($/ton)**
FF	0.015	1,534	$43,130,000	$1,779,000	$5,892,000	$3,841
New ESP	0.015	1,534	$50,550,000	$445,000	$4,948,000	$3,226
COHPAC	0.015	1,534	$25,310,000	$1,671,000	$4,210,000	$2,744
Fuel Switch with Flue Gas Conditioning	0.054	830	$1,247,000	$8,835,000	$10,650,000	$12,830
Existing ESP	0.100	Baseline	Baseline	Baseline	Baseline	Baseline

[1] Annual emissions are based on Future PTE Case.

Life, years	20
Cost of Money, %	6%
Capital Recovery Factor	0.08718

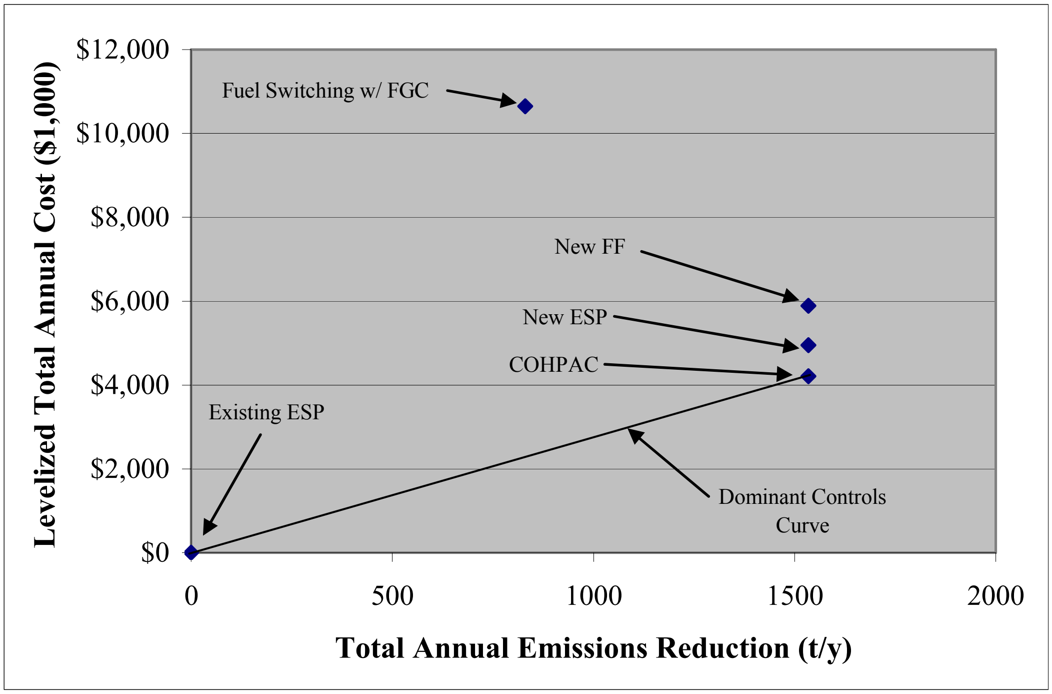
Conversion Tax (New ESP), $	15,849
Conversion Tax (COHPAC), $	15,032
O &M Levelization Factor	1.19314

Figure 4.5-1 is a plot of the Levelized Total Annual Cost (LTAC) for each alternative versus the annual removal in tons. The purpose of Figure 4.5-1 is to identify the Dominant Controls Curve, which is the rightmost boundary of the control cost envelope. The Dominant Controls Curve is the best fit line through the points forming the rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual removal tonnage for the various BART alternatives. Points distinctly above and to the left of this curve are inferior control alternatives on a cost effectiveness basis. The existing ESP was chosen as the baseline for levelized cost and annual emissions. Therefore, the existing ESP is shown graphically as not having any emission reduction benefits or any added cost.

Of the technically feasible BART alternatives considered for LOS Unit 2 the data point for the fuel switching with flue gas conditioning lies distinctly above the least cost boundary of the control cost envelope. This chart also displays that a new FF and/or a new ESP are inferior to a COHPAC as all three of these options can achieve the same emissions reduction; however, the FF and the new ESP have a greater LTAC. The reason for this is clear from Table 4.5-6 where the unit control costs for all of the BART alternatives are listed. In a BART analysis each of the PM control technologies represented by a data point above the Dominant Control Curve can be excluded from further analysis on a cost efficiency basis. Therefore, the fuel switching with flue gas conditioning, the new FF and new ESP options are shown not to be cost effective PM control alternatives for LOS Unit 2 and could be excluded from further analysis.

FIGURE 4.5-1 – LOS Unit 2 Least Cost Envelope for PM Control Alternatives



The next step in the cost effectiveness analysis for the remaining BART alternatives is to review the incremental cost effectiveness between a given alternative and those above and below it in the ranking shown in Table 4.5-7. The incremental cost effectiveness is the slope of a line between any two adjacent points shown in Figure 4.5-1. Table 4.5-7 contains a repetition of the cost and control information from Table 4.5-6 and the incremental cost effectiveness between each successive set of alternatives.

TABLE 4.5-7 – Incremental Cost Effectiveness of Unit 2 BART PM Control Alternatives

Alternative	Levelized Total Annual Cost ($2005)⁽¹⁾	Annual Reduction (tpy)	Incremental Cost Effectiveness ($/ton)
COHPAC	$4,210,000	1,534	$2,744
Existing ESP	$0	0	ND⁽²⁾

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

(2) - Not Defined - baseline condition.

In the BART Determination guidelines, EPA neither proposes hard definitions for reasonable, or unreasonable, Unit Control Costs nor for incremental cost effectiveness values. The incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the dominant control cost curve) between successively less effective alternatives. The alternatives involving the installation of new PM control equipment were all evaluated at the same particulate matter control efficiency and thus the incremental analysis does not provide any useful information for comparing these alternatives. However, based on the cost estimates for each, the COHPAC is more cost effective than a new FF or ESP and thus only the COHPAC alternative needs to be carried forward from this analysis as representative of a general BART alternative for control of emissions to the 0.015 lb/mmBtu level.

4.5.2 ENERGY AND NON-AIR QUALITY ENVIRONMENTAL IMPACTS

The energy requirement for an ESP is due to the pressure drop across the ESP, expressed as fan power, and the power required to operate the T/R sets and rappers. The power consumption of the existing ESPs is estimated to be approximately 1,180 kW. Because two existing ESPs are installed on LOS Unit 2, it was assumed there would not be an additional energy impact with the installation of a new ESP.

There are no significant non air quality environmental impacts associated with the existing ESP versus a new ESP. One difference between the two options is that the new ESP will have a greater control efficiency. Therefore, a new ESP will collect 73 more tons per year of fly ash that would be sent to the landfill.

4.5.3 VISIBLITY IMPACTS

Visibility impacts for Historical pre-control and Future PTE post-control emission levels were estimated using CALPUFF. CALPUFF is used to model long-range transport of PM to determine the visibility impacts measured in deciViews (dV). Unlike emissions from NO_X and SO_2, PM emissions for LOS never significantly contribute to visibility impacts. As part of the CALPUFF results, each modeled impact includes a percent contribution for each pollutant. That percentage is used to calculate the PM contribution to the modeled impact for each Class 1 area and then is averaged for the 3 modeled years. When pre-control PM contributions are calculated for the 90th percentile, the highest impact is 0.015 dV for Unit 2 and occurs in Lostwood NWR.

The 0.015 dV visibility impact contribution was estimated by modeling the pre-control ESP emission rate. Since this is the highest impact attributed to PM emissions from Unit 2, any reduction in impact caused by the use of more effective controls would be only a percentage of this impact. To be conservative, this report uses a 100% reduction in visibility impairment reduction for the visibility impairment impact reduction evaluation. Although three control alternatives provide the same PM emission reduction, which would be an 85% reduction of PM emissions compared to the existing ESP, the potential visibility impairment reduction is very low and thus an improvement of 0.015 dV was the maximum possible visibility impairment impact reduction. The LTAC, maximum visibility impairment impact reduction and resultant cost per dV of improvement are given in Table 4.5-8. The LTAC for each control technology was divided by the visibility improvement to obtain a cost per dV of visibility impairment reduction for each alternative.

LOS Unit 2 has a particulate control device in operation that satisfactorily meets the permit limitation for PM emissions of 0.1 lb/mmBtu. Therefore, any PM control alternative was expected to be inordinately expensive on a Unit Control Cost basis as was shown in Section 4.5.1.3. The maximum potential visibility impairment reduction of 0.015 dV is approximately three percent of the 0.5 dV impact that the BART guidelines define as contributing to visibility impairment. Achieving this slightly greater visibility improvement requires a significantly higher cost per dV when compared with other pollutants addressed in this study. Therefore, the maximum achievable visibility impairment impact reduction would be extremely expensive on a unit cost basis and would not result in any discernible change in visibility in the affected Class 1 areas.

TABLE 4.5-8 – Visibility Improvement and Associated Costs

Alternative	Levelized Total Annual Cost ($2005)(1)	Maximum Visibility Impairment Impact Reduction (dV)	Unit Cost Effectiveness ($/dV)
Fuel Switch w/ FGC	$10,650,000	0.015	$710,000,000
New FF	$5,892,000	0.015	$392,800,000
New ESP	$4,948,000	0.015	$329,900,000
COHPAC	$4,210,000	0.015	$280,700,000
Existing ESP	$0	0	ND(2)

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.
(2) - Not Defined - baseline condition.

Although condensable PM was removed from the BART analysis in Section 4.0.1, one additional aspect should be mentioned with regard to the effect of condensable PM on visibility in the nearest Class 1 area. As discussed above, the modeled visibility impact for the filterable portion of PM was 0.015 dV when modeled at the Permit Emission limit of 0.1 lb/MMBtu. Compared to a BART guideline that defines a contributing impact as more than 0.5 dV of visibility impairment impact, the filterable PM emission impact is insignificant. Current estimated emissions of condensable PM are approximately 8 percent of the amount of filterable PM emissions. Because condensable PM emission rates are significantly less than filterable PM emissions and the modeled visibility impairment impact attributable to filterable PM is insignificant even at the permit conditions, it is reasonable to assume that the visibility impairment impact attributable to condensable PM would also be insignificant. Thus, the elimination of condensable PM from this analysis is supported by the insignificant visibility impairment impact of filterable PM as determined by the visibility modeling included in this report.

4.5.4 IMPACT SUMMARY

As stated at the beginning of this report, the cost, energy, non-environmental and visibility impacts of each PM_{10} BART alternative were evaluated in this Section. Table 4.5-9 summarized the various impacts discussed in Sections 4.5-1 through 4.5-3. The cost of compliance analysis examined the capital cost of each alternative and any Balance of Plant cost necessary to implement the alternative. In addition, the cost analysis examined the operating and maintenance cost associated with each alternative. These costs were then combined into the Levelized Total Annual Cost for a comparative assessment of the total implementation cost of each alternative. Finally, as part of the top down analysis, a Dominant Control Curve was plotted and the Unit Control Cost for each alternative was evaluated. Two alternatives, the existing ESP and installation of a new COHPAC following the existing ESP, were on the Dominant Controls Curve and thus were identified as the more cost effective alternatives. Three of the BART alternatives, a new Fabric Filter, a new ESP and a new COHPAC following the existing ESP, were evaluated at the same PM control level and only the least expensive of these, the COHPAC alternative, fell on the Dominant Controls Curve. The range of the cost estimates for these three alternatives was approximately 40% and thus the COHPAC was perceived to be significantly more cost effective than the other two alternatives.

The visibility impairment impact analysis evaluated the modeled impact of PM emissions and determined that even if 100% of the visibility impairment attributed to PM emissions were eliminated, the change in visibility impairment would be significantly less than detectable by the human eye. As can be determined from the information summarized in Table 4.5-9, the cost of any PM BART alternative would be prohibitively high on both a unit cost and visibility impairment basis.

TABLE 4.5-9 – LOS Unit 2 Impacts Summary for PM Control Alternatives

PM Control Alternative	Emission Reduction (tons/yr)	Levelized Total Annual Cost ($2005)(1)	Unit Control Cost ($/ton)	Maximum Visibility Impairment Impact Reduction (dV)	Unit Cost Effectiveness ($/dV)
New FF	1,534	$5,892,000	$3,841	0.015	$710,000,000
New ESP	1,534	$4,948,000	$3,226	0.015	$392,800,000
COHPAC	1,534	$4,210,000	$2,744	0.015	$329,900,000
Fuel Switch w/ FGC	830	$10,650,000	$12,830	0.015	$280,700,000
Existing ESP	Baseline	$0	Baseline	0	Baseline

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.19314.

5.0 BART RECOMMENDATIONS

This report presents the analysis of control technologies for each of three major pollutants (nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM)) for Basin Electric Power Cooperative's (BEPC's) Leland Olds Station (LOS) Units 1 and 2. The final result of this analysis is a recommendation of the Best Achievable Retrofit Technology (BART) for each unit based upon "the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology" (70 FR 39163). The presented emission rates in this section are the BART recommendation. However, because the accuracy of the cost estimate is ± 30% and in some cases is greater than the variance of the estimated costs between control alternatives, the technology used to meet the BART recommendation may change. This section summarizes the analysis performed for each unit and its associated pollutants.

5.0 UNIT 1 BART RECOMMENDATIONS

In previous sections of the report, the 5 steps of the technology evaluation provided in the BART Determination Guidelines were completed for Unit 1 and the results for each pollutant were summarized. Each pollutant required a different approach in order to determine BART. This section provides a brief description of the approach used for each pollutant and summarizes the results for Unit 1.

5.0.1 UNIT 1 NO_X BART

In the BART Guidelines, the EPA lists the presumptive NO_X emission limits for BART-eligible coal-fired units, distinguished by unit type, and coal type. The analysis performed by the EPA for establishing the presumptive limits for NO_X emissions from pulverized coal-fired EGUs assumed only the application of low-NOx burners and overfire air combustion controls. For dry-bottom, wall-fired electric generating units (EGUs) burning lignite coal, the NO_X presumptive limit is 0.29 lb/mmBtu. These presumptions apply to EGUs greater than 200 MW at power plants with the generating capacity greater than 750 MW and are based on control strategies that the EPA determined are generally cost-effective for all such units.

Unit 1 at Leland Olds Station is a dry-bottom, wall-fired unit greater than 200 MW output located at a power plant less than 750 MW total output capacity. The actual highest 24-month rolling NO_X summation total from 2000-2004 divided by the actual 24-month rolling summation unit heat input for the same time period for Unit 1 at LOS meets the presumptive BART NO_X emission limits stated above. The requirements of performing a NO_X BART analysis, on a BART-eligible coal-fired unit with a nameplate capacity greater than 200 MW at a powerplant less than 750 MW that has a historic 24-month average unit NO_X emission rate that meets the EPA's presumptive BART NO_X emission limit for larger power plants, are not apparent in the BART Guidelines. However, this BART analysis performed a NO_X control technology feasibility evaluation, with impact analysis for a separated overfire air (SOFA) alternative. This included the four prescribed impact criteria plus the impact assessment for visibility impairment improvement following the general procedures of the BART Guideline.

The impacts analysis for separated overfire air at LOS Unit 1 found only insignificant negative energy and non-air environmental impacts; remaining useful life of the source was assumed to exceed the 20-year project life utilized in the cost impact estimate.

Average predicted visibility impairment impacts decreased significantly for the presumptive BART NO_X emission rate and high levels of SO_2 control, and slightly more with post-control SOFA-enhanced NO_X emission rates compared to the average predicted visibility impairment impacts at the pre-control (NDDH protocol) baseline emission rates for NO_X, SO_2, and PM. An analysis of the incremental cost-effectiveness of reducing predicted visibility impairment impact for the SOFA alternative was performed for LOS Unit 1. The comparison showed that the ratio of the estimated additional annualized costs of installing and operating SOFA to the average predicted visibility impairment improvement relative to the presumptive BART NO_X baseline emission rate for the future Potential-To-Emit boiler heat input (future coal case) scenario applied to LOS Unit 1 would result in millions of dollars per deciView-year of visibility impairment improvement. The range for this incremental visibility impairment impact reduction was \$7.8M to \$25.4M per deciView-yr, depending on the Class 1 area and SO_2 control associated with the SOFA NO_X control alternative.

The actual highest 24-month rolling average NO_X unit emission rate meets the EPA's presumptive BART NO_X emission limit of 0.29 pounds per million Btu of fuel heat input for BART-eligible coal-fired EGU's greater than 200 MW nameplate capacity at power plants with the generating capacity greater than 750 MW. Use of existing low-NO_X burners and close-coupled overfire air translates into a BART emission rate of 0.29 pounds per million Btu of fuel heat input for the future PTE coal case scenario applied to LOS Unit 1. Thus, this evaluation recommends the presumptive limit of 0.29 lb/MMBtu as BART.

5.0.2 UNIT 1 SO_2 BART

In step 1 of the technology evaluation, 7 control processes were identified for SO_2 control. The identified processes included Fuel Switching, Coal Cleaning, Wet Limestone Flue Gas Desulfurization (FGD), Spray Dryer Absorber (SDA), Circulating Dry Scrubber (CDS), Flash Dryer Absorber (FDA), and the Powerspan ECO™ process. While evaluating the availability and applicability of each process in step 2, the Coal Cleaning and the Powerspan ECO™ processes were eliminated. In step 3 the remaining 5 processes were ranked by effectiveness. After ranking the processes, the impacts analysis including visibility was conducted in steps 4 and 5. The main result of the impacts analysis was quantifying the cost effectiveness of each process. The SDA, CDS and FDA were quantified as being inferior on a cost effectiveness basis.

After conducting all steps of the evaluation for SO_2, 90% removal remains as the best possible control alternative. Based upon the cost analysis, none of the feasible BART alternatives were exceedingly expensive. Due to the relative closeness of the cost estimates and fluctuation in market conditions, all of the alternatives had similar cost impacts. The visibility impairment impact analysis examined the visibility impairment impact reduction attributable to each alternative and determined that the marginal change in visibility impairment impact between any two feasible BART alternatives was less than ten percent of the minimum change in visibility impairment discernible by the human eye. So, similar to the cost analysis, the visibility impairment impact analysis reached the conclusion that there is no definitive difference between alternatives. Since 90% control is cost effective and provides indiscernible visibility impact compared to other alternatives, it is recommended as BART. Application of 90% control for LOS Unit 1 translates into an emission rate of 0.34 pounds per million Btu.

5.0.3 UNIT 1 PM BART

Five control technologies were identified for step 1 of the PM control evaluation. The identified technologies included Fuel Switching with Flue Gas Conditioning, a Fabric Filter, a COHPAC Baghouse, a New Electrostatic Precipitator (ESP), and the Existing ESP. In step 2, all five of the control technologies were determined as feasible alternatives based upon availability and applicability. In step 3, the 5 processes were ranked by effectiveness. While evaluating the impacts of each technology during steps 4 and 5, visibility impairment became the principle factor for determining BART. PM emissions, unlike other pollutant emissions, use existing controls and do not significantly contribute to visibility impairment. In addition, using a new control technology to achieve a slightly greater visibility improvement requires a significantly higher cost per deciView when compared with other pollutants. Based upon these two factors, this analysis recommends that the existing ESP be maintained as the technology used for controlling particulate matter. The evaluated emission rate for the existing ESP was 0.10 pounds per million Btu.

5.1 UNIT 2 BART RECOMMENDATIONS

Unit 2 uses the same 5 steps of the technology evaluation provided in the BART Determination Guidelines. Previous sections provide the evaluation results for each pollutant and describe the different approaches used to determine BART. This section provides a brief description of the approach used for each pollutant and summarizes the results for Unit 2.

5.1.1 UNIT 2 NO_X BART

In step 1 of the technology evaluation, three basic categories of NO_X control for EGUs were-identified: pre-combustion, combustion, and post-combustion. Eleven basic types of NO_X control processes were derived from these three categories. Twenty two variations of these eleven processes were reviewed for NO_X controls potentially available and applicable to cyclone-fired EGUs burning North Dakota lignite. While evaluating the availability and applicability of each process for LOS Unit 2's NO_X control in step 2 of the BART analysis process, low NO_X burners, Selective Catalytic Reduction (SCR), and the Powerspan ECO™ process were eliminated. Controls such as oxygen-enhanced combustion, water/steam injection, hydrocarbon-enhanced SNCR, and fuel reburn with SNCR all lack appropriate demonstration or permanent installation experience in full-scale, full-time applications for NO_X emissions reduction on cyclone-fired boilers. Of the pre-combustion and combustion-related NO_X control processes, fuel switching, basic combustion control improvements, basic separated overfire air, flue gas recirculation, fuel lean gas reburn, and conventional gas reburn were considered technically feasible but have zero or low control effectiveness, or are economically unattractive due to the high capital costs and on-going natural gas consumption costs for implementation and operation.

An “advanced” form of separated overfire air, alone and in combination with coal reburn, and Selective Non-Catalytic Reduction (SNCR) with and without Rich Reagent Injection, were evaluated for cost-effectiveness. Of these four alternatives, coal reburn with ASOFA was determined to be an inferior control from a cost-effectiveness standpoint, and thus eliminated from further impacts analysis for LOS Unit 2. For Rich Reagent Injection + SNCR with ASOFA, the small incremental reduction in annual NO_X emissions (approximately 10 percent) for a 60 percent increase in levelized total annual cost yields a 220 percent increase in incremental dollars per ton control cost versus the SNCR with ASOFA alternative. The control cost-effectiveness analysis favored the SNCR with ASOFA alternative for LOS Unit 2 NO_X control.

The impacts analysis for remaining NO_X control alternatives at LOS Unit 2 found only insignificant negative energy and non-air environmental impacts; remaining useful life of the source was assumed to exceed the 20-year project life utilized in the cost impact estimate.

Average predicted visibility impairment impacts decreased significantly for the post-control ASOFA-enhanced NO_X emission rate, and slightly more with a SNCR-enhanced NO_X emission rate, and a very small incremental amount for the RRI + SNCR-enhanced NO_X emission rate when modeled with the single sulfur emission control rate for LOS Unit 2. These impacts were compared to the average predicted visibility impairment impacts at the pre-control (NDDH protocol) baseline emission rates for NO_X, SO_2 , and PM. An analysis of the incremental cost-effectiveness of SNCR and RRI + SNCR controls in reducing predicted visibility impairment impact beyond the ASOFA alternative was performed for LOS Unit 2. Installing and operating SNCR applied to LOS Unit 2 relative to the ASOFA NO_X emission rate for the future Potential-To-Emit boiler heat input (future coal case) scenario would result in hundreds of millions of dollars per deciView-year of control cost effectiveness visibility impairment improvement. The range for this incremental visibility impairment impact reduction was \$105M to \$310M per deciView-yr for SNCR -based control added to the ASOFA NO_X control alternative, depending on the Class 1 area. Adding RRI to the SNCR with ASOFA NO_X control alternative would reduce average predicted visibility impairment impact by 0 to 12.5 percent on a deciView basis while increasing control cost of the incremental visibility impairment improvement by 25 to 40 percent on a M\$ per deciView-year basis, depending on the Class 1 area. The range for this incremental visibility impairment impact reduction was \$148M to \$423M per deciView-yr for adding RRI + SNCR to the ASOFA NO_X control alternative, depending on the Class 1 area.

After conducting all steps of the evaluation for NO_X emissions control, Rich Reagent Injection + SNCR with ASOFA and SNCR with ASOFA alternatives remain as the highest and next highest-performing feasible control technologies for LOS Unit 2. An incremental analysis for control costs and visibility impairment impacts shows that the SNCR with ASOFA alternative was significantly more cost-effective. SNCR with ASOFA is recommended as BART for LOS Unit 2. Application of SNCR with ASOFA for 54.5 percent NO_X control translates into a BART emission rate of 0.304 pounds per million Btu of fuel heat input for the future PTE coal case scenario applied to LOS Unit 2.

5.1.2 UNIT 2 SO_2 BART

Steps 1 through 3 of the technology evaluation for Unit 2 ended with the same results from Unit 1. The 5 remaining processes, ranked in order by efficiency, are Wet Limestone Flue Gas Desulfurization (FGD), Circulating Dry Scrubber (CDS), Spray Dryer Absorber (SDA), Flash Dryer Absorber (FDA), and Fuel Switching. After ranking the processes, the impacts analysis including visibility was conducted in steps 4 and 5. The main result of the impacts analysis was quantifying the cost effectiveness of each process. The SDA, CDS and FDA were quantified as being inferior on a cost effectiveness basis. After conducting all steps of the evaluation for SO_2, Fuel Switching and Wet Limestone FGD remain as the best possible control technologies. Of the two BART alternatives remaining under consideration, wet FGD, achieving 95% SO_2 reduction, consistently achieves the greatest visibility impact reduction and meets presumptive BART limits. Because 95% SO_2 reduction is cost effective and meets presumptive BART limits, it is recommended as BART. Application of ninety-five percent control for LOS Unit 2 translates into an emission rate of 0.17 pounds per million Btu.

5.1.3 UNIT 2 PM BART

The approach used to recommend BART for Unit 2 was exactly the same as was used for Unit 1. The only difference was the higher costs associated with using a new control technology for Unit 2. The increased size of Unit 2 requires new controls to be larger and results in higher costs. Using a new control technology to achieve a slightly greater visibility improvement requires a significantly higher cost per deciView when compared with other pollutants and compared to Unit 1. However, using existing PM controls, emissions from Unit 2 still never significantly contribute to visibility impairment. Based upon these two factors, this analysis recommends that the existing ESPs be maintained as the technology used for controlling particulate matter. The evaluated emission rate for the existing ESP was 0.10 pounds per million Btu.

*****

6.0 PERMIT LIMIT RECOMMENDATIONS

To complete the determination process, the BART guidelines state that an enforceable emission condition must be established for each subject emission unit and for each pollutant subject to review. (70 FR 39172) The guidelines suggest that emission limits be developed on a 30-day rolling average for Electric Generating Units (EGUs). Unfortunately, the guidelines do not provide a methodology to calculate the limit for permitting purposes and only state that an enforceable limit that reflects BART requirements must be established.

The BART Determination was conducted based upon historical operating conditions for LOS. However, because the fuel characteristics of the North Dakota lignite fired at LOS will be changing in the future, a Future PTE case was developed for the recommended BART determination. Two additional factors, boiler Heat Input and short term variations in fuel composition were reviewed prior to recommending enforceable permit conditions for BART.

In general, when the Boiler Heat Input increases, emission rates of fuel borne pollutants increase. Although the design Heat Input is specified by the boiler manufacturer, factors such as fuel characteristics and operating procedures can affect the maximum Heat Input of a boiler that is actually experienced in practice. Historical Heat Input values from 2000-2004, for both LOS Unit 1 and Unit 2, were reviewed to determine the amount of time in which the Nameplate Heat Input Rating used as the basis for the predicted future emissions in this report was exceeded. The review showed that the design boiler Heat Input was exceeded 10.6% and 7.6% of the operating time for Units 1 and 2 respectively. Because a 30-day averaging period should mitigate some of the effect of higher Heat Input on emissions somewhat, a five percent increase in heat input was used for calculating the recommended emission limits for each pollutant. With this approach, Basin Electric Power Cooperative (BEPC) is provided a bit of a cushion between operating conditions and permit limits such that minor short term variations in operating conditions would not result in an apparent permit violation where BEPC had not, in fact, materially changed any of their normal daily operating conditions.

Variability in coal composition was the second factor that was taken into account because the emission rate of SO_2 and PM are directly related to the sulfur and ash content of the fuel. Sulfur content of the fuel is the primary constituent of concern because SO_2 emissions are directly related to the amount of sulfur in the coal and cannot be improved with combustion improvements as NO_X and

PM. When BART compliance is required for LOS, they will still be burning coal from the Freedom Mine in Beulah, ND. A forty year mining plan, provided by the mining company and containing projected coal quality data, was analyzed to determine the future annual average sulfur content of the coal (Appendix B2). The results indicated that the future coal will have a higher maximum annual average sulfur content of approximately 1.13%. A further analysis of the short term variability of fuel sulfur content and Higher Heating Value (HHV) was conducted by the mining company at the train load level, for LOS fuel deliveries over the 2000-2004 period. The detailed analysis identified one standard deviation in sulfur content as being equal to ± 0.12% change in fuel sulfur content and one standard deviation in the heat content as ± 158 Btu/lb. Assuming a normal distribution of both the fuel sulfur and heat content, the annual average, plus or minus one standard deviation, would represent approximately 68.27% of the possible range of sulfur and heat content LOS is expected to experience. This range was taken to be representative of the range of sulfur and heat content that LOS would experience over a given year on a 30 day rolling average. For determining a 30 day rolling average for the purpose of calculating SO_2 emissions, the average annual sulfur content of 1.13% plus one standard deviation of 0.12%, plus an average annual fuel heat content of 6,520 Btu/lb was utilized. Therefore, the basis for the recommended permit conditions for recommended BART for each unit was 105% of the nameplate Heat Input, while firing 1.25% sulfur fuel with a heat content of approximately 6,520 Btu/lb. In this manner, an owner's margin of one standard deviation on fuel and heat content would be preserved. This margin is important to protect the owner from variations in fuel properties over shorter operating periods than the annual average taken as the basis for the remainder of this analysis.

For NO_X emissions, the five percent higher Boiler Heat Input was the only variation from the BART Determination basis that was used to develop the proposed permit conditions. The Boiler Heat Input is the single most important variable affecting the NO_X emissions rate. Fuel nitrogen content may vary slightly but, because it is a minor contributor to overall NO_X emissions rates, potential variations were not taken into account while developing the recommended permit conditions. After performing emissions calculations for Unit 1 using the higher Heat Input and applying recommended BART, the resulting recommended NO_X permit limit is 0.29 lb/mmBtu.

For Unit 2, it is generally seen that when the Boiler Heat Input increases, the NO_X emission rate increases. Applying recommended BART to LOS Unit 2's boiler operating at a higher heat input rate with a higher pre-control baseline 30-day rolling average emission rate, the recommended NO_X

permit limit is 0.35 lb NO_X/mmBtu. These recommendations are summarized in Tables 6.0-1 and 6.0-2 below.

The recommended NO_X permit conditions are based upon performance estimates considering recognized operational factors and equipment designs that are different from emission reduction experience achieved by other coal-fired cyclone boilers. The combustion characteristics of the future lignite supply are expected to include a decrease in higher heating value (Btu/lb) and an increase in ash content. Operation of Unit 2 with air-staged cyclones with the advanced form of separated overfire air system and with low Btu/high ash lignite can cause conditions to occur that exceed the ability to adjust operational practices sufficiently to maintain low NO_X emissions. A provisional operating period of one year of operational experience is recommended in conjunction with the recommended BART 30-day rolling average NO_X emission rate limit. This provisional period will allow BEPC to demonstrate the actual control system capabilities of an SNCR system in addition to the ASOFA system specifically designed for lignite firing in Unit 2's boiler. At the end of that period, it is recommended that the BART NO_X emission limit be reviewed considering the demonstrated operating history.

To account for predicted variations in future fuel sulfur and heat content, a representative SO_2 emission rate was calculated based upon a five percent higher heat input, the maximum sulfur content plus 1 standard deviation and the future annual average fuel HHV minus one standard deviation). After performing emissions calculations for Unit 1 using the basis described above and applying the recommended BART SO_2 reduction level of 90%, the resulting recommended 30 day rolling average SO_2 permit limit for LOS Unit 1 is 0.39 lb SO_2/mmBtu. Similar calculations for Unit 2, applying recommended BART of 95% SO_2 control, yield a recommended SO_2 permit limit of 0.19 lb SO_2/mmBtu. These recommendations are summarized in Tables 6.0-1 and 6.0-2 below.

Emission rates for particulate matter are based upon the design of the existing electrostatic precipitator and the boiler heat input. To maintain the same methodology that was used for both NO_X and SO_2, the heat input used to calculate the emissions in pounds per hour was increased by five percent. Note that the emission rate in pounds per million Btu did not change. Along with recommended emission limits for NO_X and SO_2, PM emission limits for each unit are tabulated below.

Table 6.0-1 – Recommended 30-Day Rolling Average BART Emission Limits LOS Unit 1

Pollutant	Emission Rate lb/million Btu
SO_2	0.39
NO_X	0.29
PM	0.10

Table 6.0-2 – Recommended 30-Day Rolling Average BART Emission Limits LOS Unit 2

Pollutant	Emission Rate lb/million Btu
SO_2	0.19
NO_X	0.35
PM	0.10

Although the emission limits presented above for each unit are recommended for permitting purposes, this analysis also recommends discussing an alternative compliance method as suggested in the BART Guidelines. The guidelines provide that states, "should consider allowing sources to ''average'' emissions across any set of BART-eligible emission units within a fence line, so long as the emission reductions from each pollutant being controlled for BART would be equal to those reductions that would be obtained by simply controlling each of the BART-eligible units that constitute a BART-eligible source." (70 FR 39172) During the process of developing enforceable permit conditions, the opportunity to apply a plant-wide limit using an "averaging" or "bubbling" strategy should be considered.

Retrofit NO_X Control Projects' Technical Literature Summary (A4)

EERC Report – Ash Impacts on SCR Catalyst Performance (A5)

A1 Technical Feasibility Assessment of NO_X Control Alternatives

A1.1 Pre-Combustion Controls – Fuel Switching/Blending

Fuel switching can be a viable method of NO_X emission reduction in certain situations. Often, coal combustion facilities are constructed to take maximum advantage of the particular combustion characteristics of a specific fuel. In the case of Leland Olds Station, the Unit 1 and Unit 2 boilers were designed and constructed specifically for firing North Dakota lignite, which has a low fuel higher heating value (Btu/lb), medium to high ash, and high moisture content. Based on available emission data for LOS, switching fuel from a lignite/PRB coal blend to 100% PRB coal is expected to yield little or no significant additional NO_X reduction. Ottertail Power Company's Big Stone Unit 1's boiler, located in South Dakota, was originally designed to burn northern Midwest lignite, and has cyclone furnaces and the same physical size and arrangement as LOS Unit 2's boiler. Big Stone Unit 1's boiler was converted from firing lignite to PRB coal in 1997. Based on available EPA Acid Rain Program's Clean Air Market Division (CAMD) emission data for Big Stone Unit 1, switching fuel from a lignite coal to PRB coal is the expected to yield no significant additional NO_X emissions reduction relative to current baseline levels for Unit 2 at Leland Olds Station.

Conversion of Leland Olds Station Unit 1 and Unit 2 to fire lignite/western subbituminous coal blends up to 100% PRB coal is technically possible. It is expected that various off-site, plant site, and powerplant modifications will be required. This has not been closely examined for all aspects of design, construction, operation and maintenance. A relatively modest quantity of PRB coal is currently burned annually at this plant. Rail service is presently installed at this site, so the additional operational and capital costs to bring in large quantities of PRB coal are expected to be of modest significance. This is described in more detail in the main report, Section 2.4.1.5 for LOS Unit 1 and Section 2.5.1.5 for LOS Unit 2. PRB coal cost (delivered) will be approximately 60% more per ton or 29% more per mmBtu delivered than North Dakota lignite from Basin Electric's existing source. However, with such a negligible amount of NO_X emissions reduction expected from application of fuel switching, this alternative will not be economically competitive with other technologies that offer similar or better results expected for a much lower combination of capital and operational costs. This alternative was not included in the NO_X control cost-effectiveness analysis.

A1.2 Combustion Controls

Nitrogen oxides (NO_X) are produced when nitrogen in the fuel and combustion air are exposed to high temperatures. Nitrogen oxide (NO) is the most predominant form of NO_X emissions, along with nitrogen dioxide (NO_2). The formation of these compounds in utility powerplant boilers is sensitive to the method of firing and combustion controls utilized. The techniques employed for mixing the combustion air and fuel, which creates flames and high temperature combustion products, results from the rapid oxidization of carbon, hydrogen, and other exothermic reactions. Cyclone-fired boilers, by design, create intense heat release rates to melt and fluidize the coal ash introduced into the barrel-shaped furnaces. This produces very high uncontrolled NO_X emissions.

Combustion controls employ methods that reduce the amount of NO_X emissions created in the combustion zone of the boiler prior to exhausting the flue gases from the furnace (upstream of the convective heat transfer zones). This results in fewer emissions that may require subsequent reduction from applicable post-combustion techniques.

A1.2.1 Basic Combustion Improvements

Combustion improvements are commonly-applied, combustion-related NO_X emission reduction techniques. In their most basic form, these typically provide improvements to combustion air flow distribution, measurement, and pressure, together with fuel flow measurement and metering, to promote consistent combustion performance by burning fuel with more accuracy in maintaining a desired fuel/air ratio[1].

These improvements may allow, or be combined with, a technique called “low excess air” (LEA) operation of the pulverized lignite burners or cyclones, where a slight decrease in the total amount of combustion air is supplied to the burners, thus reducing the amount of thermal NO_X emissions produced during combustion. Other operational techniques to reduce NO_X emissions may utilize burners out-of-service (BOOS) and biased firing (BF). With BOOS, selected burners are removed from service by stopping fuel flow but maintaining airflow, so as to force the remaining active (i.e. firing) burners or cyclones to operate fuel-rich, thus promoting lower NO_X emissions. In biased firing, often the lower burners or cyclones are operated with more fuel than the upper levels, which also produces low excess air or “fuel-rich” combustion conditions in the lower burners. These basic techniques are often applied prior to, or along with, other combustion techniques and technologies associated with NO_X emission control. The amount of potential NO_X emission reduction is highly-dependent on the specific type of firing, fuel, and conditions which apply to the boiler(s) being reviewed. Typically, the operation of burners in an air-starved, fuel-rich mode is similar to that included as part of separated overfire air system implementation.

Significant additional long-term NO_X emissions reduction at LOS from these improvements is not expected. Improvements to the operation of the combustion equipment in a manner that allows modest amounts of burner/cyclone air staging, along with reducing combustion air inputs have already decreased pre-control baseline annual average NO_X emissions. This will subsequently affect (limit) the amount of further NO_X reduction possible from these basic combustion improvements. The benefits from this alternative were assumed to be included in the alternatives involving separated overfire air. This alternative was eliminated from consideration as a separate stand-alone option for additional NO_X reduction at LOS Station.

A1.2.2 Low-NOx Burners (LNB)

Low NO_X burners (LNBs) of various designs have been commonly applied to pulverized coal-fired utility and industrial boilers for more than ten years. These are often, but not always, installed with some form of overfire air to allow for air-staged or "starved air" combustion to lower NO_X emissions. LOS Unit 1 already has low NOx burners suitable for good combustion performance and low NO_X emissions with pulverized lignite fuel. Installed low-NO_X burners at Leland Olds Station Unit 1 with close-coupled overfire air have already decreased pre-control baseline annual average NO_X emissions to approximately 0.29 lb/mmBtu. Installing the latest multi-zone LNBs would not be expected to significantly lower NO_X emissions without potentially introducing adverse operational consequences, such as unstable pulverized fuel ignition and high unburned carbon content in the boiler's particulate emissions.

LNBs are not applicable to cyclone-fired boilers[1]. This is due to the physical constraints imposed by the cyclone furnaces' (barrels) length and diameter, and the incompatibility with the amount of heat released and flame dispersion patterns, and insufficient amount of fine coal particles required to sustain stable combustion associated with air-staged firing of coal using low-NO_X burners with pulverized fuel. This alternative was eliminated from consideration for potential additional NO_X emissions reductions from LOS boilers.

A1.2.3 Separated Overfire Air (SOFA)

Separated overfire air (SOFA) is a commonly-applied, combustion-related NO_X emission reduction technology. Separated Overfire Air (SOFA) is an air-staging NO_X reduction technique that is usually based on withholding 15 to 20 percent of the total combustion air conventionally supplied to the firing zone. LOS Unit 1 operates with close-coupled overfire air (CCOFA), which has ports that are closer in vertical distance above the top row burners than optimized separated overfire air ports. It is believed that LOS Unit 1's boiler would be a suitable candidate for the installation of SOFA and removal of CCOFA ports for additional NO_X control, if this is necessary. This technology is feasible for LOS Unit 1's boiler if NO_X control beyond the presumptive BART level of 0.29 lb/mmBtu is required.

For typical cyclone coal-fired boilers, the operation of SOFA involves diverting approximately 20 percent of the secondary combustion air from the burner barrels, forcing the cyclones to operate fuel-rich. The diverted combustion air is then injected in the upper furnace, where combustion is completed.

SOFA can achieve significant NO_X reduction, typically 50 to 70 percent on typical cyclone coal-fired boilers with this typical amount of air staging. A summary of several of the first OFA retrofits to cyclone-fired boilers is described in published technical papers[1,2]. At least thirty nine existing cyclone-fired boilers, firing eastern bituminous, midwestern bituminous, and western subbituminous ("Powder River Basin") coals in units ranging in size from 50 to 1150 MW, have been retrofitted with commercial SOFA since 1998[3]. Additional cyclone-fired boilers have installed separated overfire air systems in conjunction with commercial fuel reburn retrofit projects[4]. Other NO_X emission reduction demonstration projects, primarily sponsored by U.S. Department of Energy National Energy Technology Laboratory's Clean Coal Technology Program[5], and other fuel reburn retrofit projects[6] have also installed separated overfire air on cyclone boilers. These cyclone boiler retrofit SOFA installations are listed in the U.S. NO_X Reduction Projects Summary in Appendix A.3.

A cyclone-fired boiler at Ameren Electric's Sioux plant (Unit 1) reduced NO_X emissions from 1.2 lb/mmBtu to as low as 0.38 lb/mmBtu in 2002 when operating with air-staged cyclones and separated overfire air, dropping NO_X as much as 68% at full load (480 MW) firing a blend of 85% western subbituminous (PRB) fuel and 15% Illinois bituminous coals[7]. This 500 MW unit, typically firing a blend of PRB and Illinois coals, is close in unit output to LOS Unit 2. Further operation at greater amounts of overfire air and deeper cyclone air-staging in 2004 demonstrated NO_X emissions down to 0.30 lb/mmBtu, a 75% reduction[8]. Additional testing in May-June 2005 achieved NO_X emissions as low as 0.20

lb/mmBtu by "deep air-staging" the cyclones using high amounts of overfire air when firing an 80:20 PRB/Illinois coal blend at 480 MWg, an 83% reduction[9].

A basic form of separated overfire air (SOFA) can be applied and installed on LOS Unit 1 and Unit 2 boilers. There are potential impacts and limitations unique to cyclone boilers firing North Dakota lignite that should be recognized as part of this emission reduction technology application.

A key aspect of successfully applying and operating separated overfire air on a cyclone-fired boiler is the ability to maintain adequate molten coal ash (slag) formation and flow within the barrels and slag taps. As secondary combustion air is diverted, less heat is released during air-staged combustion from the intentional formation of carbon monoxide, and temperatures within the cyclones decreases. The degree to which the cyclones can be operated with less than theoretical (stoichiometric) combustion air directly contributes to less NO_X formation and further in-furnace emission reduction but also risks solidification of the molten coal ash. Due to the variability of the combustible and ash components of North Dakota lignite, and the complex behavior of lignite ash when exposed to high temperatures, the ability to achieve NO_X control similar to percentages demonstrated while firing bituminous or subbituminous coals with significant amounts of air-staged cyclone combustion is uncertain. Basin Electric has operated Leland Olds Station (LOS) Unit 2 with low excess air and a cyclone barrel air/fuel ratio estimated to be approximately 95% of the theoretical amount required for complete combustion, yielding a highest 24-month period average NOx emission rate during the 2000-2004 output around 0.67 lb/mmBtu while firing a high lignite/Powder River Basin (PRB) coal blend. The lignite drying systems' vents add moisture and oxygen, raising furnace excess oxygen to appropriate levels. Using a basic SOFA system, assuming a sustainable level of NO_X emissions control with the operation of modestly air-staged cyclone furnaces with suitable combustion controls, is considered feasible for LOS Unit 2.

In order to potentially achieve lower NO_X emission rates with air-staged combustion for LOS Unit 2's boiler, additional combustion improvements can be installed. One potential improvement is to implement a unique form of SOFA for North Dakota-lignite–fired cyclone boilers. "Advanced" SOFA for lignite-fired cyclone boilers offers the highest performing version of this technology, and includes relocated lignite drying system vent ports, and relocated flue gas recirculation ports.

The basic version of separated OFA for LOS Unit 2 is expected to be technically feasible to design, furnish, install, and operate. There are several challenges anticipated for implementing advanced SOFA, primarily involving the ability to route large SOFA ductwork for diverting secondary air from the windboxes and extend the existing vent piping to new lignite drying systems' vent ports relocated from the lower to the upper furnace walls. These are believed to be solvable.

For LOS Unit 1's wall-fired boiler, basic SOFA is expected to have a modest NO_X reduction of approximately 20% below the 2000-2004 pre-control highest 24-month average baseline level, down to 0.23 lb/mmBtu. For LOS Unit 2's cyclone boiler, ASOFA alone is expected to have a modest NO_X reduction of approximately 28% below the 2000-2004 pre-control highest 24-month average baseline level, down to 0.48 lb/mmBtu. This estimate is based on the premise that cyclone air/fuel stoichiometric ratios will be restricted (limited to around 0.95) because of concerns for possible slag freezing, and that air-staged NOx control effectiveness will be diminished compared to demonstrated SOFA performance at other cyclone boilers.

Forms of separated overfire air described above are considered feasible as a combustion-related NO_X control technique for application to LOS Station Unit 1 and Unit 2 boilers.

Another form of separated overfire air being marketed commercially is "Rotating Opposed Fired Air" (ROFA). For utility applications in the United States, this has only been applied to pulverized coal-fired boilers, primarily small to medium-sized tangentially-fired units. It is different than basic SOFA in that it includes a hot air booster fan, and injects the overfire air in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row. The vendor (Mobotec USA) claims ROFA maximizes air-staged in-furnace combustion NOx reduction while minimizing negative impacts on carbon monoxide and flyash unburned carbon. More than three tangentially-fired utility boilers burning eastern bituminous coal or Illinois bituminous coal have been retrofitted with ROFA, each achieving a NO_X reduction of approximately 53-62% from pre-installation baselines of 0.54 to 0.60 lb/mmBtu without low-NO_X burners[10,11,12]. Even though boosted SOFA (ROFA) is not expected to produce a significant NO_X control reduction advantage compared with conventional SOFA to compensate for the higher costs of supplying, installing, and operating the hot air booster fan for LOS Unit 1, it was considered technically feasible for additional NO_X reduction on Unit 1 at LOS Station. For LOS Unit 1's wall-fired boiler, boosted SOFA (ROFA) is expected to reduce NO_X emissions approximately 24.3% below the 2000-2004 pre-control highest 24-month average baseline level, down to 0.216 lb/mmBtu.

While this variation of separated overfire air could potentially be applicable to cyclone boilers, it has not been marketed to serve such applications. Since cyclone boilers do not require the addition of hot air booster fans for SOFA, this technique is not distinct enough from basic SOFA from functional and air-staged cyclone NO_X reduction performance standpoints to warrant individual consideration. This alternative was eliminated from consideration for additional NO_X reduction on Unit 2 at LOS Station.

A.1.2.4 Oxygen-Enhanced Combustion (OEC)

A supplier of liquid oxygen (Praxair) has developed a method of replacing some of the combustion air supplied to the burners with pure oxygen. Combustion air, which is normally input through the secondary air system ductwork downstream of the forced draft (FD) fan and air heater, is supplemented with pure oxygen directly injected into the burners. Oxygen-enhanced combustion (OEC) can reduce boiler NO_X emissions resulting from " thermal NO_X", a reaction of the nitrogen in the combustion air admitted to the burners with the available oxygen component of the air in the flame or peak temperature regions of the fuel combustion process. The use of pure oxygen instead of air reduces the availability of nitrogen from the air to be oxidized in the high temperature regions, thus reducing formation of thermal NO_X. This technique has only been demonstrated in a boiler with pulverized fuel burners firing bituminous coal[13,14]. OEC was considered technically infeasible for additional NO_X reduction on Unit 1 at LOS Station.

The lack of adequate experience on any cyclone-fired coal burning boiler, on a temporary demonstration or permanent full-scale basis, for a coal-fired facility of this size precludes consideration of oxygen-enhanced combustion at Leland Olds Station for the Unit 2 boiler. This is deemed to be infeasible technology at LOS for Unit 2 at the present time.

A1.2.5 Flue Gas Recirculation

Flue gas recirculation has been commonly applied to coal-fired boilers, primarily to inject flue gas into the lower furnace, just above the burners, supplied from the boiler's economizer flue gas outlet via a hot gas booster fan. This modifies the amount and temperature of hot furnace gas either in the lower-middle or upper furnace and convection heat transfer zones. Flue gas recirculation for NO_X control is most commonly applied with gaseous or liquid fossil fuels to reduce the high temperatures which convert nitrogen in the combustion air to nitrogen oxides.

No examples of using or installing FGR on wall-fired or cyclone-fired coal-burning boilers strictly for NO_X emissions control were found in available technical literature. Although FGR could be installed on LOS Unit 1's boiler, it has not been necessary for steam temperature or furnace exit gas temperature control purposes, and is not expected to reduce NOx emissions. This technology is considered technically infeasible as a stand-alone, effective NO_X emissions control option for LOS Unit 1's boiler.

This technique is already practiced at Leland Olds Station in the Unit 2 boiler, primarily for operational reasons. As this flue gas typically has an oxygen content around 2-5%, it limits the availability of oxygen in a high temperature, possibly fuel-rich lower furnace zone. For LOS Unit 2's boiler, FGR could aid in potentially providing some additional NO_X emissions control if it were modified from its current configuration, as part of an advanced form of separated overfire air.

Although FGR is technically feasible for LOS Unit 2 in conjunction with other combustion improvements as part of the advanced form of SOFA, it has not been considered further as a stand-alone, effective NO_X emissions control option for LOS Unit 2's boiler.

A1.2.6 Water/Steam Injection (Combustion Tempering)

When applied to older gas-fired and oil-fired utility and industrial boilers, water and/or steam injection adds moisture into the lower furnace, concurrent with or near (to the side or slightly above) the burners, supplied from the boiler's treated feedwater or auxiliary steam systems via a metering pump or valve. Water/steam injection has been applied and practiced on natural gas-fired utility boilers for NO_X emissions control, but is believed to be relatively uncommon for continuous use on large pulverized coal utility boilers. There has been some limited testing and practice of water injection for NO_X emissions control on coal-fired and natural gas-fired cyclone boilers, respectively, demonstrating up to 30% reduction at full load[1,15]. This technique is most effective on gas-fired or bituminous coal-fired boilers. However, no examples of using or installing water injection and continuously operating such applications strictly for NO_X emissions control on wall-fired or cyclone-fired boilers burning subbituminous coal were found in available technical literature. Successful long-term operation of water injection would be difficult for lignite-fired boilers, due to the high moisture levels in the coal and the need to readily ignite and sustain stable combustion (and molten slag formation in the cyclone furnaces). For these reasons, water/steam injection is considered technically infeasible for NO_X control application at Leland Olds Station.

A.1.2.7 Fuel Reburn

Another combustion technology that may be applicable to control NO_X emissions from the Leland Olds Station units is fuel reburn. In a similar manner that overfire air diverts a portion of the combustion air input to the main firing zone, the reburning process involves supplying a portion of the fuel heat input to the boiler at a higher elevation in the furnace. In consideration of applying fuel reburn to LOS boilers, the existing burners/cyclones will be supplied with the majority of the fuel in the form of pulverized coal/crushed coal, respectively, and the balance of fuel is supplied to feed the reburn injection ports, such that the total heat input to each boiler is essentially the same as without fuel reburn. This creates an upper furnace atmosphere where the reburn fuel's combustion products causes some of the NO_X formed in the main burner combustion zone and reburn zone to be converted into molecular nitrogen. Depending on the amount of reburn fuel added and the amount of oxygen available in the furnace gases to combine with the reburn fuel introduced, additional combustion air may be supplied as supplemental or overfire air. Downstream of the air injection elevation, the intention is to complete the reaction of any remaining carbon monoxide (CO) to carbon dioxide (CO_2), plus reduce the amount of combustible matter remaining in the entrained flyash.

The most common forms of reburn technology applied to utility powerplant boilers are:

- Pulverized or micronized coal reburn (PCR or MiCR); and
- Gas reburn (GR).

Pulverized coal reburning and micronized coal reburning have been applied to pulverized coal and cyclone-fired boilers. NO_X reduction efficiencies of 50 to 60 percent have been demonstrated on eastern bituminous coal and midwestern bituminous and Powder River Basin (PRB) western subbituminous coals while supplying up to approximately 20-30% of the boiler's total fuel heat input to the reburn zone[5].

For utility powerplant boiler applications, natural gas has been utilized as reburn fuel most often, demonstrated in two basic approaches:

- Conventional gas reburn (CGR); and
- Fuel-lean gas reburn (FLGR™).

Either natural gas or pulverized coal (lignite) can be used as the reburn fuel. A sufficient quantity of natural gas is not currently available at the Leland Olds Station plant site. Supplying enough natural gas to provide 6 to 30% of the total heat input to either or both boilers at LOS is expected to be technically feasible, although transport pipeline installation capital costs, and current and predicted future unit natural gas costs and operating economics, are expected to be unfavorable.

Various forms of fuel reburning have been demonstrated and operated routinely on pulverized coal and cyclone boilers for NO_X emission controls[1,2,4,5,6,,16,17,18,19]. This technique has been applied to units firing eastern bituminous coal, and western subbituminous or PRB/bituminous coal blends, using pulverized or micronized coal or natural gas as the most common reburn fuel. Reburning for NO_X emissions reduction has never been demonstrated on a full-scale utility boiler firing high moisture, low heat content North Dakota lignite. Pulverized and micronized coal, along with conventional and fuel lean gas reburn technologies, are discussed below.

A.1.2.7.1 Coal Reburn

Conventional pulverized or micronized coal reburn (PCR or mCR) have been installed and demonstrated as effective for NO_X control on pulverized coal and cyclone boilers[5,6,16,17,18,19]. PCR/mCR replaces around 15-30% of total boiler fuel heat input with reburn fuel injected downstream of burners and upstream of SOFA, with or without air-staging the burners/cyclones. PCR/mCR will likely involve operation with fewer active pulverized coal main burners/cyclones. As a NO_X control technology, PCR/mCR is considered technically feasible for application on Leland Olds Station Unit 1 boiler. Examples of PCR/mCR applied to several pulverized coal-fired boilers are included in Appendix A3. Potential application of this alternative as a NO_X control option for LOS Unit 1's pulverized coal-fired boiler has similar combustion-related fuel- and air-staging, fuel preparation, and particulate emission issues as coal reburn applied to LOS Unit 2's cyclone boiler.

Pulverized or micronized coal reburn with the basic and boosted forms of separated overfire air (ROFA) can be applied and installed on Leland Olds Station Unit 1 boiler. PCR/mCR with basic SOFA is expected to reduce NO_X emissions approximately 46.2% from 2000-2004 pre-control highest 24-month average baseline levels, down to 0.154 lb/mmBtu for the LOS Unit 1 boiler. PCR/mCR with boosted SOFA is expected to reduce NO_X emissions approximately 48.7% from 2000-2004 pre-control highest 24-month average baseline levels, down to 0.147 lb/mmBtu for the LOS Unit 1 boiler. These expected levels of NO_X reduction are considered to be a reasonable estimate, given the concerns expressed about the potential impacts of this technique. Using finely pulverized lignite for reburn fuel is considered technically feasible for NO_X emissions control under evaluation for application to the LOS Unit 1 boiler.

In the case of applying conventional coal reburn to cyclone boilers, the existing cyclones are supplied with the majority of the fuel, with either natural gas or pulverized coal (lignite) used as the reburn fuel such that the total heat input to the boiler is essentially the same as without fuel reburn. Separated OFA ports are located above the reburn fuel injection section of the furnace. These SOFA ports provide sufficient oxygen in a conventional fuel reburn installation to complete the combustion process that begins in the main combustion zone and is supplemented in the reburn and burnout zones. This is shown schematically for a pulverized coal reburn application on a cyclone-fired boiler with SOFA in Figure A.1-1.

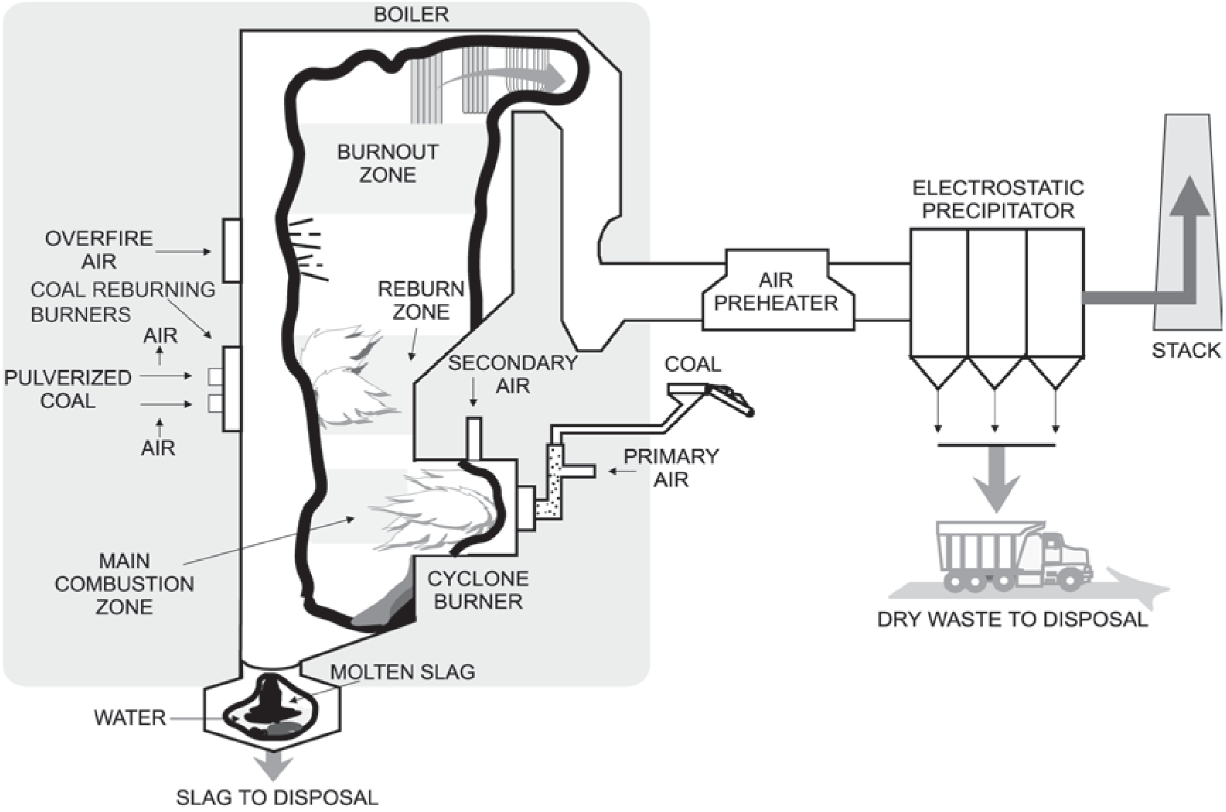

Figure A.1-1 Pulverized Coal Reburn Application on Cyclone Boiler With Overfire Air[19]

In the United States, pulverized coal reburning and micronized coal reburning techniques for utility powerplant NO_X emissions reduction have been applied on a very limited full-scale, full-time basis to cyclone-fired boilers in field demonstration tests and longer-term demonstration operation, respectively. There have been only two known pulverized or micronized coal reburn installations in the United States on cyclone boilers, one on a utility boiler in Wisconsin, and one on a small industrial-size cyclone boiler in New York state[5]. NO_X emissions reduction efficiencies of 57 percent have been demonstrated on cyclone boilers firing eastern bituminous coal, or midwestern bituminous and Powder River Basin (PRB) western subbituminous coals while supplying up to approximately 20-30% of the boiler's total fuel heat input to the reburn zone. With the exception of the U.S. Department of Energy's (DOE) Clean Coal Technology Program demonstration projects[7,21], no known commercially-available coal reburn systems have been installed and were/are routinely operated on cyclone boilers in the United States to date. The DOE-CCTP projects for coal reburn applied to cyclone boilers are described below.

Pulverized coal reburning for NO_X emissions reduction in a cyclone-fired boiler was demonstrated on the 110 MW Nelson Dewey Unit 2 for Wisconsin Power & Light in 1991-1992. Reburn fuel preparation and handling, reburn burners with flue gas recirculation, and a separated overfire air system were added. Coal reburn tests were conducted on this unit while firing bituminous and PRB coals. NO_X emission control efficiencies of 50 to 60 percent, with reductions from 0.75-0.83 lb/mmBtu baselines to around 0.38 lb/mmBtu, but as low as 0.29 to 0.32 lb/mmBtu, with PRB coal at full load with approximately 25-30% of the total fuel heat input from reburn fuel were demonstrated[5,17,18]. The reburn system is no longer operated on Nelson Dewey Unit 2.

Micronized coal reburning has been demonstrated in 1997-1998, and continues to operate year-round on a small industrial cyclone boiler (400,000 lb/hr steam output, 50 MW gross equivalent) for Eastman Kodak Company at their Kodak Park facility in Rochester, NY. This unit (Boiler #15) achieves a NO_X reduction efficiency of approximately 57 percent on eastern bituminous coal, involving limited cyclone air-staging (cyclones believed to be slightly above 0% excess air) and a modest amount of overfire air injection downstream of the micronized reburn fuel input nozzles. Approximately 17% of the boiler's total fuel heat input is typically supplied to the reburn zone. This coal reburn system continues to operate routinely at this facility. This installation is reported to use a Fuller MicroMill to produce micronized coal with 80% passing through a 325 mesh screen[5,16].

Similar to the application of separated overfire air, there are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. As a reburn fuel, lignite is expected to behave appropriately upon introduction in the lower middle furnace to help reduce NO_X emissions. The concerns are that the diversion of a significant amount of heat input from the cyclone barrels to use as a source of reburn fuel in the form of pulverized or micronized lignite may reduce active cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Coal reburn can be applied with or without air-staging the cyclones, i.e. operate in normal-low excess air mode or substoichiometrically. Air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction as part of this reburn technique will further risk slag “freezing” in the barrels and lower furnace. Reducing the number of active cyclones to maintain fuel and heat input rates comparable to normal pre-control baseline (i.e. non coal reburn) operation can accommodate reduced total cyclone coal firing rates while operating a coal-fired boiler with reburn and separated overfire air is the typical approach to avoid slag tapping problems. However, if the fewer number of active cyclones are air-staged, this limits the amount of in-furnace NO_X reduction that may be achieved with this technique.

Significant additions to the fuel preparation equipment in the existing plant facilities will be required. The coal reburn system expected to be applied to each of the LOS boilers would use two new dedicated fine-grind pulverizers and dynamic classifiers for each boiler to achieve the level of coal particle size distribution required.

Higher unburned carbon levels in the flyash exhausted from the boiler may occur, especially when the reburn fuel is coal, and the main burners/cyclones are fired with less than theoretical amounts of combustion air commonly practiced with the use of overfire air.

Particulate emissions and flue gas opacity from the stack will increase during coal reburn operation with particulate matter (PM) removal performed by an electrostatic precipitator (ESP), due primarily to higher inlet particulate loadings and smaller particle sizes of the flyash. The estimated increase in LOS Unit 2’s ESP inlet PM during coal reburn will be approximately +50% of the baseline amounts. This magnitude of flyash increase is usually not significant enough to preclude the use of reburn fuel due to exceeding permitted opacity limits, unless the ESP is already marginal on flyash removal efficiency. However, assuming that LOS Unit 2’s ESP outlet PM emissions are not allowed to increase due to the coal reburn conditions as described above, then additional PM collection equipment to increase PM collection capacity, or boiler firing restrictions, will need to be implemented. This is very significant for LOS Unit 2. Since the LOS Unit 2 boiler is fired with crushed coal, and the cyclone boiler’s typical PM emission is approximately one third to one half of the boiler’s total ash input, the existing ESPs are designed for relatively modest inlet dust loadings. There is likely to be insufficient flyash collection efficiency if coal reburn were to be applied without additional PM collection equipment to increase PM collection capacity.

An issue that affects the feasibility of lignite reburning is the uptime required for the lignite reburn fuel pulverizing system, and impact of the reburn system on effectiveness in reducing NO_X emissions during load changes and lower loads. Typically, one new pulverizer is dedicated to prepare reburn fuel in existing pulverized fuel-fired boiler applications. Cyclones may be fired with less fuel or deactivated during current boiler operation in order to accommodate changes in fuel combustion characteristics, boiler load, and for scheduled or unscheduled individual crusher maintenance. Leland Olds Station Unit 2 has twelve crushers for cyclone coal grinding, each dedicated to one of the twelve cyclones. Diverting as much as 30% of the total heat input as reburn fuel could require two to four existing cyclones to be deactivated, and two new MPS-89 pulverizers to be dedicated to reburn fuel preparation. As each of these mills requires periodic maintenance, boiler emissions and/or load could be negatively impacted during individual reburn mill outage periods while the boiler remained in service. A high level of fineness of coal particles from the reburn mills is important to achieve and maintain in order to limit increases in flyash combustibles. A minimum of 60 percent passing through 200 mesh fineness is recommended by one of the reburn technology vendors (B&W) for pulverized lignite reburn. Micronized coal reburn requires even greater fineness: 70-80 percent passing through a 325 mesh screen.

Pulverized or micronized coal reburn with the advanced form of separated overfire air (ASOFA) can be applied and installed on Leland Olds Station Unit 2 boiler. These combined techniques are expected to reduce NO_X emissions approximately 52% from 2000-2004 pre-control highest 24-month average baseline levels, down to 0.32 lb/mmBtu for the LOS Unit 2 boiler. The expected level of NO_X reduction is considered to be a reasonable estimate, given the concerns expressed about the potential impacts of this technique. Using finely pulverized lignite for reburn fuel is considered technically feasible for NO_X emissions control under evaluation for application to the LOS Unit 2 boiler.

A1.2.7.2 Conventional Gas Reburn

Natural gas has been preferred as the reburn fuel of choice. Natural gas has been utilized for reburn fuel in two basic approaches: conventional gas reburn (CGR) and fuel-lean gas reburn. In the conventional approach, up to 30% of the boiler's total fuel heat input is supplied to the reburn zone, followed by a significant amount of overfire air for completion of combustion prior to flue gases exiting the boiler.

One example of CGR applied to a pulverized coal-fired boiler is included in Appendix A3. Potential application of this alternative as a NO_X control option for LOS Unit 1's pulverized coal-fired boiler has similar issues as gas reburn applied to LOS Unit 2's cyclone boiler.

A schematic graphic of conventional gas reburn on a pulverized coal-fired boiler is shown in Figure A.1-2.

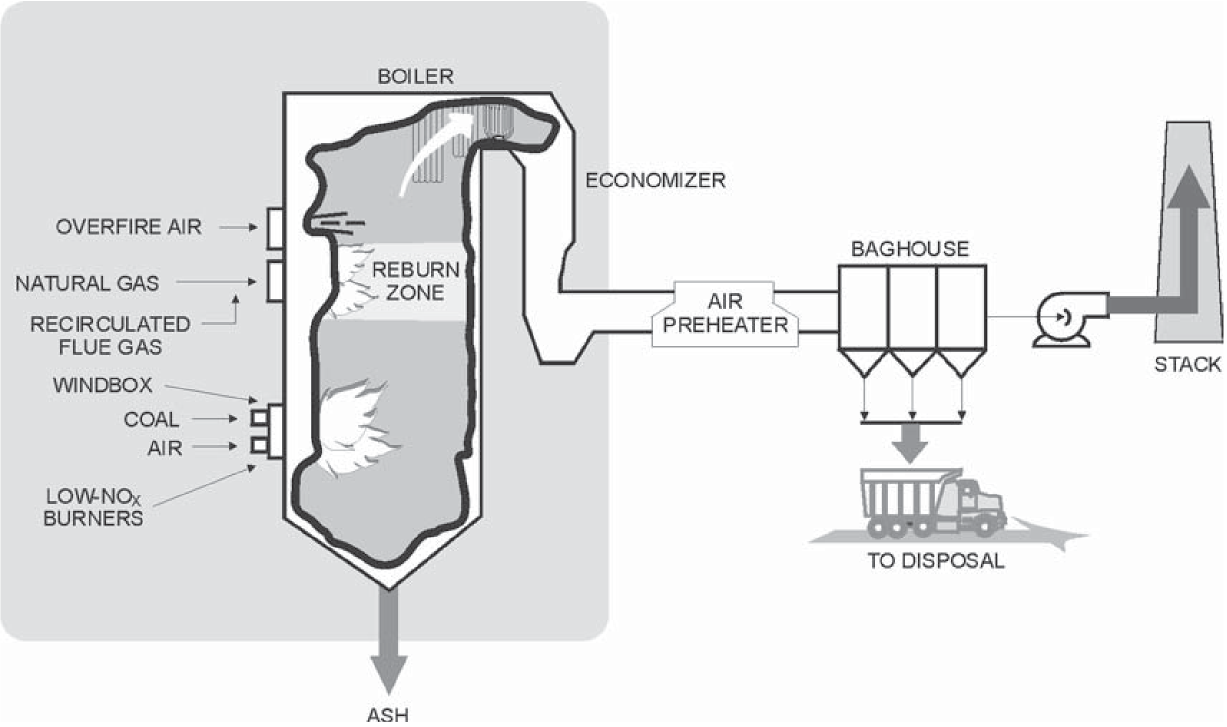

Figure A.1-2 Natural Gas Reburn Application on Wall-Fired Pulverized Coal Boiler with Overfire Air[19]

As a NO$_X$ control technology, conventional gas reburn is considered technically feasible for application on Leland Olds Station Unit 1's boiler. Natural gas unit costs are expected to be approximately nine times more expensive per million Btu than coal. Leland Olds Station does not have a supply of large quantities of high-pressure natural gas to consume for reburn fuel. Bringing a high-pressure gas pipeline approximately 26 miles to the plant site is considered technically feasible. An order of magnitude estimated cost of $1 Million per mile would be significant; the installed capital cost of such an asset, and the expected high unit gas prices are significant economic disadvantages, and make this alternative economically unfavorable compared to other NO$_X$ control options with similar expected performance. For these reasons, conventional gas reburn was not evaluated for consideration as an option for LOS Unit 1.

Conventional gas reburning in a cyclone-fired boiler has been available at Tennessee Valley Authority's Allen Station Boiler #1 (300 MW) since 1998. The reburn technology provider (vendor) claims NO_X emissions were reduced 67% from a full-load baseline of 1.29 (down to 0.42) lb/mmBtu when firing a blend of western bituminous and PRB coals[8]. Conventional gas reburn fuel input rates were not available from the technology vendor's literature. Another reference source of information stated NO_X emissions were reduced 65% from a full-load baseline of 0.86 (down to 0.30) lb/mmBtu with 7 percent of the total fuel heat input supplied as reburn fuel[5].

Similar to the application of separated overfire air, there are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. As a reburn fuel, natural gas is expected to behave appropriately upon introduction in the lower middle furnace to help reduce NO_X emissions. The concerns are that the withholding of a significant amount of heat input from the cyclone barrels to use natural gas as a source of reburn fuel may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Air-staging the cyclones for use of separated overfire air to further complement combustion NO_X reduction as part of this reburn technique will further risk slag "freezing" in the barrels and lower furnace. Reducing the number of active cyclones which are air- and fuel-staged to accommodate reduced firing rates while operating a coal-fired boiler with reburn and separated overfire air is the typical approach to avoid slag tapping problems.

Natural gas reburn with the advanced form of separated overfire air (ASOFA) can be applied and installed on Leland Olds Station Unit 2's boiler. There are no published CFD model studies showing potential results of applying conventional gas reburn techniques to a North Dakota lignite-fired cyclone boiler to predict the level of NO_X control that may be achievable. For lignite-fired cyclone boilers, conventional reburn fuel firing with a basic form of separated overfire air is expected to be much less effective in reducing NO_X emissions than previously demonstrated elsewhere. Using high-pressure natural gas for reburn fuel is considered technically feasible for NO_X emissions control applicable to Leland Olds Station'a Unit 2's boiler. However, due to the expected high installed capital cost of bringing a high-pressure gas pipeline to the plant site, and high unit gas prices make this alternative economically unfavorable compared to other NO_X control options with similar expected performance. CGR was not evaluated for consideration as an option for LOS Unit 2.

A1.2.7.3 Fuel Lean Gas Reburn

Another approach to gas reburning is “fuel-lean gas reburn” (FLGR™) technology, which injects limited amounts of natural gas above the burners (or cyclones) with or without significant air-staging of the burners (cyclones) or the addition of overfire air upstream of the fuel injection elevation.
More commonly, FLGR™ has been applied on medium to large pulverized coal wall-fired boilers burning eastern bituminous or western subbituminous coals. On Wisconsin Electric Power Company’s (WEPCO’s) Pleasant Prairie Unit 1, a 620 MWg Riley turbo-fired wet-bottom (slagging) pulverized coal boiler, FLGR™ alone was predicted to reduce NO_X emissions by 35-39 percent at a gas reburn rate of 7-8 percent but only achieved 20% from a baseline of 0.45 lb/mmBtu[21,23]. This is presumably without burner air-staging or SOFA. It has also been applied in combination with SNCR at this WEPCO site. Several other examples of FLGR™ applied to pulverized coal-fired boilers are included in Appendix A3.

As a NO_X control technology, FLGR™ is considered technically feasible for application of Leland Olds Station Unit 1 boiler. Potential application of this alternative as a NO_X control option for LOS Unit 1’s pulverized coal-fired boiler has similar issues as conventional gas reburn. Leland Olds Station does not have a supply of large quantities of high-pressure natural gas to consume for reburn fuel. Bringing a high-pressure gas pipeline to the plant site is considered technically feasible. However, the installed capital cost of such an asset, and the expected high unit gas prices are significant economic disadvantages, and make this alternative economically unfavorable compared to other NO_X control options with similar expected performance. For these reasons, fuel lean gas reburn was not evaluated for consideration as an option for LOS Unit 1.

FLGR’s first field-test on a cyclone-fired boiler was at Commonwealth Edison’s Joliet Unit 6 (327 MW), a 9-cyclone-furnace boiler[20]. NO_X emissions reduction with FLGR (without SOFA) was believed to be approximately 35-40% with 7% of the boiler’s total fuel heat input supplied in the reburn zone. This test yielded 0.59 lb/mmBtu NO_X emissions from a baseline of 0.98 lb/mmBtu[21]. One other cyclone boiler has been modeled using computational fluid dynamics (CFD) as part of a study looking at applying FLGR at Owensboro Municipal Utilities’ Elmer Smith Station Unit 1 (150 MW single-wall, eastern bituminous coal-fired boiler with three cyclones). This model predicted that NO_X emissions could be reduced by 25-30% over that achievable from overfire air and SNCR[22].

Similar to the application of separated overfire air, there are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. As a reburn fuel, natural gas is expected to behave appropriately upon introduction in the upper furnace (above the SOFA elevation) to help reduce NO_X emissions. There are concerns that the withholding of a modest amount of heat input from the cyclone barrels to use natural gas as a source of reburn fuel may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Limited additional potential NOx reduction is anticipated when FLGR™ is operated with lignite-fired cyclones, due to the potential need to remove one or more cyclones from active firing to maintain adequate heat input in the remaining active cyclones for keeping satisfactory slag formation and flow. This creates lower furnace conditions where oxygen (cooling air from the idle cyclones) is introduced in proximity to the reburn fuel, disrupting the desired in-furnace reduction process for nitrogen oxides.

In the case of FLGR™ applied to lignite-fired cyclone boilers, the amount of fuel injected above the existing lignite drying system vent ports is expected to be substantially more than previously demonstrated in order to compensate for the higher oxygen levels due to the introduction of moist air in the lower furnace above the cyclones without relocating the vent ports. The existing lignite drying systems' vent ports' locations and introduction of oxygen to the lower furnace below the presumed FLGR™ injection points (as part of the basic form of SOFA) will likely limit the NO_X emission reduction potential of the FLGR™ component.

Fuel lean gas reburn can be applied and installed on LOS Unit 2 boiler. There are no published CFD model studies showing potential results of applying fuel lean gas reburn techniques to a North Dakota lignite-fired cyclone boiler to predict the level of NO_X control that may be achievable. Although this technique is considered technically feasible for application to LOS Unit 2 boiler, the unit operating and capital costs to supply large quantities of gaseous fuel not currently available at this site are economic disadvantages compared to other NO_X control options with similar expected performance. It was not evaluated for consideration as an option for LOS Unit 2.

Other demonstrated forms of fuel lean gas reburning, such as FLGR™ with various forms of separated overfire air, and amine-enhanced fuel lean gas reburn (FLGR™ with SNCR), are discussed under the layered technologies section.

A1.2.7.4 Fuel Oil Reburn

Fuel oil has been substituted for natural gas in a conventional reburn application. This is much less common in the United States than using natural gas as a reburn fuel, due to the general lack of demand and difficulties in supplying the volume of fuel oil which would be required. It has been installed commercially on three 350 MW oil-fired boilers in New Brunswick (Canada) at the Coleson Cove plant[4,5,17]. NO_X emissions reduction with reburn and SOFA was 78% with 25% of the boiler's total fuel heat input supplied in the reburn zone. This yielded 0.22 lb/mmBtu NO_X emissions from a baseline of 1.0 lb/mmBtu[7]. One example of conventional fuel oil reburn applied to a very large (800 MW) pulverized coal-fired boiler is included in Appendix A3. No examples of conventional fuel oil reburn applied to a coal-fired cyclone boiler were found in available literature.

Fuel oil reburn could potentially be considered for application to LOS Unit 1 and Unit 2's boilers. Potential application of this alternative as a NO_X control option for LOS Unit 1's pulverized coal-fired boiler and Unit 2's cyclone-fired boiler has similar issues as conventional gas reburn. Investigation of the specific source, distance, and costs for supplying significantly increased quantities of fuel oil via transport trucks hauling tanker trailers or underground pipeline to LOS has not been performed. The expected high unit operating and capital costs to supply large quantities of high-volume liquid fossil fuel at this site are economic disadvantages. The concerns regarding potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application are similar to those expressed for conventional gas reburn. It is believed that potential NO_X control with oil reburn would be slightly less than comparable conventional gas reburn systems.

Although fuel oil reburn could potentially be considered for application to LOS Unit 1's and Unit 2's boilers, the lack of any distinct potential NO_X reduction advantages and demonstration on cyclone-fired boilers does not appear to support its consideration. This alternative was not included in the NO_X control cost-effectiveness analysis for Unit 1 and Unit 2 at Leland Olds Station.

A1.3 Post-Combustion Controls

Post-combustion controls deal with techniques that thermally or chemically-treat the flue gases to reduce NO_X emissions after they have exited the boiler's lower furnace. In the case of Leland Olds Station Units 1 and 2, this primarily involves forms of selective catalytic reduction (SCR) and selective non-catalytic reduction (SCR) technologies. Another emerging technology that has recently entered the commercial market is Powerspan's Electro Catalytic Oxidation®, which treats utility boiler flue gas for removal of nitrogen oxides, sulfur oxides, and mercury. Another emerging technology that has recently entered the pilot-scale commercial demonstration phase of development in the utility air pollution control market is Powerspan's Electro Catalytic Oxidation®, which treats boiler flue gas for removal of nitrogen oxides, sulfur oxides, and mercury.

A1.3.1 Selective Non-Catalytic Reduction (SNCR)

Selective Non-Catalytic Reduction (SNCR), and variations such as hydrocarbon-enhanced SNCR (sold under the trade name of NOxStar™), and Rich Reagent Injection (RRI), are all post-combustion types of boiler NO_X emission controls. While these technologies promote NO_X reduction with chemical reactions that are insensitive to the specific fuel types whose combustion products are being treated, the large majority of boiler applications to date have been on pulverized coal-fired units burning eastern bituminous fuels. SNCR has been used to reduce NO_X emissions on numerous utility boilers burning eastern bituminous coal, midwestern bituminous coal, and, to a lesser extent, western subbituminous coal. SNCR has also been used with fuel oil and natural gas-fired units. SNCR (and hydrocarbon-enhanced SNCR) technologies can each be applied to fossil fuel-fired boilers with or without the use of a SOFA system. The ability to apply SNCR does not appear to be dependent directly on the type of burners (wall-fired, tangentially-fired, and cyclone-fired) employed in the boilers where it has been installed, with or without overfire air in full operation. Operation at these plants has demonstrated that SNCR can decrease NO_X emissions as much as 15-40% at full load, most typically between 25-35%[23,24,25].

In the conventional SNCR process, urea or ammonia is injected into the boiler in a region where the combustion gas temperature is in the 1700 to 2100 degrees F range. Under these temperature conditions, the urea reagent [$CO(NH_2)_2$] or ammonia [NH_3] reacts with the nitrogen oxides [NO_X], forming elemental nitrogen [N_2] and water, reducing NO_X emissions.

Several examples of SNCR applied to pulverized coal-fired boilers are included in Appendix A3. Long-term examples where SNCR has been used to reduce NO_X emissions on two cyclone-fired boilers are on a 138 MW unit and 160 MW unit burning eastern bituminous coal at Conectiv's B.L England Station (Units 1 and 2) since 1995 and 1996, respectively. Tests at this cyclone-fired boiler powerplant demonstrated that SNCR can decrease NO_X emissions as much as 30-36% at full load, from around 1.3-1.4 lb/mmBtu respectively to as low as 0.85 lb/mmBtu (without overfire air)[23,24,25]. These boilers, located near Atlantic City, New Jersey, continue to operate SNCR (with OFA) for NOx emissions control recently reported annual average emission rates around 0.55 and 0.45 lb/mmBtu, respectively.

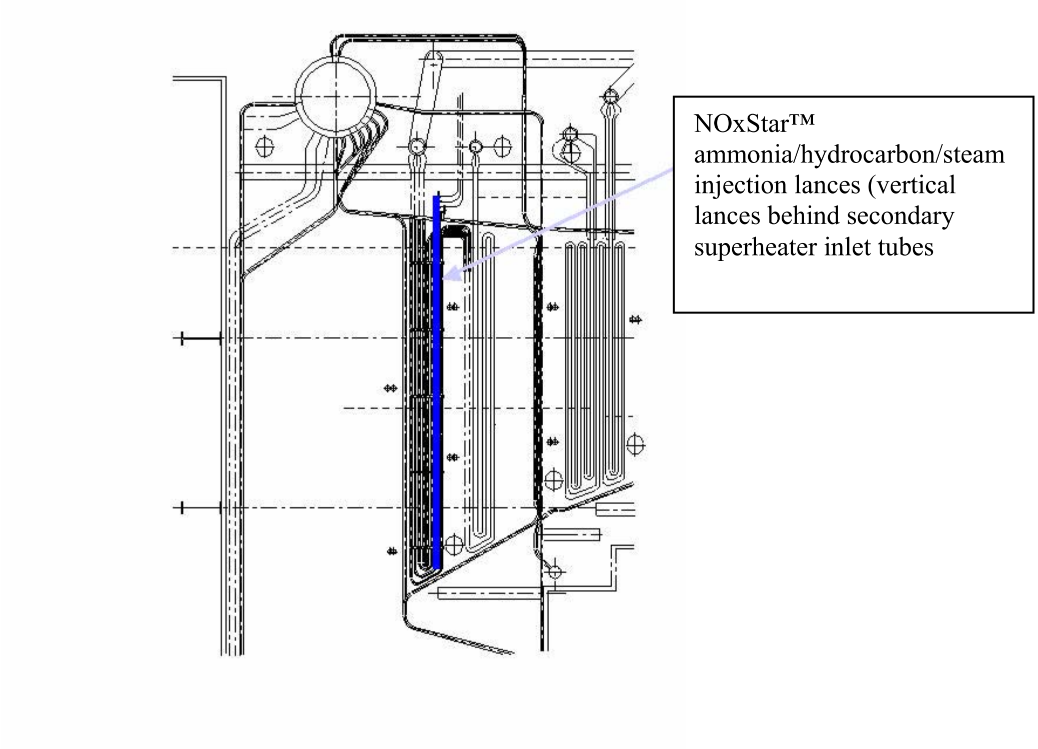
SNCR can be applied and installed on the Leland Olds Station boilers. However, with much higher installation and operation costs compared with SOFA, this alternative (without SOFA) was not evaluated for consideration as a stand-alone option for LOS Unit 1 or Unit 2.

SNCR can be installed in combination with existing close-coupled OFA, or basic or boosted forms of separated overfire air for Unit 1. The highest-performing feasible versions of conventional SNCR for LOS Unit 2 are combinations of SNCR with ASOFA with and without Rich Reagent Injection. The predicted NO_X emissions for these combinations are included in the "Layered NO_X Reduction Technologies" section of this report.

A1.3.1.1 Hydrocarbon-enhanced SNCR (NOxStar™)

Hydrocarbon-enhanced SNCR technology, commercially marketed as NO_XStar™, is offered by a single vendor (Mitsui Babcock) as a post-combustion type of enhanced SNCR technology. This involves an ammonia-based reagent that is continuously injected into the superheater/reheater pass of an operating boiler with small amounts of gaseous hydrocarbon (typically either natural gas or propane) and air or steam to provide lance cooling and aid reagent dispersion. The targeted combustion gas temperature range is between 1500°F and 2000°F. The amount of gaseous hydrocarbon introduced is small enough (0.1 to 0.2% of total fuel heat input) that this is not intended to act as a form of reburn or staged fuel combustion. An array of permanently-installed injection lances are located within the boiler convection pass, divided into numerous discrete zones across the full width and height of the duct. The hydrocarbon auto-ignites, forming hydroxyl (OH) radicals which react with the NO_X and ammonia to produce elemental nitrogen (N_2) and water vapor (H_2O).

An example of a hydrocarbon-enhanced SNCR installation on a wall-fired pulverized fuel boiler is shown as a sectional side elevation view of the upper furnace[29] in Figure A.1-3.



NOxStar™ ammonia/hydrocarbon/steam injection lances (vertical lances behind secondary superheater inlet tubes

Figure A.1-3 Hydrocarbon-enhanced SNCR Application on PC-fired Boiler[29]

NO_XStar™ was demonstrated at Tennessee Valley Authority's Kingston Power Station Unit 9 (tangentially-fired 200 MW twin-furnace boiler firing eastern bituminous coal) in 2002[26]. This technology was subsequently permanently-installed at TVA's Colbert Station Unit 4 in late 2003 on a 192 MW wall-fired boiler burning eastern bituminous coal[27]. NO_X reduction was stated as 68-80% for these applications, which included the impact of overfire air and air-staged combustion upstream of the ammonia and propane injection locations. The specific NOx reduction strictly attributable to the enhanced reagent injection without combustion effects was not disclosed.

The supplier (Mitsui Babcock) of hydrocarbon-enhanced SNCR technology claims there is little sensitivity to the type fuel (coal) or burners this technique can be potentially applied to in order to reduce NO_X emissions. Non-retractable ammonia injection lances arranged in a parallel-series manner are permanently mounted inside the upper furnace zone, attached to convective tube elements. Different sections of the injection "grid" can be turned off or on, depending on load and firing conditions and amount of NO_X reduction required. Injection nozzles are continuously purged and cooled by extracted superheated steam from the boiler's main steam outlet, whether ammonia reagent is being introduced into the flue gas stream or not. Ammonia slip can be minimized by injecting less reagent, although NO_X control performance will be reduced.

There are a number of issues related to firing North Dakota lignite that make the applicability of hydrocarbon-enhanced SNCR more difficult than in other coal-fired powerplants. These issues include:

- The chemical reagent injection for hydrocarbon-enhanced SNCR (NO_XStar™) NO_X control technology must be precisely located and carefully controlled to be effective. Operation outside of the required operating ranges can even result in increased NO_X emissions. Extensive computational fluid dynamic (CFD) model simulations are needed to determine the optimum injection points and spray patterns. Boiler operating conditions change with unit load and varying fuel characteristics. The NO_XStar™ process control system must be able to adjust for these changing conditions in order to be effective throughout the intended load range and firing conditions encountered.
- The physical arrangement of the NO_XStar™ reagent injection lances expected to be required in LOS boilers' upper furnaces will be difficult to install. Limited convection heat transfer surface is installed, resulting in high flue gas temperatures entering the air preheater so it can produce very hot combustion air for effective coal pre-drying and cyclone lignite firing. The reheater pendants or area between the reheater and primary superheater tubes are in the gas path where the temperature window is believed to be suitable for effective NO_X control. The convection heat transfer surfaces in this zone are either tightly spaced or non-existent. Since the NO_XStar™ reagent injection lances are permanently installed within the flue gas path, and attached to the convection heat transfer surfaces, this situation is not conducive to this type of reagent injection lance installation.
- Hydrocarbon-enhanced SNCR (NO_XStar™) technology has been only applied on pulverized coal-fired boilers burning eastern bituminous fuels to date. It has not been applied to cyclone boilers, especially on units firing high-slagging coals such as western subbituminous (PRB) and lignite. The heat transfer surfaces in the convective heat transfer zone of the LOS boilers where the reagent mixture would be injected are prone to severe fouling from flyash constituents common in North Dakota lignite coals. Flyash deposit accumulation on the outside of the NO_XStar™ lances in LOS boilers' upper furnaces is expected to be significant, potentially occurring within a matter of a few weeks from startup and nearly impossible to prevent or remove effectively during boiler operation. Such buildup is expected to cause significant maldistribution of the NO_X

> reduction chemical reagent from the injection nozzles. Effective on-line removal of these deposits from the injection nozzles is anticipated to be insufficient to maintain effective injection distribution and volume control. It is anticipated that this would significantly reduce the NO_X emission reduction performance consistently achieved on a sustainable basis.

This technology is considered to be technically infeasible for application on North Dakota lignite-fired boilers. The expected difficulties for installation and susceptibility of the embedded reagent injection nozzles to rapid, severe fouling will prevent consistent performance. The specific conditions of reagent lance placement and lack of experience with this type of boiler and this high-slagging coal makes the application of hydrocarbon-enhanced SNCR technically infeasible for NO_X reduction over the long term on North Dakota lignite-burning wall-fired and cyclone boilers.

A1.3.1.2 Rich Reagent Injection (RRI)

Rich Reagent Injection (RRI) is a NO_X control technology that has been developed and demonstrated specifically for use on cyclone boilers. RRI is not applicable to pulverized coal-fired boilers, and therefore is technically infeasible for LOS Unit 1. Rich Reagent Injection is an SNCR process that involves the injection of urea into the lower furnace between the cyclones and the SOFA ports. RRI targets a high temperature, fuel-rich zone within the boiler-furnace environment immediately adjacent to the cyclone burners, and requires temperatures in the range of 2400 to 3100 degrees F. The combustion gases must be essentially devoid of free oxygen, in order to avoid oxidizing the nitrogen contained in the injected reagent, which would create NO_X emissions instead of reducing them.

The RRI process for NO_X reduction must be used in conjunction with air-starved (substoichiometric staged-air) cyclone combustion resulting from the installation and operation of an OFA system, with or without SNCR. The cyclones' air/fuel stoichiometry must be carefully controlled to maintain fuel-rich conditions for the RRI process to be effective. The existing lignite drying system's vent ports are immediately above the top rows of cyclones. This introduces oxygen in the same vicinity as the reagent injection ports, and will disrupt the beneficial action of the fuel-rich zone and amine reagent to significantly reduce NO_X emissions. Without the "advanced" version of SOFA, RRI will not contribute positively to NO_X emissions control on Leland Olds Station Unit 2 boiler. This places a large emphasis on the expected performance of ASOFA in order for RRI to be successful in producing significant additional NOx emissions reduction on lignite-fired cyclone boilers.

The three zones of a Rich Reagent Injection SNCR application on a boiler with separated overfire air are shown as a sectional side elevation view of the furnace[29] in Figure A.1-4.

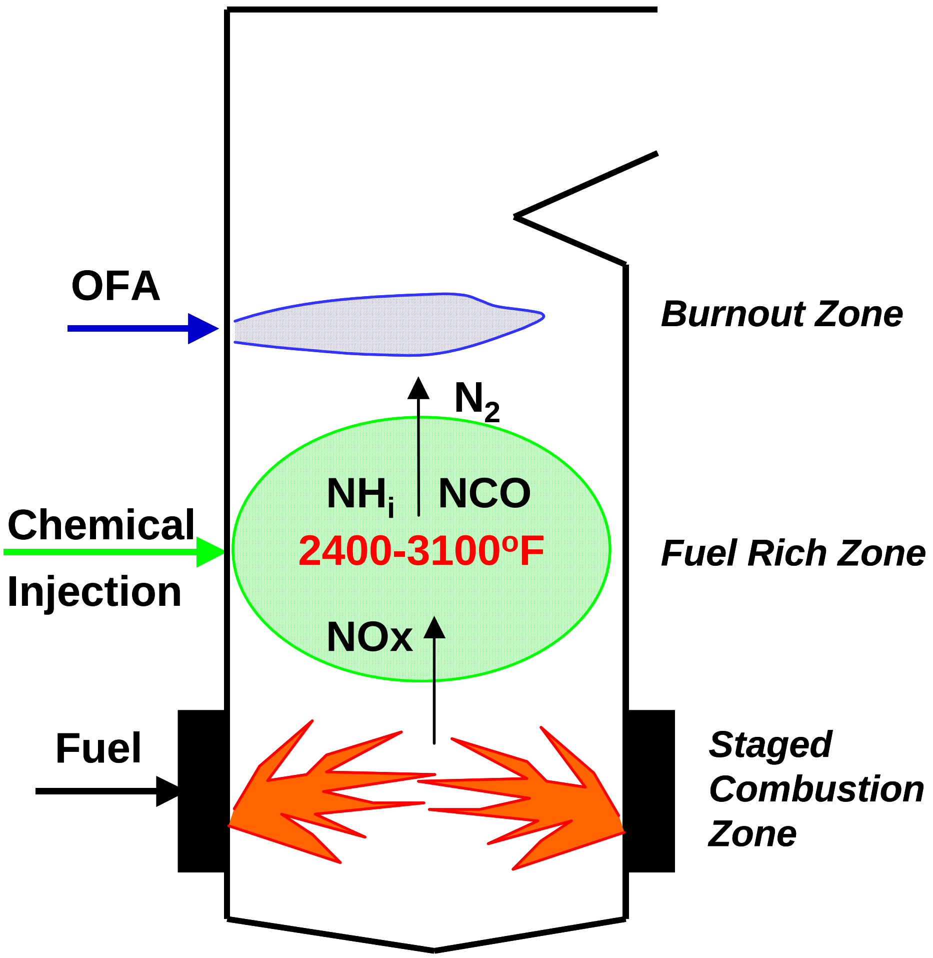


Figure A.1-4 Rich Reagent Injection Application on Boiler With Overfire Air[29]

The Rich Reagent Injection (RRI) process has been successfully demonstrated on at least two cyclone-fired boilers, with the most recent installation at Ameren's Sioux Unit 1, a 500 MW boiler firing a blend of PRB and midwestern bituminous coals. Short-term testing of the RRI process has been performed alone and in combination with SNCR on B.L. England Unit 1 in 1999[25,28,29], and more recently at Ameren's Sioux Unit 1 in 2002[7,8,29], and in the first half of 2005[9] (RRI + OFA with and without SNCR).

The NO_X emission reduction reagent injection for RRI processes must be precisely located and carefully controlled to be effective. Operation outside of the required operating ranges can even result in increased NO_X emissions. Extensive computational fluid dynamic (CFD) simulations are needed to determine the optimum injection points. Boiler operating conditions will change with unit load and varying fuel characteristics. The RRI process control systems must be able to adjust for these changing conditions.

RRI has the potential to provide a moderate degree of NO_X reduction on coal-fired cyclone boilers. Short-term parametric demonstration test data from B.L. England and Sioux show this technology can reduce NO_X emissions between 10 and 36 percent[7,8,9,28,29]. So far, the RRI process is feasible to be used only in conjunction with air-starved (substoichiometric staged-air) cyclone combustion resulting from the installation and operation of an OFA system.

The RRI process has not been demonstrated on any unit that fires North Dakota lignite. As of May 2006, commercial installation of a permanent Rich Reagent Injection system has not been made on any cyclone-fired boiler. There is only one holder of a commercial license for modeling and conceptually designing RRI (Reaction Engineering International), with two vendors sub-licensed to design and sell RRI equipment (Fuel Tech and Combustion Components Associates). Since these license agreements are in place, and considering that successful demonstration testing has been performed at two boiler powerplants, this technology is considered to be commercially available for potential application on LOS Unit 2's lignite-fired cyclone boiler.

Rich Reagent Injection can potentially be applied and installed on LOS Unit 2's boiler, which must only be with an advanced form of separated overfire air (ASOFA), in combination with and without SNCR. The predicted NO_X emissions for these combinations are included in the "Layered NO_X Reduction Technologies" section of this report.

A1.3.2 Selective Catalytic Reduction (SCR)

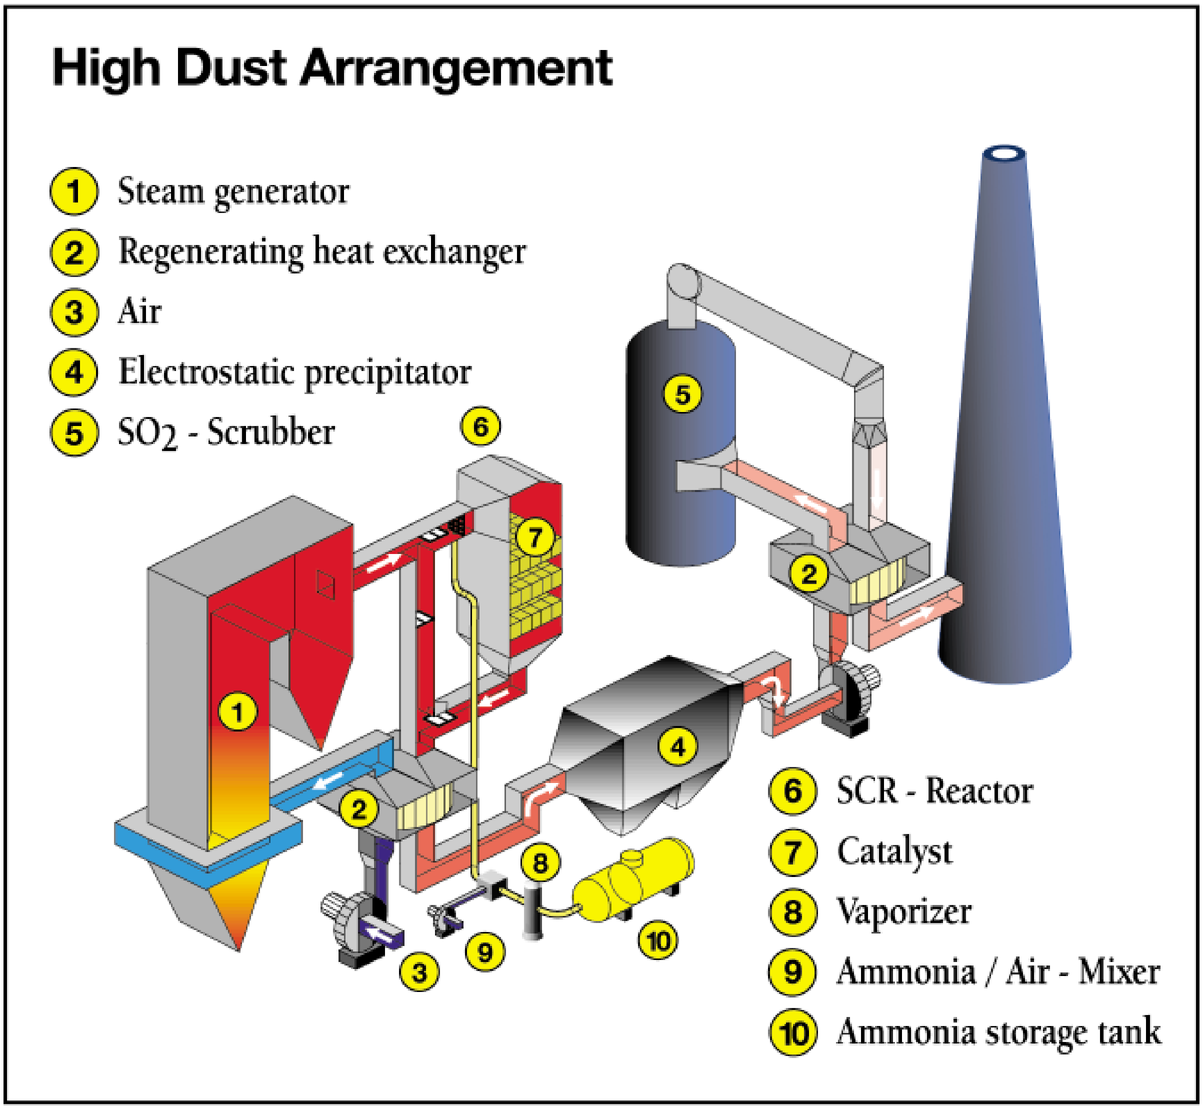
The lowest NOx emission levels from coal-fired utility boilers are typically achieved by installing and operating selective catalytic reduction (SCR) technology. In the SCR process, the gas stream is passed through a catalyst bed in the presence of ammonia to reduce NO_X to molecular nitrogen and water. The process is termed "selective" because the ammonia preferentially reacts with the NO_X rather than with the oxygen in the flue gas. A catalyst is used to enhance NO_X reduction and ammonia utilization at appropriate flue gas temperatures. SCR is usually applied to flue gas in the 600°F to 750°F temperature range. There are variations in the SCR process for coal-fired boilers that mostly involve locations in the flue gas path where the catalyst is placed in order to promote the desired NO_X emission reduction effect. These are described below.

A1.3.2.1 High-Dust Selective Catalytic Reduction (HD-SCR)

For coal-fired boilers, a conventional SCR reactor utilizes readily-available catalyst materials and reagent in the form of ammonia. A conventional SCR reactor is commonly installed in a high-dust, hot-side arrangement, located between the economizer outlet and air heater inlet, where the flue gas temperature is within the desired operating range for the SCR catalyst.

A schematic graphic diagram for a conventional high-dust, hot-side SCR system on a boiler with a flue gas desulfurization system and stack gas reheat is provided in Figure A.1-5.

Figure A.1-5 Conventional High-Dust SCR Arrangement with FGD Scrubber Outlet Reheat



(figure copied from Wheelabrator Air Pollution Control literature)

The conventional SCR reactor arrangement is preferred for most coal-fired applications in utility boilers because it avoids the added expense of reheating the flue gas if placed after the air heaters which cool the flue gas, and downstream of any flue gas treatment to remove acid gases. Conventional SCR technology uses an ammonia injection grid (AIG), which consists of multiple nozzles, for distributing the reagent into the flue gas at the boiler's economizer flue gas outlet.

Conventional high-dust, hot-side SCR technology has been installed on several pulverized coal and cyclone boilers firing bituminous and subbituminous coal in the United States. There are also a limited number of European SCR installations on steam electric generating units (SEGUs) firing lower grade (brown) coal. There are, however, no existing full-scale SCR installations on units that fire North Dakota lignite. The feasibility of this alternative was evaluated for consideration as an option for LOS Unit 1 following many of the same arguments as for cyclone-fired lignite-burning boilers, as discussed below.

There are 56 BART-eligible cyclone-fired units. Over half of these units are planning to install conventional high-dust, hot-side SCR systems in response to the EPA's NO_X SIP call. The installation of conventional high-dust, hot-side SCR systems has been completed on approximately 22 of these units. Appendix A3 lists several conventional high-dust hot-side U.S. SCR installations on pulverized coal and cyclone-fired utility boilers, along with measured NO_X emissions. Initial data from these units indicate that conventional high-dust, hot-side SCR systems operated on suitable cyclone-fired units may be able to reduce NO_X emissions to as low as 0.07 lbs/mmBtu. Several SCR installations have been retrofit on existing cyclone-fire boilers burning western subbituminous coal (or PRB blended with midwestern bituminous coal). For cyclone coal-fired utility boilers retrofitted with SCR technology, all were originally designed to burn bituminous coal.

Two byproducts from the high-dust, hot-side SCR process are ammonia slip and SO_3:

- Ammonia Slip: Slip is ammonia that is unreacted in the NO_x emission reduction process. Maximum ammonia slip for a gas fired unit is usually 10 ppmvd whereas, on a coal fired unit, ammonia slip below 2 ppm is desired. For certain applications, this concentration can be problematic, therefore requiring more catalyst to reduce slip. Most new SCR applications have ammonia slip guaranteed at a 2 ppmvd maximum for an initial operating period, and are expected to continue to operate at these low ammonia slips levels beyond the end of the initial period.
- SO_3: Due to the composition of typical SCR catalysts, a small percentage of inherent SO_2 will be oxidized to SO_3. This oxidation can be controlled by catalyst selection and can be less than 1 percent. SO_2 to SO_3 oxidation must be carefully controlled to avoid creating SO_3 levels sufficiently high to raise the possibility of air heater fouling. A unit firing high-sulfur coal with SCR technology is especially vulnerable to SO_2 oxidation and ammonia slip-related fouling problems. The deposition and fouling is due to formation of solid ammonium sulfate ($(NH_4)_2SO_4$) and liquid ammonium bisulfate (NH_4HSO_4). The most important design variable is optimizing the catalyst selection and amount of catalyst that will reduce NO_X emissions, control ammonia slip, and minimize SO_2 oxidation.

Recent technology has allowed catalyst suppliers to make more rigorous and lengthy guarantees. A reasonable initial operating period for conventional catalysts in high-dust reactor arrangements on boilers firing eastern or midwestern bituminous coal is around 24,000 active operating hours (i.e. when the catalyst is exposed to flue gas). Limited annual operation (i.e. ozone season only) is a significant factor with respect to SCR equipment reliability, maintenance, operational costs, and catalyst life. The demands on the SCR system are much more severe if the equipment is required to operate on a full-time, annual basis. Factors that need to be taken into account in design of a high-dust, hot-side SCR application that affect the need for catalyst replacement are:

- Pressure drop: The amount of restriction to flue gas flow through the SCR inlet, ammonia injection grid, SCR reactor, and downstream ductwork directly increases induced draft fan horsepower required to maintain adequate boiler draft. This is an important parameter to consider and minimize during the design stage. Pressure drop is a function of the average and maximum SCR reactor duct velocities, the amount of restriction caused by flow distribution correction devices (baffles or vanes), and the number and geometrical aspects of the catalyst layers. Many retrofit SCR installations require a booster fan or upgraded induced draft fan to overcome the added flow resistance. This increase in auxiliary power consumption increases operating cost and loss of saleable electric power. The type and pitch of the catalyst are factors most influential in determining the amount of pressure drop.
    - Catalyst type: The most common types or forms of catalyst material are honeycomb or plate. The former offers more surface area per volume, but can be more restrictive and prone to pluggage from ash deposits. The latter is usually less restrictive but requires more catalyst per layer or more layers to achieve the active surface needed to achieve the intended NO_X emission reduction.
    - Catalyst pitch: The pitch of the catalyst, a term used to describe the size of the gas path openings through the catalyst, varies depending on the manufacturer and design dust loading. Pitch is generally on the order of 6 to 7 millimeters for plate-type catalyst, and 7 to 8 mm for honeycomb-type. Potential pluggage of flow channels within the catalysts layers is therefore an issue that must be dealt with during design.
- Catalyst performance: The amount of NO_X emission reduction expected is a function of the specific activity level of the catalyst material and the amount of catalyst installed, over a given period of time. Catalyst formulation selection and features of construction have a significant impact on long-term NO_X emission reduction and subsequent costs for reagent and catalyst replacement.

- Catalyst replacement: The frequency of catalyst replacement is influenced strongly by:
    - Catalyst erosion: Erosion of the catalyst material in coal fired units from entrained flyash or sootblowing action reduces the amount of active surface available for reacting with the reagent and flue gas, and can cause distortions in gas distribution ("channeling") through the SCR reactor. Catalyst material is fragile and can be easily damaged. Some catalyst is provided with erosion-resistant top edges to mitigate this tendency.
    - Moisture absorption: Many types of catalyst are damaged by absorption of moisture. The reactor must be kept above ambient dewpoint temperatures or protected from freezing during outages in order to protect the catalyst from moisture damage. Spare catalyst must be carefully packaged to keep it dry and must be handled delicately to prevent damage.
    - Thermal degradation: The specific active elements of the catalyst surface, or the matrix structure itself upon which the catalyst material is applied, can degrade when exposed to flue gas temperatures greater than the intended design of the formulation. High flue gas temperatures within the reactor causes sintering, leading to a permanent loss of catalyst activity due to a change in the pore structure of the catalyst.
    - Catalyst poisoning: The loss of performance or activity of the catalyst over time can be due to chemical damage or poisoning. Two elements especially detrimental to the life of common titanium-supported vanadium pentoxide SCR catalyst are arsenic and zinc. Vanadia/tungsten-based catalysts are particularly susceptible to rapid deactivation due to gaseous arsenic poisoning. In some German SCR installations, a 50% loss of activity has been reported within 10,000-15,000 operating hours. Addition of molybdenum to a plate-type vanadia-titanium SCR catalyst on similar applications shows relative activity reductions of 20-25%. Progressive loss of SCR NO_X reduction performance from catalyst deactivation due to poisoning is not possible to restore without effective cleaning to remove the deposits, or eventual replacement.
    - Catalyst fouling: The surface area potentially exposed to the reagent (ammonia) and nitrogen oxides in the flue gas can become fouled with flyash or sulfur-related compounds. The presence of excess sodium or calcium oxide in the presence of sulfur in the flue gas can form a sodium sulfate or calcium sulfate surface coating that can be extremely dense, masking the pores of the catalyst. Progressive loss of SCR NO_X reduction performance from catalyst deactivation due to fouling is difficult to restore without effective cleaning to remove the deposits, or eventual replacement.

SCR technology has been installed on numerous coal-fired utility boiler facilities around the world and there are a large number of manufacturers that market the catalyst. The effectiveness of the SCR process is highly dependent upon the ability of the nitrogen oxides in the flue gas being able to contact the active sites within microscopic pores of the catalyst in the presence of ammonia reagent with minimal interference from contaminants. The question is whether SCR is a feasible technology for a unit firing North Dakota lignite. There are serious concerns whether installation of SCR technology on a North Dakota lignite-fired unit can be successful, especially in a conventional "hot-side, high-dust" configuration.

A recent article "Ash and Mercury Behavior in SCR Catalysts When Firing Subbituminous and Lignite Coals" by the Energy & Environmental Research Center (EERC) of the University of North Dakota was published in the February 2005 issue of Fuel Processing Technology magazine[30]. This paper summarized the results of SCR catalyst slipstream testing at two PRB-fired plants and one North Dakota lignite-fired powerplant. The evaluation included determination of impacts of ash on SCR catalyst plugging and blinding. Flue gas was isokinetically extracted from the convective pass of the boiler upstream of the air heater. Pressure drop across the catalyst was measured during the initial 2-month test period, and the two consecutive 2-month test periods following the initial trial, while holding flue gas flow and temperatures constant. Ammonia was injected downstream of a screen, upstream of a flow straightener and air pulse section. Compressed air was injected ahead of the reactor, and was periodically pulsed to simulate sootblowing to minimize ash deposit accumulation.

This slipstream SCR testing examined the significance of ash accumulations on SCR catalyst on both the macroscopic and microscopic levels. Very small flyash particles were found bonded together by a matrix of sodium-, calcium-, and sulfur-rich materials, likely in the form of calcium sulfate. North Dakota lignite coal contains many alkali and alkaline-earth elements, and sulfur. The firing of lignite coal which produces fine (less than 5-µm diameter) flyash particles that enter the pores of the catalyst, react with SO_3 in the flue gas, and form sulfates which bind other ash particles into the matrix.

As posted on Electric Power Research Institute Inc.'s (EPRI's) website regarding the impact of coal type on SCR catalyst life and performance, a recent EPRI study[31] produced field data analyzed from an "In-Situ Mini SCR Reactor" system installed in a typical "high-dust" location at seven different test sites, including four firing PRB coal, one firing Texas lignite, one firing high-sulfur eastern bituminous coal, and one firing a PRB/eastern bituminous coal blend. The PRB/bituminous coal blend test was performed at AmerenUE's Sioux Station, on one of the two 500 MW cyclone-fired boilers. This study found that the cyclone unit firing the PRB/bituminous coal blend exhibited the fastest rate of catalyst activity degradation. Also, the higher deactivation rates seen at this site were due to economizer exit flue gas temperatures being significantly higher than at the other sites. A comparison of the Texas lignite and one of the PRB-fired sites of two different catalysts' deactivation was more a function of trace elements in the flue gas and flyash than the specific catalyst type or formulation.

North Dakota lignite produces an ash that is very sticky and creates severe ash deposition problems. There have been no installations of SCR systems (full-scale) on units that fire North Dakota lignite. A technical assessment was conducted for the installation of SCR technology on North Dakota lignite-fired cyclone boilers. In order to further evaluate the feasibility of installing a conventional SCR system on North Dakota lignite-fired cyclone boilers, the Energy & Environmental Research Center (EERC) at the University of North Dakota was consulted. EERC has extensive experience investigating the deposition characteristics of North Dakota lignite ash. A technical paper[32] was produced, from which the following technical feasibility analysis was developed. A copy of EERC's paper is included in Appendix A5. Although the source of North Dakota lignite supplied to the cyclone-fired boilers of interest in the technical paper is different than the mine supplying lignite to Leland Olds Station, it is considered similar in characteristics and suitable for comparison purposes in this feasibility analysis.

Technical difficulties and anticipated operating problems that are unresolved with respect to installing conventional SCR technology at Leland Olds Station include the impacts of severe ash deposition, "popcorn ash", high temperatures, and erosion on the catalyst. For these reasons, application of available conventional high-dust SCR technology is considered technically infeasible for Leland Olds Station, especially on Unit 2's boiler. These concerns can be divided into four categories. Each category is addressed below. An explanation of the factors that make conventional SCR technology infeasible for these boilers follows:

1. Ash Deposition: North Dakota lignite contains a variable and complex variety of inorganic compounds that contribute to ash deposition. This fuel produces ash with severe deposition characteristics that are not typical with other coals. When exposed to the heat of the combustion process inside the cyclone burners, the majority of the fuel ash becomes molten and flows into the bottom of the furnace. A significant portion of the fuel ash is entrained into the flue gas exiting the cyclone barrels at high velocity, where it comes into contact with the lower furnace

waterwalls. The portion that is carried with the rising flue gas cools and some is deposited on heat transfer surfaces in the upper furnace and boiler convection pass. Ash deposition on heat transfer surfaces is a substantial problem for units that fire North Dakota lignite. The problem is serious enough at Leland Olds that the Unit 2 boiler must be shut down to allow for cleaning of ash deposits from the boiler heat transfer surfaces in order to restore reasonable furnace exit gas velocities and temperatures.

Sodium is a significant contributor to the "stickiness" of the ash produced from firing North Dakota lignite. Sodium content of the LOS lignite ash averages approximately 7.6%, and can be above 9% for some of the lignite produced from the Center mine, for which the following numbers were calculated. PRB coal typically averages around 1.5% sodium content. Boilers firing North Dakota lignite typically have a 2.5% higher heat rate (million Btu per kilowatt of electric generation) than a typical boiler firing PRB coal, thus requiring more heat input and firing more fuel per megawatt of electric output. A cyclone boiler firing North Dakota lignite also converts as much as 50% of the fuel ash to flyash, compared with a 35% conversion rate for PRB coal-fired cyclone boilers. Overall, this results in an amount of sodium emitted from a cyclone boiler firing North Dakota lignite of approximately 7.3 lbs/MW-hr compared with 0.9 lbs/MW-hr for a PRB-fired cyclone boiler.

The catalysts in coal-fired boiler SCR reactors are exposed to flue gas with entrained particulate matter. In a typical conventional high-dust SCR reactor, the flue gas typically passes through two to four layers of catalyst modules. The catalyst modules have numerous narrow passages to provide intimate contact between the flue gas, ammonia and catalyst. The clearance (pitch) in these passages is typically 6-10 millimeters. A typical catalyst layer is approximately 1 to 1.5 meters deep. The catalysts in coal-fired boiler SCR reactors must be cleaned frequently using soot blowers and/or sonic horns. This is true even on units firing fuels that do not produce a sticky ash that contributes to ash deposition.

Sulfur in the coal is oxidized during excess air combustion to form sulfur dioxide (SO_2), and a small amount of sulfur trioxide (SO_3). Some of the ammonia-based reagent injected upstream of the SCR reactor will combine with SO_3 to form ammonium bisulfate. The catalyst in the SCR reactor will also oxidize a portion of the SO_2 to SO_3. Excess unreacted ammonia reagent carryover ("ammonia slip") from the SCR reactor will also react with these sulfuric acid compounds in a similar fashion. The dominance of sodium and calcium compounds present in North Dakota lignite ash emitted from the LOS cyclone boiler will also combine with sulfur to form blinding deposits within the catalyst. The ash deposition characteristics for a cyclone-fired unit burning North Dakota lignite will create difficult-to-remove ash deposits and pluggage of a conventional high-dust catalyst, and increase the probability that the air preheater downstream and flue gas ductwork will be prone to accumulations which could be severe. It is anticipated that high-dust SCR performance and catalyst life for a cyclone-fired unit burning North Dakota lignite will be severely impacted. Such a high-dust SCR's catalyst life may be shortened from 3-6 years (typical) to as little as 2-12 months, requiring extended, frequent outages for replacement.

Hot-side air preheaters are susceptible to gas-side fouling. Tubular air pre heaters typically supplied with cyclone boilers tolerate moderate dust loadings and gas-side fouling, since their height and size make them difficult to maintain gas-side cleanliness. Leak tightness of the air preheater is important on cyclone-fired boilers with relatively high forced draft fan discharge (combustion air supply) pressures. It is expected that a high-dust SCR installation on a cyclone-fired unit burning North Dakota lignite will be prone to air preheater tube fouling and pluggage, requiring extended, frequent outages for cleaning.

2. "Popcorn Ash": A second consideration in the application of conventional high-dust SCR technology on a lignite-fired unit is the potential of the SCR reactor catalyst pluggage resulting from carry over of "popcorn ash" from the boiler. Boilers firing North Dakota lignite have severe problems with ash deposition on boiler furnace and convection pass fireside surfaces. For lignite-fired units, the boiler's heat transfer surfaces must be cleaned by sootblowing and other methods (e.g. water lances) frequently to maintain satisfactory boiler operation. Some of the removed deposits released by the cleaning action within the boiler and convection passes form "popcorn ash", which will be entrained in the flue gas. There is concern that carry over of boiler ash deposits will contribute to pluggage of the "popcorn ash" screen ahead of the top layer of SCR reactor catalyst in a high-dust, hot-side installation on a cyclone-fired unit burning North Dakota lignite. This can cause distortions in gas distribution ("channeling") through the SCR reactor, which can concentrate the amount of NO_X passing through unrestricted areas with insufficient reagent, thus producing ineffective performance of the catalyst.

3. Temperature: A third issue that impacts the feasibility of installing high-dust SCR technology on the North Dakota lignite-fired units is gas temperature. The performance of any SCR catalyst is highly dependent on the flue gas temperature. Typically, a temperature of 600 – 750 degrees F is required to obtain satisfactory operation of an SCR reactor. Operation of commonly-supplied catalyst suitable for a high-dust SCR reactor at temperatures above 800°F results in severe and rapid deterioration of the catalyst and SCR reactor's NO_X emission reduction performance. For bituminous and sub-bituminous coal-fired units, boiler flue gas passing between the economizer outlet and air heater inlet is generally within a temperature range acceptable for conventional SCR catalysts without additional heating or cooling of the flow stream.

   North Dakota lignite-fired cyclone boilers, including those at Leland Olds Station, have limited gas-path economizer surface and high temperatures at the economizer's flue gas outlet by design. The highest gas temperatures downstream of the convection pass economizer sections and upstream of the air heater inlet in Leland Olds Unit 2 can be significantly higher than 750°F.

   High gas temperatures at the air heater inlet of North Dakota lignite-fired cyclone boilers are required to produce the high air temperatures (700°F) needed for the pre-combustion lignite drying system, along with primary and secondary combustion air supplied to the cyclones. Such air preheater arrangements and capabilities have been taken into account in the design of the North Dakota lignite-fired cyclone boilers. Reducing this high gas temperature to accommodate conventional catalysts for a conventional high-dust SCR reactor would result in pre-combustion air temperatures that are too low to provide satisfactory drying and rapid ignition of the high-moisture fuel. This will seriously impact reliable combustion, slag formation and tapping in the cyclone burners. Consequently, it is not feasible to modify the Leland Olds unit to operate with the lower economizer outlet flue gas temperatures.

   Catalysts for a conventional high-dust, hot-side SCR system have not been installed nor successfully demonstrated in a full-scale installation of an operating solid fuel-fired unit that are designed to continuously operate at the high temperatures (above 800°F) that exist between the convection pass economizer and air heater on the Leland Olds Station Unit 2's boiler.

4. Erosion: A final consideration on whether hot-side, high-dust SCR technology can be successful on a North Dakota lignite-fired unit is the potential for erosion of the SCR catalyst. North Dakota

> lignite has a modest to high ash content. Lignite supplied from the Center mine, for which the following numbers were calculated, has an average annual fuel ash content of 10.5%, and can have an ash content up to 25.5 percent. PRB coal fuel ash content typically averages approximately 5 percent. As previously stated, a cyclone boiler firing North Dakota lignite converts a significantly greater amount of flyash than a PRB-fired cyclone boiler. Overall, this results in a flyash output rate from a cyclone boiler firing North Dakota lignite of approximately 83 lbs/MW-hr compared with 21 lbs/MW-hr for a PRB-fired cyclone boiler. High ash contents in the flue gas stream can result in physical erosion of the catalyst. Severe ash depositions can cause distortions in gas distribution ("channeling") through the SCR reactor, which will aggravate erosion in the high velocity areas and create conditions leading to ineffective performance of the catalyst. In addition, effective on-line cleaning of the high-dust catalyst will likely require steam or compressed air sootblowing. Cleaning cycles of the catalyst in a high-dust SCR installation for a cyclone boiler firing North Dakota lignite may need to be more frequent than a typical conventional SCR installation due to the ash deposition characteristics of the North Dakota lignite. Frequent sootblowing of the catalyst to remove fouling deposits and ash accumulations will contribute to erosion and decreased catalyst life. There is some European experience with high ash brown coals that catalyst manufacturers will be able to draw upon. This experience, however, will not be directly applicable to these United States units because of the severe deposition characteristics of the North Dakota lignite ash compared to brown coal.

The EPA's BART Guideline states that for a technology to be feasible it must be "available and applicable". SCR technology is an available technology which has been installed on numerous powerplant facilities around the world and there are a large number of manufacturers that market the technology. The question is whether SCR technology is "applicable" for a cyclone-fired unit burning North Dakota lignite.

In accordance with EPA's BART Guideline, a "commercially available control option will be presumed applicable if it has been used on the same or similar source type" [70 CFR 39165]. Hot-side, high-dust SCR technology has been retrofitted on existing coal-fired units featuring cyclone boilers. However, there are no SCR installations in operation or planned on units that include cyclone burners firing North Dakota lignite with severe slagging and fouling tendencies combined with such high boiler economizer outlet gas temperatures (over 750°F) required for high-moisture fuel pre-drying systems and tubular air preheaters.

The EPA's BART Guideline also states a technology identified as technically infeasible, "[the States] should demonstrate that the option is either commercially unavailable, or that specific circumstances preclude its application to a particular emission unit" [70 CFR 39165]. Such a demonstration of technical infeasibility "involves an evaluation of the characteristics of the pollutant-bearing gas stream and the capabilities of the technology. Alternatively, a demonstration of technical infeasibility may involve a showing that there are unresolvable technical difficulties with applying the control to the source (e.g. size of the unit, location of the proposed site, operating problems related to specific circumstances of the source, space constraints, reliability, and adverse side effects on the rest of the facility)"[70 CFR 39165]. In this SCR technology application, it appears that a cyclone-fired utility powerplant firing North Dakota lignite would experience extended time delays or be required to devote significant internal resources and engage outside research, followed by extended field trials to learn how to apply a conventional high-dust, hot-side SCR technology on such a fuel source. The risk of failure and uncertainty of successfully applying high-dust, hot-side SCR technology to a cyclone-fired utility powerplant firing North Dakota lignite appears substantial.

Based upon this technical assessment that looked at the various design and operational issues associated with the installation of hot-side, high-dust SCR technology on a North Dakota lignite-fired steam-electric generating unit, this control option is considered technically infeasible for the pulverized coal-fired Unit 1 boiler and the cyclone-fired boiler on Unit 2 at Leland Olds Station.

A1.3.2.2 Low-Dust Selective Catalytic Reduction (LD-SCR)

Low-dust SCR (LD SCR) technology could potentially be applicable to North Dakota lignite-fired boilers for NO_X emission control. Low-dust SCR refers to the location of the SCR system downstream of a particulate collection system, such as an electrostatic precipitator or a fabric filter. If the low-dust SCR is downstream of a hot-side electrostatic precipitator and prior to the air preheater, flue gas reheating is unnecessary. This has been the prevalent form of alternative retrofit SCRs in the United States for coal-fired utility boilers. There are ten known hot-side low-dust SCR installations (without flue gas reheat) operating in the United States as of July 2005. These are listed in the U.S. NO_X Control Project Summary listing in Appendix A. If applied to LOS Unit 1's pulverized coal-fired boiler and Unit 2's cyclone-fired boiler, the low-dust SCR equipment would be downstream of a cold-side electrostatic precipitator; flue gas reheat prior to the LD SCR reactor inlet would be required for proper NO_X emission reduction performance.

For a cold-side LD SCR, the ESP outlet flue gas passes through a low-dust gas-to-gas heat exchanger (LD GTG-HE), prior to passing to the low-dust SCR reactor. After the LD GTG-HE, the flue gas will travel through new ductwork leading to a supplemental heat addition section ahead of an ammonia injection grid, turning vanes and then into the LD SCR reactor. The flue gas entering the inlet to the LD GTG HE is expected to be near the air heater outlet temperature (330-340°F) in a cold-side LD SCR application. The supplemental heat added upstream of the LD-SCR reactor can be supplied from high pressure/temperature steam coils (indirect heat exchange) or directly from fossil fuel (natural gas, fuel oil, or propane)-fired duct burners. The flue gas must be heated to a minimum of approximately 600°F for the LD SCR NO_X– ammonia reaction to be effective. The LD gas-to-gas heat exchanger is used to recover part of that supplied heat, prior to exhausting to the FGD system (if applicable) and stack. The use of rotary regenerative-type heat exchangers has been applied in European LD SCRs. With this design, there will be a small amount of leakage between the untreated and treated gas streams such that the exit flue gas has higher NO_X concentrations than the LD SCR outlet gas. The direct-fired flue gas reheat duct burners will also create NO_X emissions, which will add to the amount from the boiler input into the LD SCR reactor. The GTG-HE outlet flue gas temperature on the downstream side of the LD SCR has to be higher than the inlet gas temperature.

The LD SCR reactor, GTG HE, and connecting ductwork will increase the pressure drop through the flue gas system. This normally requires an induced draft fan upgrade or a booster fan addition.

The factors that make low-dust SCR technology infeasible for Leland Olds Station’s pulverized coal-fired Unit 1 boiler and Unit 2’s cyclone-fired boiler with existing particulate collection via electrostatic precipitators are as follows:

- Catalyst Fouling and Deactivation: An existing electrostatic precipitator upstream of a low dust SCR reactor will still expose the catalyst to the acid gas content and fine particulate containing high alkali mineral content of the entrained lignite flyash not removed by the ESP upstream. Although the total amount of flyash carryover into the LD-SCR reactor is greatly reduced compared with a high-dust design, there is concern that the low-dust SCR catalyst life will still be unacceptably short. The small particle flyash passing into the reactor could cause pluggage of the catalyst pores, resulting in deactivation of the catalyst. The firing of lignite coal produces fine (less than 5-µm diameter) flyash particles, which are also least likely to be removed by the existing particulate collection equipment (e.g. ESP) upstream of a low-dust or low-dust/tail-gas SCR. This creates conditions that allow these small flyash particles to enter the pores of the catalyst, react with SO_3 in the flue gas, and form sulfates which bind other ash particles into a matrix of sodium-, calcium-, and sulfur-rich materials (likely in a form of sodium or calcium sulfate). Once such a matrix forms within the catalyst, it can be extremely tenacious and difficult to remove. One catalyst vendor has stated it is their "experience that low-dust catalyst is more difficult to clean than that from high-dust"[33]. Ash deposition characteristics for a cyclone-fired unit burning North Dakota lignite will create difficult-to-remove ash deposits and blinding of conventional catalyst. Low-dust SCR performance and catalyst life could be severely negatively impacted. Shortened lifespans of the LD SCR catalyst will require premature, extended, frequent outages for replacement.

Deposits on the gas-to-gas heat exchanger ahead of the low-dust SCR reactor will decrease heat transfer between the incoming (warm) flue gas and the outgoing (warmer) flue gas and be increasingly difficult to successfully remove over time. Low flue gas temperatures are inadequate to promote the effective activity of the catalyst in reducing NO_X emissions. Thus, increased consumption of supplemental heat, preferably in the form of propane or natural gas, will be required to raise the temperature of the flue gas ahead of the LD-SCR reactor. Sootblowers could be used to remove the accumulated deposits from the GTG HE, but the SCR reactor could still suffer catalyst fouling from the deposits dislodged from the rotary regenerative-type GTG HE cleaning cycle becoming reentrained in the reheated flue gas. This can lead to further accumulation of deposits at the inlet and within the catalysts layers of the TG-SCR reactor, creating a vicious cycle of diminishing performance.

The challenges for installation of new ductwork, SCR reactors, and flue gas reheating equipment are numerous. The lack of pertinent experience with all aspects of design, construction, operation, and maintenance of low-dust SCRs on such high-fouling coals as North Dakota lignite are significant. The flue gas conditions that the LD-SCR catalyst will be exposed to will create unresolvable fouling and blinding that makes successful application of this technology difficult, expensive, and uncertain.

The risk of failure and uncertainty of successfully applying low-dust, cold-side SCR technology to a cyclone-fired utility powerplant firing North Dakota lignite appear substantial.

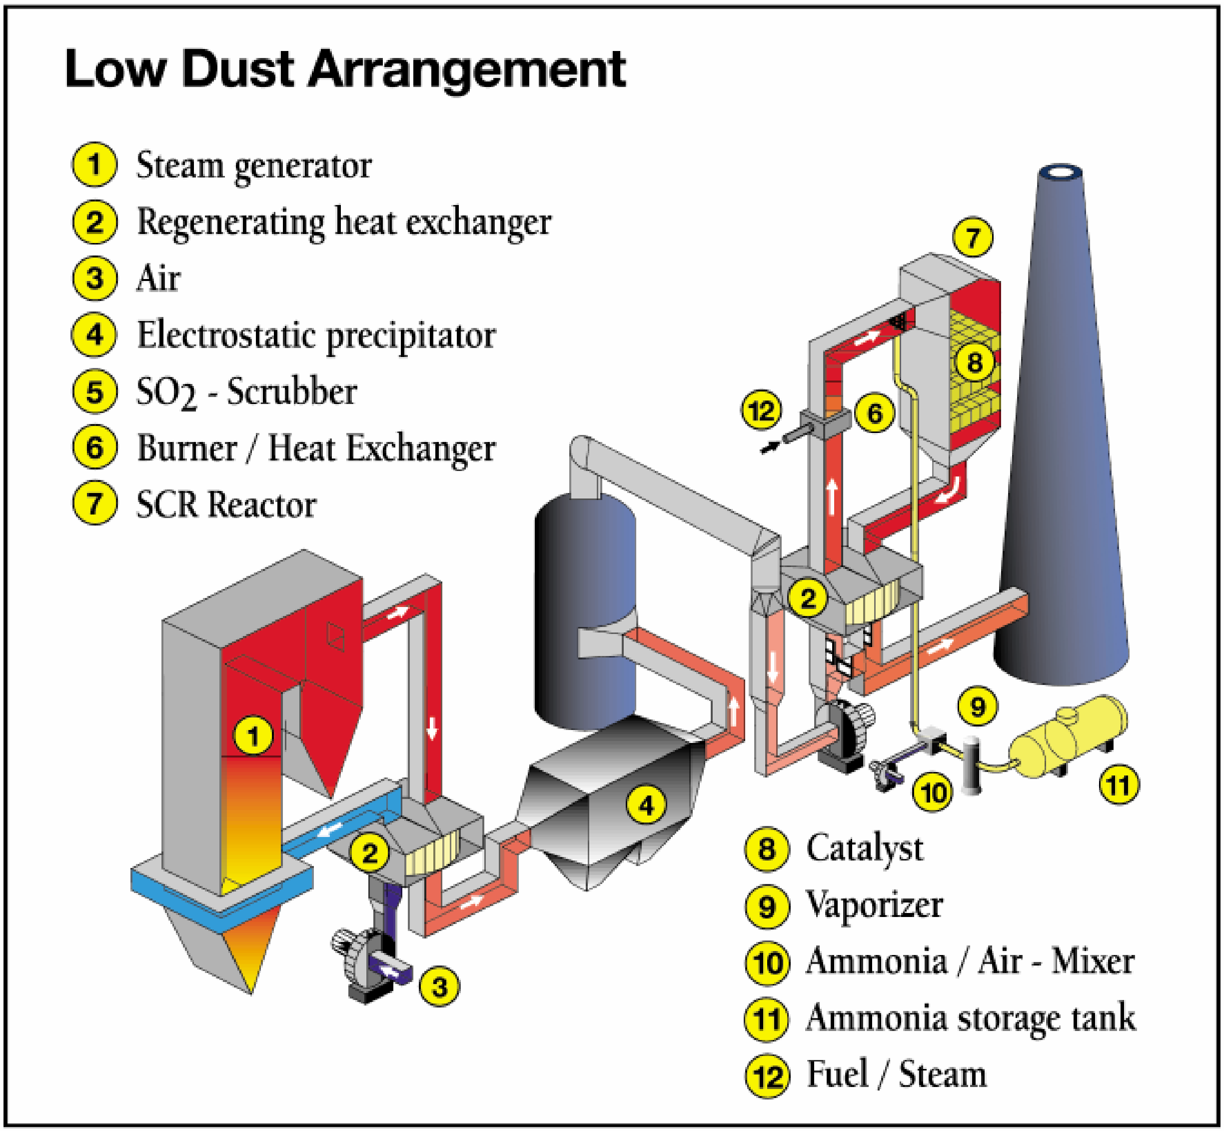
Based upon a technical assessment that looked at the various design and operational issues associated with the installation of low-dust SCR technology on a North Dakota lignite-fired steam-electric generating unit with a cyclone-fired boiler, this control option is considered technically infeasible for Leland Olds Station's pulverized coal-fired Unit 1 boiler and the cyclone-fired boiler of Unit 2.

A1.3.2.3 Tail-Gas Selective Catalytic Reduction (LD-SCR)

A tail-gas (TG) SCR is a low-dust SCR system where the SCR reactor is installed on the cold side of the air preheater downstream of a FGD scrubber. The FGD outlet flue gas passes through a low-dust gas-to-gas heat exchanger (GTG-HE), prior to passing to the tail-gas SCR reactor. After the LD GTG-HE, the flue gas will travel through new ductwork leading to a supplemental heat addition section ahead of an ammonia injection grid, turning vanes and then into the TG SCR reactor. The TG SCR reactor, GTG HE, and connecting ductwork will increase the pressure drop through the flue gas system. This retrofit normally requires an induced draft fan upgrade or a booster fan addition.

A schematic graphic diagram for a low dust arrangement is shown in Figure A.1-6.

Figure A.1-6 Tail-Gas SCR Arrangement



(figure copied from Wheelabrator Air Pollution Control literature)

The flue gas from a wet FGD scrubber outlet entering the inlet to the gas-to-gas heat exchanger is expected to be near the saturation temperature (140°F) in a TG SCR application. The supplemental heat added downstream of the TG GTG-HE can be supplied from high temperature steam coils (indirect heat exchange) or directly from fossil fuel-fired duct burners. The flue gas must be heated to a minimum of approximately 600°F for the NO_X – ammonia reaction in the presence of the TG SCR catalyst to be effective. The gas-to-gas heat exchanger is used to recover part of that supplied heat, prior to exhausting to the stack. With a rotary regenerative-type gas-to-gas heat exchanger, there will be a small amount of leakage between the untreated and treated gas streams. With a positive flue gas pressure FGD system upstream, the leakage will be such that the GTG-HE outlet exit (stack inlet) flue gas has a higher NO_X concentration than the TG SCR reactor outlet gas. The direct-fired flue gas reheat duct burners will also create NO_X emissions, which will add to the amount from the boiler input into the TG SCR reactor. The GTG-HE outlet flue gas temperature on the downstream side of the TG SCR going to the stack will be significantly lower than would occur in a conventional high-dust, hot-side SCR or low-dust, cold-side SCR application.

There is no experience with low-dust/tail-gas SCR technology on eastern bituminous, western subbituminous coal or lignite-fired SEGUs requiring full flue gas reheat prior to the reactor inlet in the United States. As of 1997, there was one low-dust/tail-gas SCR on a 220 MWe German cyclone-fired boiler with a 1988 retrofit installation. This boiler was reported to be operating without combustion controls or FGD, burning low sulfur, low ash, moderate moisture bituminous coal with an average pre-SCR NO_X emission rate of approximately 1.07 lb/mmBtu, and was meeting a 30-day rolling average emission limit of approximately 0.16 lb/mmBtu (85% reduction)[34].

Leland Olds Station Unit 1 and Unit 2 boilers do not currently incorporate any flue gas desulfurization equipment, which without such FGD would place the reactor catalyst in a low-dust SCR configuration, which is considered infeasible when burning North Dakota lignite. Both Unit 1's boiler and Unit 2's boiler will have new FGD systems to implement future BART sulfur control requirements associated with the North Dakota State Implementation Plan (SIP).

The factors that make tail-gas SCR technology infeasible for the pulverized coal-fired Unit 1 boiler and the cyclone-fired Leland Olds Station Unit 2 boiler with existing particulate collection via electrostatic precipitators are as follows:

- The TG SCR reactor downstream of a FGD scrubber will still be exposed to flue gas with entrained fine particulate matter, including some involving sodium and sulfur-containing compounds passing through and carried-over from a wet FGD scrubber. The treated gas stream will carry sodium sulfate solids, formed by homogenous condensation after exiting the boiler and not removed by the FGD system, into the catalyst layers of the TG-SCR reactor. There is serious concern that these fine particles will accumulate within the catalyst, and be resistant to removal by conventional sootblowers and other cleaning technologies. Catalyst that is exposed to such conditions will be ineffective at maintaining adequate activity upon which the performance of the TG-SCR's NO_X removal is based.

- Deposits on the gas-to-gas heat exchanger ahead of the tail gas SCR reactor will decrease heat transfer between the incoming (cool) flue gas and the outgoing (warm) flue gas and be increasingly difficult to successfully remove over time. Low flue gas temperatures are inadequate to promote the effective activity of the catalyst in reducing NO_X emissions. Thus, increased consumption of supplemental heat, preferably in the form of propane or natural gas, will be required to raise the temperature of the flue gas ahead of the TG-SCR reactor. Sootblowers could be used to remove the accumulated deposits from the GTG HE, but the TG SCR reactor could still suffer catalyst fouling from the deposits dislodged from the rotary regenerative-type GTG HE cleaning cycle becoming reentrained in the reheated flue gas. This can lead to further accumulation of deposits at the inlet and within the catalysts layers of the TG-SCR reactor, creating a vicious cycle of diminishing performance.

The challenges for installation of new ductwork, SCR reactors, and flue gas reheating equipment and the lack of pertinent experience with all aspects of design, construction, operation and maintenance of tail-gas SCRs on such high-fouling coals as North Dakota lignite are significant. The flue gas conditions that the TG-SCR catalyst will be exposed to will create unresolvable fouling and blinding that makes successful application of this technology difficult, expensive, and uncertain.

The risk of failure and uncertainty of successfully applying low-dust, tail-gas SCR technology to a pulverized coal-fired boiler and the cyclone-fired utility powerplant firing North Dakota lignite appear substantial.

Based upon a technical assessment that looked at the various design and operational issues associated with the installation of tail-gas SCR technology on a North Dakota lignite-fired steam-electric generating unit including a cyclone boiler, this control option is considered technically infeasible for the Leland Olds Station pulverized coal-fired Unit 1 boiler and the cyclone-fired Unit 2 boiler.

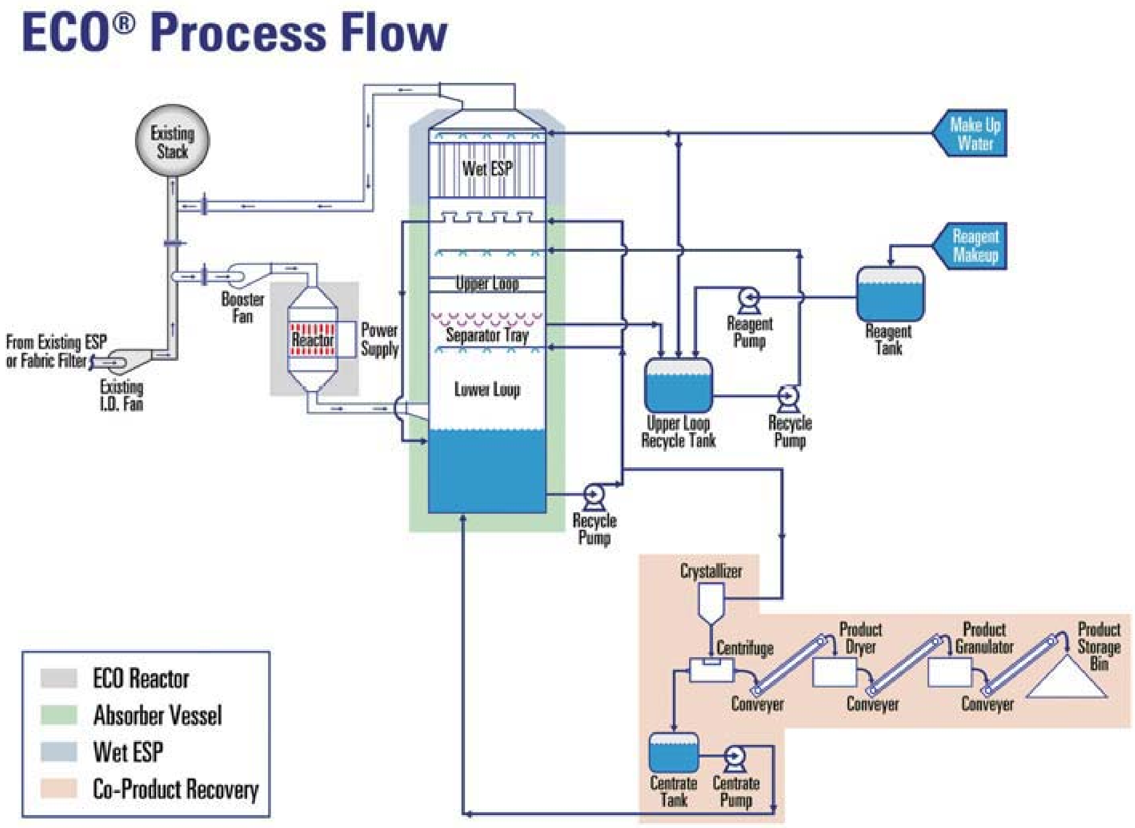
A1.3.3 Electro-Catalytic Oxidation (ECO®)

Powerspan's Electro-Catalytic Oxidation (ECO®) system is a multi-pollutant technology designed to control emissions of NO_X, SO_2, fine particulate, mercury and certain Hazardous Air Pollutants (HAPs). The ECO® process has two main process vessels, a barrier discharge reactor, and a multi-level wet scrubber. The barrier discharge reactor utilizes an electrical discharge to create oxygen and hydroxide radicals which then react with NO_X, and other constituents in the flue gas stream. The flue gas stream then enters the bottom of the ECO® scrubber where the lower loop cools the flue gas and removes a portion of the acid gasses [sulfur trioxide (SO_3), sulfuric acid (H_2SO_4), nitric acid (HNO_3)] produced in the barrier reactor and oxidized metals such as mercury, with a low pH aqueous ammonia reagent. A second scrubbing loop is then entered where additional SO_2, NO_2, acid gases and oxidized metals are removed with an aqueous ammonia reagent, though at a higher pH. Above the second scrubber loop is an absorber section for absorbing fugitive ammonia from the first and second scrubbing loops. The final step in the ECO® process is a wet electrostatic precipitator (WESP) which collects fine particulate matter, aerosols generated in the scrubber and additional mercury.

An updated schematic process flow diagram for the basic ECO® process is shown in Figure A.1-7.

Figure A.1-7 – Electro-Catalytic Oxidation (ECO®) Process Flow Diagram

(copied from http://www.epa.gov/appcdwww/aptb/EPA600R03110.pdf)



Powerspan has been involved in an extended ECO® process demonstration using a 28 MW equivalent “slipstream” Commercial Demonstration Unit (CDU) at R.E. Burger Station Units 4&5. The ECO® CDU project treated a slipstream and demonstrated performance, reliability and economics for approximately one year. The demonstration program started in January, 2004. NO_X removal is stated to be up to 90% with a claimed 0.05 lb NO_X/mmBtu outlet condition achievable for the front-end of the ECO® process. Further sustained operational tests of the ECO® CDU were performed during the second and third quarters of 2005.

As this is a post-combustion multi-pollutant control technology, it is claimed that there is little sensitivity to the type boiler or burners that Powerspan's Electro-Catalytic Oxidation (ECO®) process can be potentially applied to in order to reduce NO_X emissions. The effectiveness of this ECO® process for NO_X control has been demonstrated on a slip-stream commercial demonstration unit (CDU) associated with pulverized fuel boilers firing midwestern or eastern bituminous coal.

Powerspan's published data from the commercial demonstration unit's performance of up to 90% when treating flue gas with an inlet NO_X concentration around 0.5 lb/mmBtu. This would result in a stack NO_X emission around 0.05 lb/mmBtu.

As of May, 2006, the ECO® process has not been demonstrated in a full-scale (or less-than full-scale) configuration on any boiler that fires western subbituminous coals or North Dakota lignite. It has also not been applied to emissions from any coal-fired cyclone boiler. According the EPA's BART Guideline, "Technologies which have not been applied to (or permitted for) full scale operations need not be considered available: an applicant should be able to purchase or construct a process or control device that has already been demonstrated in practice" [70 CFR 39164].

There are a number of issues with firing North Dakota lignite that make the applicability of the ECO® process technically infeasible for Unit 1's pulverized coal-fired boiler and the LOS Unit 2 cyclone boiler. These issues include:

- Deposits and Pluggage: The flyash deposition characteristics of the North Dakota lignite are extremely severe. Anything that contributes to flyash deposition and pluggage within the barrier reactor is expected to have a detrimental impact on the multi-pollutant control performance of the ECO® process, and thus could have a serious impact on Leland Olds Station operations. The lack of demonstrated operation on treating the emissions from a boiler firing coal with a high slagging index precludes the use of the ECO® process as technically feasible for BART as applied to a boiler firing North Dakota lignite.

- Reliability and Availability: Leland Olds Station's major planned outages for each unit are scheduled to occur once every three years. Any NO_X control technology selected as BART will need to operate year-round, year in and year out, on a routine basis, while performing at high levels of pollutant reduction. The Powerspan ECO® system is a new technology and is not as highly developed as other more common NO_X and SO_2 control technologies such as SCR or SNCR plus wet or semi-dry flue gas desulfurization (FGD). It is expected to require a full-time, full-scale application with sustained continuous operation to confirm levels of currently demonstrated reliability and availability from the ECO® CDU are acceptable to meet the expectation of infrequent major outages over long time periods while maintaining high levels of control.

There are additional factors that make the application of the ECO® process potentially more difficult than other established emission control technologies available for coal-fired powerplants:

- There is a lack of experience with the ECO® downstream ammonia scrubber's coproduct crystallization and granulization equipment design, operation, and maintenance, which was not included with the initial commercial demonstration unit. The coproduct stream that would normally feed into the crystallization and granulation processes was collected and transported offsite for this process step during CDU operation. Because crystallization and granulation of ammonium sulfate from an ammonia scrubber solution is not a new technological process, this was not considered a technical feasibility deficiency. For instance, the Dakota Gasification Company (DGC) in Beulah, ND currently operates an SO_2 scrubber utilizing ammonia as a reagent. Following the generation of ammonium sulfate, DGC crystallizes and granulates a fertilizer product on site. However, at LOS, considerable costs would be incurred for interim storage and shipment of the ECO® process scrubber's liquid bleedstream until sufficient experience has identified and eliminated potential failures and repairs for the crystallization and granulation equipment should it prove to be unreliable.
- Size of the barrier reactor: Powerspan recently indicated that they would scale the barrier reactor for optimum cost and space arrangement based upon lessons learned from the CDU plant operation. The number of individual passages within a barrier reactor sized for LOS Unit 1's pulverized coal-fired boiler and Unit 2 cyclone boiler's maximum flue gas flow and gas stream

constituents is expected to require a cross-sectional area comparable to half of a large electrostatic precipitator. Although this has not been closely examined for all aspects of design, construction, operation and maintenance, the amount of physical space required to hold the barrier reactor and inlet and outlet ductwork could be limited for potential retrofit to LOS Unit 1's pulverized coal-fired boiler and Unit 2's cyclone boiler. Site space constraints are considered to be a detriment to technical feasibility for potential application of the ECO® process at Leland Olds Station for Unit 1 and Unit 2's boilers.

- Additional station auxiliary power consumption: The barrier reactor, plus the ammonia scrubber and wet electrostatic precipitator additions by an ECO™ system, require an increase in station auxiliary power consumption. For NO_X control, this includes more horsepower required by the booster fan needed to compensate for the flue gas pressure drop created across the barrier reactor. It also includes the power consumed by the electrodes of the barrier reactor itself.

Because of the lack of full-time, full-scale experience, especially on such high fouling coals as North Dakota lignite, and other operational issues, the ECO® system was considered technically infeasible as a BART alternative for Leland Olds Station for Unit 1's pulverized coal-fired boiler and Unit 2's cyclone-fired boiler.

A1.4 "Layered" NOx Reduction Technologies

Many of the NO_X emission reduction technologies which involve furnace or convection pass areas for their introduction into the flue gas stream have been, or can potentially be, applied in combinations so as to result in an overall higher level of removal. Separated overfire air, various types of fuel reburn, and various forms of SNCR could potentially be combined in series to reduce NO_X emissions prior to a boiler's flue gas exit. However, all the possible NO_X control technology combinations have not been installed on coal-fired powerplants, so actual feasibility of some combinations have not been demonstrated as viable, particularly in consideration of the special challenges posed by firing lignite coal.

A1.4.1 SOFA Combined With Other NO_X Reduction Technologies

Separated Overfire Air (SOFA) can be favorably combined with every other method in order to reduce the amount of reagent or reburn fuel required to achieve the resulting level of NO_X emission reduction. Some control technologies, especially conventional fuel reburn systems, require overfire air to complete the combustion of the staged fuel admitted to the upper furnace.

A1.4.1.1 SOFA with SNCR

Selective non catalytic reduction technologies are post-combustion, in-furnace NO_X control alternatives that have been installed in numerous boilers of various designs, fuel types, with and without overfire air. It is usually advantageous to apply overfire air so that the mass rate of NO_X will be lower, thus allowing the amount of chemical reagent consumption to be minimized in order to achieve the targeted NO_X emission rate from the boiler outlet.

Several examples of SNCR technology applied to pulverized coal-fired boilers are included in Appendix A3. As a NO_X control technology, SNCR with close-coupled OFA, or basic or boosted SOFA is considered technically feasible for application on Leland Olds Station Unit 1's boiler. SNCR with close-coupled OFA is expected to reduce NO_X emissions approximately 24.5% below 2000-2004 pre-control highest 24-month average NO_X baseline levels for the LOS Unit 1 boiler with ammonia slip limited to approximately 5 ppmvd. SNCR with basic separated OFA is expected to reduce NO_X emissions approximately 42% below 2000-2004 pre-control highest 24-month average NO_X baseline levels. The highest performing basic SNCR system combined with the boosted form of SOFA (ROFA) on LOS Unit 1's boiler is potentially able to achieve NO_X emission rates of 0.157 lb/mmBtu, an overall reduction of 45.1% below 2000-2004 pre-control highest 24-month average NO_X baseline levels during operation at full load.

Tests on the cyclone boilers at Conectiv's B.L England Station (Units 1 and 2) demonstrated that SNCR can decrease NO_X emissions as much as 31% at full load, from 0.55 to 0.38 lb/mmBtu, over and above the reduction possible from overfire air alone (approximately 60% drop, from 1.3 to 1.4 down to 0.55) in full operation. This is an overall NO_X emission reduction of 72% from pre-retrofit baseline[23,24].

SNCR with either the basic or the advanced forms of separated overfire air (ASOFA) can be applied and installed on LOS Unit 2's boiler. Air-staging the Unit 2 cyclones with the use of separated overfire air to further complement combustion NO_X reduction is an optional part of this technique. However, this will risk slag "freezing" in the barrels and lower furnace. Estimated NO_X emission rates for using SNCR techniques with North Dakota lignite considered published levels achieved by cyclone-fired units firing western subbituminous coal, and vendor predictions. SNCR with ASOFA is expected to reduce NO_X emissions approximately 38% below NO_X levels predicted for ASOFA operation, and potentially 54.5% overall from 2000-2004 pre-control highest 24-month average baseline levels for the LOS Unit 2 boiler with ammonia slip limited to approximately 5 ppmvd. This highest performing basic SNCR system is potentially able to achieve NO_X emission rates of 0.304 lb/mmBtu, respectively, when combined with the advanced form of SOFA on LOS Unit 2 boiler during operation at the pre-controlled baseline load. This expected level of sustained NO_X reduction is considered to be a reasonable estimate, given the concerns expressed about the potential limits of separated overfire air techniques to achieve typical NO_X reduction percentages when applied to lignite-fired cyclone boilers.

Another form of SNCR is combined with separated overfire air. This is currently being marketed commercially as “Rotating Mixing” (Rotamix). In the United States’ utilities industry, this has only been applied to pulverized coal-fired boilers. It is different than basic SNCR in that it includes a hot air booster fan and a small ambient air fan, and injects the ammonia (or urea) reagent into the high-pressure overfire air. This mixture is imparted into the boiler in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row. This vendor (Mobotec USA) claims that Rotamix (rotating opposed fire air or ROFA + SNCR) helps to distribute the reagent across the furnace cross section, which maximizes in-furnace NOx reduction while minimizing negative impacts on carbon monoxide and flyash unburned carbon. Three tangentially-fired utility boilers burning eastern bituminous coal or Illinois bituminous coal were retrofitted with Rotamix, each achieving a NO_X reduction of approximately 0-55% beyond the levels produced by ROFA alone, from pre-SNCR baselines of 0.22 to 0.28 lb/mmBtu down to 0.10 to 0.23 lb/mmBtu without low-NO_X burners[10,11,12].

While this variation of SNCR combined with separated overfire air could potentially be applicable to cyclone boilers, it has not been marketed to serve such applications. Because cyclone boilers do not require the addition of hot air booster fans for SOFA, and optimum injection locations for both SOFA and SNCR reagent may not coincide, Rotamix may not perform as well as, or significantly better than, a well-designed combination of conventional SOFA and SNCR. This technique is not distinct enough from basic SNCR from functional and air-staged cyclone NO_X reduction performance standpoints to warrant individual consideration for Leland Olds Station boilers. It was not evaluated for consideration as an option for LOS Unit 1 or Unit 2 boilers.

A1.4.1.2 SOFA with RRI

As previously stated, Rich Reagent Injection is not applicable to pulverized coal-fired boilers, and therefore is technically infeasible for LOS Unit 1. RRI must be combined with an advanced form of separated overfire air, and can be installed and operated with and without SNCR, for coal-fired cyclone boilers. RRI must be used in an oxygen-deprived atmosphere in order to effectively reduce nitrogen oxide emissions. This requires air-staged cyclones and separated overfire air operation. For lignite-fired cyclone boilers, the basic form of separated overfire air is incompatible with RRI, and is expected to be much less effective in reducing NO_X emissions than previously demonstrated elsewhere. This is related to the likelihood that the injection of reagent will be near the elevation of the existing lignite drying system vent ports, and that the oxygen introduced with the lignite drying system's vented moisture-laden airstream will disrupt the desired in-furnace nitrogen oxides reduction process.

Demonstration of RRI at Ameren's Sioux Unit 1 boiler, a 500 MW unit firing a blend of PRB and midwestern bituminous coals (without SNCR), with SOFA in August 2001 at a lower furnace SR approximately 1.0, NOx emissions were reduced approximately 55% to 0.55 lb/mmBtu w/ SOFA only, and an additional 15% NOx reduction from RRI (down to 0.47 lb/mmBtu) with zero ammonia slip[7]. Testing RRI with SOFA in 2002 at an average cyclone air-to-fuel stoichiometric ratio (S.R.) of 0.95 resulted in NO_X reductions as much as 29% for RRI (down to 0.27 lb/mmBtu) beyond those achieved with a modest amount of cyclone air-staging with SOFA (68% drop down to 0.38 lb/mmBtu from SOFA alone), for an 80% overall decrease from uncontrolled baseline[7]. Tested NO_X emissions with RRI+SOFA in 2002 were with a reagent normalized stoichiometric ratio (NSR) of 3 (lbs/ NH_3 per lb NO_X)[7]. In 2004, further operation of the SOFA system at lower cyclone stoichiometric ratios (S.R. of 0.90) resulted in reducing NO_X emissions down to 0.3 lb/mmBtu with approximately 26% overfire air flow without RRI[8]. Parametric testing in May 2005 reduced NO_X emissions between 15-38% with RRI+SOFA, down to 0.15 to 0.20 lb/mmBtu with reagent NSR between 1.0 and 4.0 and low ammonia slip levels less than 2 ppm from an established baseline condition of 0.20 to 0.285 lb/mmBtu level achieved with deep cyclone air-staging and SOFA operation firing an 80:20 PRB/Illinois coal blend at 480 MWg unit output[9].

It should be recognized that these demonstration tests of RRI were very limited in duration, with a particular combination of active cyclones, boiler output, active injector patterns, reagent concentration and mass flow rate, injection velocity, dispersion angle, and droplet size being established for a few hours over the course of a few days or weeks. Thus, the stated results do not reflect long-term NO_X control performance, reagent usage, or ammonia slip levels.

For LOS's Unit 2 lignite-fired cyclone boiler, RRI with ASOFA is potemtially able to be installed and operate. This option is assumed to provide a modest NO_X reduction of approximately 43% below the 2000-2004 pre-control highest 24-month average baseline level, down to 0.38 lb/mmBtu, for Unit 2's boiler, with less than 1 ppm ammonia slip. This is approximately 22% lower than the level produced by

ASOFA alone. This estimate is based on the premise that cyclone air/fuel stoichiometric ratios will be restricted (limited to around 0.95) because of concerns about possible slag freezing, and that reagent effectiveness will be diminished compared to demonstrated performance at B.L England Station Unit 1 and Sioux Unit 1 boilers. This option was not included in the cost-effectiveness analysis due to estimated lower NOx reduction and higher reagent consumption versus SNCR with ASOFA.

A1.4.1.3 SOFA with RRI and SNCR

When RRI is combined with separated overfire air and SNCR, it has demonstrated very high NO_X emissions reduction at Conectiv's B.L. England Unit 1 boiler firing eastern bituminous coal, on the order of 80% from an uncontrolled baseline around 1.2 lb/mmBtu[30]. In May 2005, testing RRI+SNCR+SOFA at Ameren's Sioux Unit 1 boiler firing a high PRB-blend coal Sioux Unit 1 reportedly demonstrated NO_X emissions as low as 0.12 lb/mmBtu. This was from an established baseline condition of 0.20 lb/mmBtu level achieved with deep cyclone air-staging and SOFA operation firing an 80:20 PRB/Illinois coal blend at 480 MWg unit output with a reagent NSR of 4 and ammonia slip limited to less than 5 ppmvd, for an overall 90% reduction with no apparent adverse short-term impacts of deeper air-staged combustion together with overfire air, RRI and SNCR applications. A technical paper by REI was presented at a late 2005 conference documenting these findings[11].

As with RRI with ASOFA, demonstration tests of RRI and SNCR with ASOFA were very limited in duration. Thus, the stated results do not reflect long-term sustained NO_X control performance, reagent usage, or ammonia slip levels.

For LOS's Unit 2 lignite-fired cyclone boiler, RRI and SNCR with ASOFA is potemtially able to be installed and operate. This combination was assumed to be capable of achieving an overall NO_X reduction of approximately 60% below a baseline level, down to 0.265 lb/mmBtu, for Unit 2's boiler, with ammonia slip limited to 5 ppmvd. This is a reduction approximately 46% beyond the level produced by ASOFA alone, with the SNCR contribution approximately 30% below RRI+ASOFA. As previously discussed, this level of NO_X emissions reduction is considered to be a reasonable estimate, given the concerns expressed about the ability of RRI to be effective due to potential limits of separated overfire air techniques when applied to lignite-fired cyclone boilers.

A1.4.1.4 SOFA with Reburn

Most, if not all, of the recent conventional fuel reburn installations include separated OFA. Coal reburn and conventional gas reburn (CGR) are combined with SOFA. Several of these examples were already described[4,5,6,7,8, 18,19,20,21].

For the most effective NO_X reduction performance by applying the various available forms of fuel reburn, the injection of gaseous fuel is usually performed using recirculated flue gas as a diluent and carrier media to aid dispersion and avoid completely oxidizing the carbon and nitrogen components in the fuel and furnace gases generated from staged burners below the fuel reburn injection location. Improved gas reburn designs have reduced or eliminated FGR with higher gas injection pressures.

For lignite-fired cyclone boilers, conventional reburn fuel firing with a basic form of separated overfire air is expected to be much less effective in reducing NO_X emissions than previously demonstrated elsewhere. This is related to the likelihood that the injection of reburn fuel will be near the elevation of the existing lignite drying system vent ports, and that the oxygen introduced with the lignite drying system's vented moisture will oxidize the reburn fuel and significantly disrupt the desired in-furnace reduction process for nitrogen oxides.

It should be recognized that application of air-staged cyclones with basic or advanced forms of SOFA in combination with reburn techniques will require the overfire air injection ports to be located at a somewhat lower elevation of the furnace compared to SOFA with air-staged cyclones without reburning. This is significant, especially for alternatives with coal reburn to allow the solid fuel introduced below the SOFA ports to burn completely prior to the furnace exit plane. This means that less air-staging of the cyclones may be practiced, or that less residence time will be available for the in-furnace NO_X reduction process to occur.

Fuel-lean gas reburn (FLGR™) can be applied with or without SOFA, as this limited amount of staged fuel is introduced into an oxygen-rich atmosphere downstream of the burners and any OFA injection points. More commonly, FLGR™ has been installed with SNCR for NO_X emission reduction[22,23,24,25]. A potential advantage of FLGR™ over conventional gas reburn is that the former involves less reburn fuel consumption. As discussed below, FLGR™ alone or in combination with basic SOFA (without ASOFA) is expected to be ineffective on lignite-fired cyclone boilers.

As a NO_X control technology, FLGR™ with SOFA is considered technically feasible for application on Leland Olds Station Unit 1 boiler. However, because of the lack of apparent NO_X control performance advantage over other similar or better performing control alternatives, high operating cost and significant capital costs for supplying natural gas, this alternative was not evaluated for consideration as an option for LOS Unit 1. More commonly, FLGR™ has been installed with SNCR for NO_X emission reduction[22,23,24,25]. This is discussed in a subsequent section involving amine-enhanced FLGR™.

In the case of FLGR™ applied to lignite-fired cyclone boilers, air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction is an optional part of this reburn technique which will further risk slag "freezing" in the barrels and lower furnace. The amount of fuel injected above the existing lignite drying system vent ports (which will not be relocated as part of the basic form of SOFA) is expected to be substantially more than previously demonstrated in order to compensate for the higher oxygen levels due to the introduction of moist air in the lower furnace above the cyclones without relocating the vent ports. The existing lignite drying systems' vent ports' locations and introduction of oxygen to the lower furnace below the presumed FLGR™ injection points will likely limit the NO_X emission reduction potential of the FLGR™ component. Limited additional potential NOx reduction is anticipated when FLGR™ is operated with lignite-fired cyclones, due to the potential need to remove one or more cyclones from active firing to maintain adequate heat input in the remaining active cyclones for keeping satisfactory slag formation and flow. Reducing the number of active cyclones, which are air- and fuel-staged to accommodate reduced firing rates while operating a coal-fired boiler with reburn and separated overfire air, is the typical approach to avoid slag tapping problems. This creates lower furnace conditions where oxygen (cooling air from the idle cyclones) is introduced in proximity to the reburn fuel, disrupting the desired in-furnace reduction process for nitrogen oxides.

FLGR™ technology with basic and advanced forms of SOFA was not included in the cost-effectiveness analysis for LOS Unit 2, because of the lack of apparent NO_X control performance advantage over other similar or better performing control alternatives, high operating cost and significant capital costs for supplying natural gas.

A1.4.2 SNCR and Reburn

Various forms of SNCR could potentially be installed downstream of separated overfire air and various types of fuel reburn, to reduce NO_X emissions prior to the boiler's flue gas exit. Conventional gas (CGR) or coal reburn systems, by and large, have not been combined with forms of SNCR, although at least one vendor (GE Energy) has promoted a combination of conventional gas reburn with SNCR and overfire air systems[18] as “advanced” gas reburn. Only one example of permanent installation of SNCR with conventional gas reburn (and overfire air) on a tangentially-fired boiler was found in available technical literature or vendor experience lists. The vendor (GE Energy) that provided the advanced gas reburn system at 120 MW NRG Somerset Station claimed NO_X emissions were reduced by 44% from a baseline of 0.45 down to 0.25 lb/mmBtu with overfire air alone; an additional reduction of 20% resulting from conventional gas reburn with overfire air, down to 0.20 lb/mmBtu; and further decrease of 45% down to 0.11 lb/mmBtu using gas reburn with SNCR with an unstated amount of ammonia slip, for an overall reduction of 75% from pre-control baseline[6,35].

As a combination of NO_X control technologies, conventional gas reburn with SNCR and SOFA may be capable of being installed on the Leland Olds Station Unit 1 boiler. However, because of the lack of any permanent commercial gas reburn experience applying this combination of technologies to wall-fired coal-burning boilers, and apparent negative economic advantage due to high operating cost and significant capital costs for supplying natural gas versus the expected slight potential gain in NO_X control performance, CGR with ASOFA and SNCR alternative was not evaluated for consideration as an option for LOS Unit 1.

No example of actual demonstration or permanent installation of SNCR with conventional gas or coal reburn (and overfire air) on cyclone-fired boilers was found in available technical literature. As previously expressed with layered technologies involving conventional reburn, an “advanced” form of SOFA is desired for lignite-fired cyclone boilers. The lack of experience with this combination on a cyclone-fired boiler, especially for lignite-firing, makes the prediction of success and the level of NO_X emission reduction potential uncertain. CGR with ASOFA and SNCR was considered technically infeasible as an option for LOS Unit 2.

Rich Reagent Injection has not been demonstrated of being capable of combining with fuel reburn, especially conventional fuel reburn alternatives with high amounts of reburn fuel injection. No example of actual demonstration or permanent installation of RRI with reburn (and overfire air) on cyclone-fired boilers was found in available technical literature or vendor experience lists. This combination of technologies is considered technically infeasible as an option for LOS Unit 2.

Because of the lack of any permanent commercial coal reburn experience applying this combination of technologies to pulverized coal-fired or cyclone-fired boilers, apparent negative economic advantage due to high operating cost and significant capital costs for preparing the reburn fuel versus the expected slight potential gain in NO_X control performance, PCR/mCR with ASOFA and SNCR alternative was not evaluated for consideration as an option for LOS Unit 1's and Unt 2's boilers. This combination of technologies is considered technically infeasible as an option for LOS Unit 1's and Unt 2's boilers.

A1.4.2.1 Amine-Enhanced FLGR™ (AEFLGR™) or FLGR™ + SNCR

Fuel-lean gas reburn has been combined with SNCR on at least five pulverized coal-fired utility powerplants retrofit installations within the United States[23]. This combination of technologies allows the boiler to be operated with FLGR™ alone, FLGR™ and SNCR, or SNCR only (without SOFA) for the specific level of control desired or required. The vendor (Fuel Tech) that provided the AEFLGR™ system at Mercer Station claimed NO_X emissions were reduced by 60% (from a baseline of 1.4 down to 0.56 lb/mmBtu) with 5 ppm ammonia slip without overfire air. A technical paper provides more details[36].

As a combination of NO_X control technologies, FLGR™ with SNCR (with or without SOFA) is considered technically feasible for application of Leland Olds Station Unit 1 boiler. However, with disadvantages of high operating cost and significant capital costs for supplying natural gas compared to other similar or better performing control alternatives, this alternative was not evaluated for consideration as an option for LOS Unit 1.

No example of actual demonstration or permanent installation of FLGR™ + SNCR (with or without overfire air) applied to a cyclone-fired boiler was found in available technical literature or vendor experience lists. It may be possible to be applied on a cyclone-fired boiler burning lignite, but the amount of NO_X control performance contribution from the FLGR™ system is expected to be limited.

Because a FLGR™ + SNCR (AEFLGR™) system (without basic or advanced versions of SOFA) lacks demonstrated and commercial experience in this application, particularly on a cyclone-fired boiler burning lignite, this combination is considered infeasible as an option for LOS Unit 2.

*****

A2 Cost of Compliance for NO_X Controls - Estimate Details

An evaluation was performed to determine the compliance costs of installing various feasible NO_X control alternatives on Leland Olds Station boilers. This evaluation includes estimated:

- Capital costs;
- Fixed and variable operating and maintenance costs; and
- Levelized total annual costs

to engineer, procure, construct, install, startup, test, and place into sustained annual commercial operation the particular control technology. The results of this evaluation are summarized in the main report, Tables 2.4-1 through 2.4-7 for LOS Unit 1, and Tables 2.5- through 2.5-9 for LOS Unit 2.

A2.1 Capital Cost Estimates for NO_X Controls

The capital costs to implement the various NO_X control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. In the cases with SNCR, preliminary vendor budgetary cost information was obtained and used in place of, or to adjust, the published unit output cost factors. The capital costs for combinations of NOx reduction technologies evaluated were typically estimated based upon simple arithmetic addition of the individual unit output capital cost factors for these technologies, multiplied by the nameplate capacity ratings of the steam-electric generating units at Leland Olds Station. These cost estimates were adjusted for inflation where appropriate (to 2005$), and are considered to be study grade, which is + or – 30% accuracy, or better.

The limitations of these capital cost estimates developed from unit capital cost factors multiplied by unit output are subject to:

- Scope basis uncertainty – inability to precisely determine what scope of supply, including such things as balance-of-plant (BOP) systems and equipment improvements were required, assumed, or accounted for when developing the unit cost factors. Some alternatives may have higher indirect or BOP capital costs than others. Similarly, the inclusion of general facilities, preproduction and inventory costs, and other indirect costs is not known. It is likely that the utility owner's final total expenditure for the implementation of the alternatives, especially options that are most capital cost-intensive, will be greater than the calculated cost estimates.
- Location-specific influences – most NO_X control techniques have been applied primarily to eastern bituminous coal-fired plants located near large metropolitan areas, not in largely rural,

upper midwestern United States locales. The amount of space available is dependent on the existing powerplant equipment and building layout and property plot area, versus what is expected to be required for implementing various control technologies. Transportation and local/regional labor costs are also variables.

- Size influences – some technologies' capital costs are more sensitive to "economies of scale" than others.
- Capacity margins – some technologies' may require higher capacity margins to allow sustained operation at high throughput rates over extended periods of time.
- Reliability concerns – some technologies' have been refined to a higher degree, and others may require more component redundancy than others in order to avoid performance reductions and potential outages for failures and repairs or replacements.
- Inflationary influences – the significant increases in 2004-2005 for raw material costs, especially steel and alloys for fabrication of structural and mechanical components, has occurred after many of these technologies were installed in projects upon which the referenced unit capital cost factors were based.
- Market conditions – as demand increases for emission controls, some alternatives become more cost-competitive, while others do not. This can be influenced by the relative supply and demand for the technology and number of suppliers who can furnish it. The demand for some alternatives can also be strongly influenced by the stringency of the local, state, and national regulatory requirements. Schedule demands for implementation and availability of local/regional labor for installation contractors are also market-driven factors.

The estimated installed capital cost for each alternative evaluated was multiplied by the capital levelization factor (0.08718) to yield levelized total annualized capital cost.

A2.1.1 Combustion Controls' Capital Cost Estimates

A2.1.1.1 Separated Overfire Air Capital Cost Estimates

Installation of separated overfire air systems typically includes windbox and/or secondary combustion air supply duct modifications, boiler waterwall tube openings, airflow distribution devices (dampers/registers), airflow controls and measurement instrumentation, and related structural and electrical tie-ins to the existing plant facilities. A basic separated overfire air retrofit system installed on LOS wall-fired and cyclone boilers includes ports across the front and rear walls of the upper furnace.

The unit capital cost factor is expected to be at the low end of the typical range[37] for LOS Unit 1: $6.3/kW or $1.4M; and near the high end of the same range for LOS Unit 2: $12.5/kW or $5.5M.

A basic form of SOFA for potential retrofit on LOS Unit 1's boiler will include providing new (or relocating the existing close-coupled) overfire air ports and waterwall tube openings adjacent and above the top row burners in the middle furnace to a slightly higher elevation across the front and rear walls. This requires extension of the existing CCOFA windbox or creation of a new SOFA windbox to supply the new ports. This retrofit will also close-off the existing CCOFA ports.

A boosted form of SOFA (ROFA) for potential retrofit on LOS Unit 1's boiler will include additional secondary air ductwork to and from a new hot air booster fan. This is expected to cost in the area of +$14.4/kW or approximately $3.1M for Unit 1's additional capital cost over and above the basic SOFA system. Overall, the boosted version of SOFA is estimated to have an installed capital cost of approximately $20.7/kW or $4.5M for LOS Unit 1. The installed capital cost estimate for LOS Unit 1's boosted SOFA (ROFA) alternative used in this cost effectiveness analysis was estimated based upon applying a 3.5% assumed inflation cost adjustment to the unit capital cost factor for ROFA of $20/kW (x 1.035 = $20.7/kW) included in a WRAP (Western Regional Air Partnership) draft report[38] published on their website, dated April 26, 2005. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BART analysis.

For LOS Unit 2, an advanced form of SOFA unique to North Dakota lignite-fired cyclone boilers will include relocation of the existing lignite drying system vent port openings from the lower primary furnace to the upper furnace, to be placed at the same elevation as the new SOFA ports. This requires extension of the lignite drying systems' vent piping to supply the new ports. This is expected to cost in the area of +$5/kW or approximately $2.1M for Unit 2's additional capital cost over and above the basic SOFA system. This retrofit will also close-off the existing FGR ports, currently coinciding with the existing pre-dry vent ports on Unit 2. These FGR ports may be relocated to the lower portion of the upper (secondary) furnace, across the front and rear walls. This is expected to cost in the area of +$5.6/kW or +$2.5M for Unit 2's additional capital cost over and above the basic SOFA system. Overall, the advanced version of SOFA is estimated to have an installed capital cost of approximately $23/kW or $10.1M for LOS Unit 2. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BART analysis.

Reduced-diameter replacement cyclone reentrant throats (boiler waterwall tubes) are hardware modifications which can be specifically designed to complement the air-staged combustion/SOFA approach and may improve the ability to increase the retention of fine coal particles during staged combustion on the Unit 2 boiler at LOS. This is estimated to cost in the area of $18.2/kW or approximately $8M for Unit 2. However, these capital costs were not included in the figures used in the determination of the NO_X control technology cost-effectiveness for any alternatives.

A2.1.1.2 Coal Reburn Capital Cost Estimates

There are several alternatives that include a new fuel reburn system. Capital cost estimates for coal reburn systems are highly dependent on the requirements for reburn fuel preparation and feeding to the boiler. For the purposes of this analysis, the application of a pulverized coal reburn system assumed the need to make extensive additions to the existing fuel preparation equipment in the existing plant facilities and feeding to new furnace injectors. At least two new fine-grind pulverizers, or MPS-89 standard pulverizers followed by dynamic classifiers are expected to supply the amount of finely ground reburn coal for this method. Addition of new electrical loads for the pulverized coal preparation equipment to the existing plant facilities will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power will be available for powering the new pulverizers/micro-mills and related new coal reburn equipment, but this has not been confirmed.

The existing LOS Unit 1 boiler's pulverizer bays do not have floor space available to allow the new milling equipment for reburn fuel preparation to be located adjacent to the existing coal pulverizers. This will require a separate building or addition to the existing powerhouse to be built to provide sufficient space to enclose the new milling and coal silo/handling equipment. Separate modified pulverized coal-style burners or coal injectors will be installed through new openings in the upper furnace front and rear waterwalls at or above the elevation of the existing cose-coupled overfire air system ports, along with new separated overfire air ports located at a higher elevation, above the reburn fuel injectors. This would have the capacity to supply approximately up to thirty percent of the total full load fuel heat input to the boiler through the coal reburn injectors. The coal reburn system design was not expected to change the existing main burner silo/feeder arrangement, such that all main burners would remain operational. Both basic and boosted forms of SOFA for pulverized coal reburn were included. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BART analysis.

The installed capital cost of pulverized coal reburn for LOS Unit 1 used in this cost effectiveness analysis was estimated based upon a Clean Air Markets Division [CAMD] of the US EPA dollar per kilowatt unit capital cost factor for cyclone boilers, because of the need to make extension additions to the existing feul prepearation system equipment/facilities. The installed capital cost estimate of $19.8M for LOS Unit 1's pulverized coal reburn alternative with basic SOFA used in this cost effectiveness analysis was estimated based upon applying a 3.5% assumed inflation cost adjustment to the CAMD unit capital cost factor for cyclones of $82.33/kW (x 1.035 = $85.2/kW) included in a WRAP (Western Regional Air Partnership) draft report[38] published on their website, dated April 26, 2005. Including the estimated additional capital costs for retrofitting basic SOFA in place of CCOFA previously described in the separated overfire air capital cost estimate section raised the installed unit capital cost factor to $91.5/kW.

Including the estimated additional capital costs for boosted SOFA previously described in the separated overfire air capital cost estimate section raised the installed unit capital cost factor to $105.9/kW, bringing the estimated subtotal of LOS Unit 1's coal reburn system with boosted SOFA to $22.9M.

As discussed in the coal reburn feasibility review, additional particulate matter collection equipment to increase PM collection capacity of LOS Unit 1 will be needed for this alternative. This was assumed to include a hybrid particulate matter collection system associated with the existing electrostatic precipitator referred to as COHPAC. A description of this technology is provided in the main report under the PM control section. The COHPAC addition due to coal reburn was estimated based on flue gas flow at the boiler design rating (2,622 mmBtu/hr) heat input rate. Installed capital cost for this COHPAC addition was $15.7M ($72.9/kW). This is generally described in more detail in the capital cost estimate portion of the main report for particulate matter controls, Section 4.5.1.1 for LOS Unit 2.

Addition of new electrical loads for the LOS Unit 1 boiler's pulverized/micronized coal preparation equipment, and associated with adding COHPAC to the existing plant facilities will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power capacity will be available for powering the new pulverizers/micro-mills, COHPAC, and auxiliary equipment related to the new coal reburn facility. Any capital costs for providing the additional auxiliary electrical power distribution capacity not included in the assumed project scope has not been estimated or included.

Adding the \$15.7M for the COHPAC PM collection capacity increase to the coal reburn system with basic SOFA subtotal of \$19.8M yields a total estimated installed capital cost of \$35.5M (\$164.4/kW) for this coal reburn alternative. Adding the \$15.7M for the COHPAC PM collection capacity increase to the coal reburn system with boosted SOFA subtotal of \$22.9M yields a total estimated installed capital cost of \$38.6M (\$178.8/kW) for this coal reburn alternative. This was deemed sufficient to use in the cost-effectiveness analysis for applying coal reburn to Leland Olds Station Unit 1's boiler.

The existing LOS Unit 2 boiler's crusher bays do not have floor space available to allow the new milling equipment for reburn fuel preparation to be located adjacent to the existing coal crushers. This will require a separate building or addition to the existing powerhouse to be built to provide sufficient space to enclose the new milling and coal silo/handling equipment. Separate modified pulverized coal-style burners or coal injectors will be installed through new openings in the upper furnace front and rear waterwalls at or above the elevation of the existing lignite drying system vent ports, along with new overfire air ports located at a higher elevation, above the reburn fuel injectors. This would have the capacity to supply approximately up to thirty percent of the total full load fuel heat input to the boiler through the coal reburn injectors. The coal reburn system design was not expected to change the existing cyclone silo/feeder arrangement, such that all cyclones would remain operational. To achieve maximum NO_X emission control, only the advanced form of SOFA for pulverized coal reburn was included. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BART analysis.

The installed capital cost of pulverized coal reburn for LOS Unit 2 used in this cost effectiveness analysis was estimated based upon a Clean Air Markets Division [CAMD] of the US EPA dollar per kilowatt unit capital cost factor for cyclones. The installed capital cost estimate of \$37.5M for LOS Unit 2's pulverized coal reburn alternative used in this cost effectiveness analysis was estimated based upon applying a 3.5% assumed inflation cost adjustment to the CAMD unit capital cost factor for cyclones of \$82.33/kW (x 1.035 = \$85.2/kW) included in a WRAP (Western Regional Air Partnership) draft report[38] published on their website, dated April 26, 2005. Including the estimated additional capital costs for relocating special lignite drying system vent ports and flue gas recirculation ports previously described in the separated overfire air capital cost estimate section raised the installed capital cost estimate subtotal of LOS Unit 2's coal reburn system to \$42.1M.

As discussed in the coal reburn feasibility review, additional PM collection equipment to increase PM collection capacity of LOS Unit 2 will be needed for this alternative. This was assumed to include a hybrid particulate matter collection system associated with the existing electrostatic precipitator referred to as COHPAC. A description of this technology is provided in the main report under the PM control section. The COHPAC addition due to coal reburn was estimated based on flue gas flow at the boiler design rating (5,130 mmBtu/hr) heat input rate. Installed capital cost for this COHPAC addition was $25.3M ($57.5/kW). This is described in more detail in the capital cost estimate portion of the main report for particulate matter controls, Section 4.5.1.1 for LOS Unit 2.

Addition of new electrical loads for the pulverized/micronized coal preparation equipment, and associated with adding COHPAC to the existing plant facilities will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power capacity will be available for powering the new pulverizers/micro-mills, COHPAC, and auxiliary equipment related to the new coal reburn facility. Any capital costs for providing the additional auxiliary electrical power distribution capacity not included in the assumed project scope has not been estimated or included.

Adding the $25.3M for the COHPAC PM collection capacity increase to the coal reburn system with ASOFA subtotal of $42.1M yields a total estimated installed capital cost of $67.425M ($153.2/kW) for this alternative. This was deemed sufficient to use in the cost-effectiveness analysis for applying coal reburn to Leland Olds Station Unit 2’s boiler.

A2.1.2 Capital Cost Estimates for Post Combustion Controls

A2.1.2.1 SNCR Capital Cost Estimate

The alternatives for LOS Unit 1 that include selective non-catalytic reduction systems assume the use of urea unless noted otherwise. The SNCR systems’ preliminary design and estimated capital costs were based upon a 2004 budgetary proposal[39] for a nominal 240 MW unit by a vendor (Fuel Tech) with experience in supplying urea-based SNCR equipment. Circulation, metering, dilution, control, in-line and storage tank heating, water dilution, and reagent metering equipment. Estimated capital costs of $3.9M ($18.06/kW) include budgetary numbers for equipment installation, including installation management, material and labor assumed for a SNCR system applied to LOS Unit 1’s 216 MW boiler. Costs for work outside the vendor’s scope, such as outdoor reagent storage tank and building enclosure/equipment foundations and containment, and balance-of-plant additions plus other indirect costs were estimated to add approximately \$1.0M (25% plus 10% contingency) to the vendor's estimated installed cost for their scope of supply. These adjustments result in a total installed capital cost for SNCR (without SOFA) estimated to be approximately \$3.9M plus \$1.0M = \$4.9M for 216 MW LOS Unit 1.

Adding the basicSOFA capital cost of \$1.4M yields a total estimated installed capital cost of \$6.2M (\$28.9/kW) for the SNCR with basic SOFA alternative for LOS Unit 1.

Including the estimated additional capital costs for boosted SOFA previously described in the separated overfire air capital cost estimate section raised the installed unit capital cost factor to \$43.3/kW, bringing the estimated subtotal of LOS Unit 1's SNCR system with boosted SOFA (Rotamix) to \$9.3M.

The alternatives for LOS Unit 2 that include selective non-catalytic reduction systems assume the use of urea unless noted otherwise. The SNCR systems' preliminary design and estimated capital costs were based upon a late 2004 budgetary proposal[39] for a nominal 450 MW unit by a vendor (Fuel Tech) with experience in supplying urea-based SNCR equipment. Circulation, metering, dilution, control, in-line and storage tank heating, water dilution, and reagent metering equipment. The conceptual SNCR project estimates a 180,000 gallon field-erected stainless steel storage tank will hold the 50% urea solution (as delivered by truck or rail). Individual and multiple nozzle lances with multiple levels of urea reagent injection will be designed and located to optimize distribution and accommodate various boiler load conditions. Capacity of the SNCR system is expected to be sufficient to be operated alone or in conjunction with other NO_X reduction technologies, such as advanced SOFA and Rich Reagent Injection. Estimated capital costs of \$4.9M include budgetary numbers for equipment installation, including installation management, material and labor assumed for a SNCR system applied to a 450 MW boiler. Costs for work outside the vendor's scope, such as outdoor reagent storage tank and building enclosure/equipment foundations and containment, and balance-of-plant additions plus other indirect costs were estimated to add approximately \$1.9M (25% plus 10% contingency) to the vendor's estimated installed cost for their scope of supply. These adjustments result in a total installed capital cost for SNCR (without advanced SOFA or RRI) estimated to be approximately \$6.7M for 440 MW LOS Unit 2. Adding the advanced SOFA capital cost of \$10.1M yields a total estimated installed capital cost of \$16.8M (\$38.3/kW) for the SNCR with ASOFA alternative for LOS Unit 2.

Addition of new electrical loads for the SNCR reagent storage, pumping, dilution, metering, and related compressed air control equipment for reagent injector cooling, will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power capacity will be available for powering the new SNCR system and associated auxiliary equipment. Any capital costs for providing the additional auxiliary electrical power distribution capacity has not been estimated or included.

A2.1.2.2 Rich Reagent Injection Capital Cost Estimate

The alternative for LOS Unit 2 that includes Rich Reagent Injection (RRI) form of selective non-catalytic reduction systems assumes the use of urea as the effective NO_X control reagent. The RRI systems' preliminary design and estimated capital costs were derived from information by the vendor licensed for this technology (Reaction Engineering International). If RRI were to be supplied without SNCR, total capital cost is assumed to be the same as SNCR with ASOFA, or $16.8M for LOS Unit 2.

Expansion of the base SNCR alternative's reagent circulation, metering, dilution, control, in-line and storage tank heating, storage and injection equipment is assumed to be included when RRI is added to this other alternative. Individual RRI lances with multiple levels of urea reagent injection in the lower furnace will be designed and located to optimize distribution and accommodate various boiler load conditions. Capacity of the RRI system is expected to be sufficient to be operated in conjunction with other NO_X reduction technologies, such as ASOFA with or without SNCR. Estimated capital costs for RRI in combination with SNCR assumed the addition was 50% of SNCR's capital costs. These adjustments result in an incremental installed capital cost for RRI estimated to be $3.4M for LOS Unit 2 (without ASOFA or SNCR costs included in the assumed RRI+SNCR w/ ASOFA "layered" alternative). Adding the SNCR with advanced SOFA estimated capital cost of $16.8M yields a total estimated installed capital cost of $20.2M ($46/kW) for this RRI+SNCR with ASOFA alternative.

Addition of new electrical loads for the RRI portion of the SNCR reagent storage, pumping, dilution, metering, and related cooling water and compressed air control equipment for reagent injector cooling and dispersion, will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power capacity will be available for powering the RRI portion of the new SNCR system and associated auxiliary equipment. Any capital costs for providing the additional auxiliary electrical power distribution capacity has not been estimated or included.

A2.2 Operating and Maintenance Cost Estimates for Leland Olds Station NO_X Controls

An evaluation was performed to determine the estimated operating, maintenance, and capital cost impacts of installing various feasible NO_X control technologies on Leland Olds Station Units 1 and 2. These were estimated to be in addition to existing O&M costs to operate and maintain the LOS equipment.

The expected loss of electrical power sales from the operation of the specific NO_X control alternative was included as an annualized cost, assuming $38 per megawatt-hour. This was determined to include estimates for:

- Reduction in annual unit output due to an expected negative reliability (i.e. uptime availability) impact for each alternative. This “lost generation” was calculated by multiplying the estimated additional numbers of outage hours per year by the average running plant capacity factor for that specific alternative.
- Net additional auxiliary electric power demand for the added control equipment for each specific alternative based on assumptions for gross horsepower and loading factor, plus additional power demand for induced draft fans caused by flue gas pressure drop, pulverizers and feeders for coal reburn, and compressed air or service water consumed for injection media and lance cooling, respectively, for SNCR and RRI alternatives.
- The average running plant capacity factor for each alternative, which may also include an expected negative impact on the unit capacity from operation of the technology. Examples are lower boiler thermal efficiency (higher unit heat rate) when firing natural gas (due to higher moisture content of the flue gas).

For alternatives that involve a chemical reagent injected for NOx control, such as urea (or ammonia converted from urea), the annual reagent consumption based on an assumed actual stoichiometric ratio (ASR) of moles of equivalent NH_3 injected per mole of uncontrolled NO_X emission estimated at the point of injection, converted to a mass rate (lbs/hr) by multiplying by the estimated annual number of hours of operation and the estimated NOx reduction fraction, and then multiplied by unit reagent cost. For SNCR-related alternatives, a December 2004 vendor proposal and subsequent followup in September 2005 is the primary basis for the reagent consumption estimates (for a specific NO_X emission reduction and ammonia slip level).

General annual maintenance costs were assumed to be 1.5 percent of the estimated installed capital cost for each alternative, except for the pulverizer portions of the coal reburn alternatives, which were assumed to be 3 percent.

Additional operating labor costs directly attributable to each alternative were assumed to be zero for all alternatives.

Other operating costs include:

- Reagent dilution water for those alternatives that involve a chemical reagent injected for NOx control, typically four times the amount of urea consumption (assumes urea is a 50% solution as delivered and is injected as a 10% solution); this follows EPA OAQPS convention.
- Heat required for reagent storage; for those alternatives that involve a chemical reagent injected for NOx control; the source of heat is assumed to be auxiliary electrical power, but could be auxiliary steam (depending on heat source availability and plant preference). All SNCR-related alternatives assume the direct use of diluted urea solution.
- Additional coal consumption for those alternatives that involve a chemical reagent injected for NOx control to compensate for the heat of vaporization of the reagent dilution water; this follows EPA OAQPS convention, but is not accepted practice by an experienced SNCR vendor (Fuel Tech) who claims that the heat produced from the exothermic reaction of urea and NO_X is approximately equal to the heat required to evaporate the dilution water. For the purposes of this study, this additional coal consumption has not been included in the annual O&M costs.

The sum of the estimated annual O&M costs was multiplied by the O&M levelization factor (1.19314) for each alternative to yield levelized total annual O&M costs.

A2.2.1 Combustion Controls' O&M Cost Estimates

A2.2.1.1 Separated Overfire Air O&M Cost Estimates

Operation of the basic form of SOFA on LOS Unit 1's boiler is expected to add a small amount of O&M cost, primarily electricity consumed by the conventional SOFA damper electric drive actuator and overfire airflow measuring system transmitter supplying each SOFA windbox on the front and rear walls. A substantial mount of additional electricity will be consumed by the hot air booster fan for operation of the boosted form of SOFA on LOS Unit 1's boiler. Using the existing forced draft, induced draft, and primary air fans is not expected to change the overall amount of fan horsepower demand to be supplied by those fans' electric motors. Boiler furnace waterwall tube maintenance may increase slightly as a result of more fireside corrosion due to substoichiometric burner operation with SOFA. Maintenance of the new windbox-style overfire air ports is expected to be similar to the expenses associated with the existing CCOFA ports of Unit 1. Maintenance costs for alternatives that include SOFA are assumed to be 1.5 percent of the installed capital cost.

Operation of the advanced form of SOFA on LOS Unit 2's boiler is expected to add a small amount of O&M cost, primarily electricity consumed by the conventional SOFA damper electric drive actuator and overfire airflow measuring system transmitter on each port. Using the existing forced draft, induced draft, and flue gas recirculation fans is not expected to change the overall amount of fan horsepower demand to be supplied by those fans' electric motors. Boiler furnace waterwall tube maintenance may increase slightly as a result of more fireside corrosion due to substoichiometric cyclone operation with SOFA. Maintenance of the new open-style overfire air ports is expected to be similar to the expenses associated with the existing flue gas recirculation ports of Unit 2. Maintenance costs for alternatives that include ASOFA are assumed to be 1.5 percent of the installed capital cost.

A2.2.1.2 Coal Reburn O&M Cost Estimates

The alternatives that include a new coal reburn system assume the use of new equipment for preparing the reburn fuel to replace 25% of each LOS boiler's total fuel heat input. Two additional lignite silos, with coal feeders and fine-grind pulverizers followed by dynamic classifier(s), or possibly four micromills, are assumed to be located in a new separate building or powerhouse enclosure for each LOS boiler. A booster fan (exhauster) is assumed to be required to overcome the pressure drop across the fine-grind pulverizers or micromills and dynamic classifiers for supplementing the existing primary air system for the additional reburn fuel milling. Using the existing forced draft, induced draft, primary air (LOS Unit 1) and flue gas recirculation (LOS Unit 2) fans is not expected to significantly change the overall amount of fan horsepower demand to be supplied by those fans' electric motors. The expected loss of electrical power sales from the additional auxiliary electric power demand for the reburn milling equipment from an estimated 0.4% (940 kW for LOS Unit 1's) and 2.5 MW for LOS Unit 2's reduction in net output was included as a cost of $0.3M/yr and $0.8M/yr, assuming $38 per megawatt-hour for LOS Unit 1 and Unit 2, respectively. The twenty existing mills on Unit 1 and twelve existing coal crushers and feeders on Unit 2 used for preparing the main (burner and cyclone) fuel fraction will have approximately 25% lower electrical demand, which was \$100,000/yr and \$150,000/yr subtracted from the additional reburn auxiliary power costs for LOS Unit 1 and Unit 2, respectively.

Maintenance of the separate reburn coal injectors is expected to be similar to the expenses associated with typical pulverized coal burners. The estimated additional annual maintenance costs for a new micronized coal reburn system was assumed to be 3.0 percent of the installed capital cost, or roughly \$0.6M per year for LOS Unit 1 and \$1.26M per year, for LOS Unit 2.

Operation and maintenance costs of the basic and boosted forms of SOFA on LOS Unit 1's boiler, and the advanced version of SOFA on LOS Unit 2, are assumed to be included for coal reburn alternatives.

Increase in auxiliary electrical power for the COHPAC addition associated with the coal reburn alternatives for NO_X control was estimated to be approximately \$0.5M/yr and \$0.8M/yr for LOS Unit 1 and LOS Unit 2 respectively. This is mostly the result of higher induced draft fan horsepower demand to overcome the resistance (pressure drop) of the filter media to the flue gas flow. Additional auxiliary electrical power must be supplied to those fans' electric motors. Maintenance of the COHPAC addition to LOS Unit 1 and LOS Unit 2 includes replacement of the filter bags, and general maintenance expenses. This was assumed to be approximately \$0.4M/yr and \$0.8M/yr for LOS Unit 1 and LOS Unit 2 respectively. Section 4.5.1.2 of the main report for LOS Unit 2 describes the O&M cost estimate portion for particulate matter controls in more detail.

A2.2.2 Post-Combustion NO_X Controls' O&M Cost Estimates

A2.2.2.1 SNCR O&M Cost Estimates

The alternatives that include selective non-catalytic reduction systems will involve higher operating costs compared with the existing operation of LOS Unit 1 and Unit 2. Urea supply is believed to be available regionally, with an estimated unit cost assumed to average \$379/ton delivered as a 50% concentration aqueous solution (2006\$). This unit price is volatile, and changes primarily on the basis of the unit cost of natural gas. Consumption of aqueous urea reagent was derived from preliminary numbers included in a late 2004 budgetary proposal by a vendor of urea-based SNCR equipment (Fuel Tech), allowing for a boiler flue gas exit ammonia slip of 5 ppmvd. This estimated urea consumption rate is significantly higher than that predicted by equations published in the EPA Office of Air Quality Planning and Standards (OAQPS) publication EPA/452/B-02-001, Section 4.2, NOx Controls – NOx Post-Combustion, Chapter 1 - Selective Non-Catalytic Oxidation[40].

New electrical loads are required for high flow urea circulation, water dilution, in-line and storage tank heating, and reagent metering equipment. These auxiliary electrical demands and reagent dilution water usage were calculated based upon equations published in the EPA OAQPS SNCR Cost Manual[40]. Compressed air for reagent atomization and lance purging and cooling, as well as multiple nozzle lance water cooling are additional demands on the existing plant facilities. These powerhouse building service supplies were assumed to be available. The new urea reagent injection nozzle lances, reagent pumps, dilution water pumps, and distribution piping/valve trains would add a minor amount of expense to current maintenance requirements, assumed to be 1.5 percent of the installed capital cost.

The O&M costs associated with an SNCR system for LOS Unit 1 and Unit 2 assumes that no additional operating labor is required, as suggested in the EPA OAQPS SNCR Cost Manual[40].

Operation and maintenance costs of the basic and boosted forms of SOFA on LOS Unit 1's boiler, and the advanced version of SOFA on LOS Unit 2, are assumed to be included for SNCR alternatives that include SOFA technology.

A2.2.2.2 RRI O&M Cost Estimates

Operating and maintenance costs for Rich Reagent Injection assumes this technology was combined with the advanced form of SOFA and SNCR for LOS Unit 2. Consumption of the 50% concentration aqueous urea reagent for RRI system operation without including the reagent consumed by the SNCR system was based upon a reagent consumption rate of two times the comparable SNCR urea usage rate for the same uncontrolled NO_X emission conditions and percent NO_X reduction. The estimated aqueous urea consumption for the combined RRI+SNCR systems was determined by simple addition of the usage of the individual technologies, based on their estimated individual performance contributions.

Additions to the new electrical loads assumed for SNCR are required for increased capacity high flow urea circulation, water dilution, in-line and storage tank heating, and reagent metering equipment. These auxiliary electrical demands and reagent dilution water usage were calculated based upon equations published in the EPA OAQPS SNCR Cost Manual[40]. Compressed air for reagent atomization and lance purging and cooling, as well as multiple nozzle lance water cooling are additional demands on the existing plant facilities. These powerhouse building service supplies were assumed to be available. The additional new urea reagent injection nozzle lances, reagent pumps, dilution water pumps, and distribution piping/valve trains would add a minor amount of expense to current maintenance requirements, assumed to be 1.5 percent of the installed capital cost for this alternative.

Similar to SNCR, the O&M costs associated with an RRI+SNCR system for LOS Unit 2 assumes that no additional operating labor is required, as suggested in the EPA OAQPS SNCR Cost Manual[40].

A2.2.4 Summary of O&M Cost Estimates for LOS NO_X Controls

The results of this evaluation for expected operating and maintenance costs for the individual NOx control alternatives are summarized in the main report (Sections 2.4 and 2.5). The expected O&M costs are dependent upon the assumptions involving reductions in unit availability (uptime) and capacity included in Tables A.2-1 through A.2-4. The O&M costs associated with electrical power demands and usage are shown in Tables A.2-5 and A.2-6. The O&M costs for expected NO_X reagent usage are shown in Tables A.2-7 and A.2-8.

TABLE A.2-1 – Expected Availability Reductions for LOS Unit 1 NO_X Controls

Alt. #[1]	NOx Control Technique	Estimated Annual Average Availability[2]	Estimated Annual Average Operating Time, hrs/yr[3]	Estimated Annual Average Outage Time, hrs/yr[4]	Estimated Annual Average Lost Operating Time, hrs/yr[5]
G	Coal Reburn w/ boosted SOFA	0.990	8,672	88	88
F	Coal Reburn w/ basic SOFA	0.990	8,672	88	88
E	SNCR with boosted SOFA	0.990	8,672	88	88
D	SNCR with basic SOFA	0.990	8,672	88	88
C	SNCR with Close-Coupled SOFA	0.990	8,672	88	88
B	Boosted SOFA	1.000	8,760		
A	Separated OFA (basic)	1.000	8,760	0	0

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.

[2] – Baseline availability is assumed at 100.0 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

[3] – Annual operating time is annual availability multiplied by 8760 hrs/yr of possible uptime.

[4] – Annual outage time is 8760 hrs/yr possible operating time minus estimated annual operating time.

[5] – Annual lost operating time resulting from the implementation of the individual NOx control technique is the difference between the baseline and expected annual outage times.

TABLE A.2-2 – Expected Availability Reductions for LOS Unit 2 NO_X Controls

Alt. #[1]	NOx Control Technique	Estimated Annual Average Availability[2]	Estimated Annual Average Operating Time, hrs/yr[3]	Estimated Annual Average Outage Time, hrs/yr[4]	Estimated Annual Average Lost Operating Time, hrs/yr[5]
D	RRI+SNCR w/ ASOFA	0.990	8,672	88	88
C	SNCR w/ ASOFA	0.990	8,672	88	88
B	Coal Reburn w/ ASOFA	0.985	8,629	131	131
A	Advanced SOFA (ASOFA)	1.000	8,760	0	0

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.
[2] – Baseline availability is assumed at 100.0 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.
[3] – Annual operating time is annual availability multiplied by 8760 hrs/yr of possible uptime.
[4] – Annual outage time is 8760 hrs/yr possible operating time minus estimated annual operating time.
[5] – Annual lost operating time resulting from the implementation of the individual NOx control technique is the difference between the baseline and expected annual outage times.

TABLE A.2-3 – Expected Capacity Reductions for LOS Unit 1 NO_X Controls

Alt. #[1]	NOx Control Technique	Estimated Annual Average Running Plant Capacity Factor[2]	Estimated Annual Average Electricity Generation Reduction MW-hrs/yr[3]	Estimated Annual Average Generation Reduction Cost, K$/yr[4]
G	Coal Reburn w/ boosted SOFA	0.995	18,827	715
F	Coal Reburn w/ basic SOFA	0.995	18,827	715
E	SNCR with boosted SOFA	0.999	18,893	718
D	SNCR with basic SOFA	0.999	18,893	718
C	SNCR with Close-Coupled SOFA	0.999	18,893	718
B	Boosted SOFA	1.000	0	0
A	Separated OFA (basic)	1.000	0	0

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.
[2] – Baseline running plant capacity factor is assumed at 100.0 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.
[3] – Annual electricity generation lost is annual lost operating time multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the unit nameplate gross output capacity rating: 216 MW for LOS Unit 1.
[4] – Annual electricity generation lost cost is the annual electricity generation lost (MW-hrs/yr) resulting from the implementation of the individual NOx control technique multiplied by the incremental value of electricity generation, assumed to be $38.00/MW-hr. All cost figures in 2005 dollars.

TABLE A.2-4 – Expected Capacity Reductions for LOS Unit 2 NO_X Controls

Alt. #[1]	NOx Control Technique	Estimated Annual Average Running Plant Capacity Factor[2]	Estimated Annual Average Electricity Generation Reduction MW-hrs/yr[3]	Estimated Annual Average Generation Reduction Cost, K$/yr[4]
D	RRI+SNCR w/ ASOFA	0.999	38,486	1,462
C	SNCR w/ ASOFA	0.999	38,486	1,462
B	Coal Reburn w/ ASOFA	0.995	57,527	2,186
A	Advanced SOFA (ASOFA)	1.000	0	0

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.

[2] – Baseline running plant capacity factor is assumed at 100.0 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

[3] – Annual electricity generation lost is annual lost operating time multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the unit nameplate gross output capacity rating: 440 MW for LOS Unit 2.

[4] – Annual electricity generation lost cost is the annual electricity generation lost (MW-hrs/yr) resulting from the implementation of the individual NOx control technique multiplied by the incremental value of electricity generation, assumed to be $38.00/MW-hr. All cost figures in 2005 dollars.

TABLE A.2-5 – Expected Auxiliary Electrical Power Demand and Usage for LOS Unit 1 NO_X Controls

Alt. #[1]	NOx Control Technique	Estimated Annual Average NOx Equipment Auxiliary Electrical Demand & Usage		
		Total Net Demand[2] kW	Net Generation Reduction kW-hrs/yr[3]	Annual Cost, K$/yr[4]
G	Coal Reburn w/ boosted SOFA	3,900	33,864,255	1,287
F	Coal Reburn w/ basic SOFA	2,220	19,160,595	728
E	SNCR with boosted SOFA	1,713	15,002,180	570
D	SNCR with basic SOFA	37	318,749	12
C	SNCR with Close-Coupled SOFA	49	423,483	16
B	Boosted SOFA	1,680	14,712,420	559
A	Separated OFA (basic)	1	8,760	0.3

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.

[2] – The estimated NOx equipment gross auxiliary electrical power demand of alternatives is the sum of individual technologies combined by simple addition. Actual power demands may differ from this due to positive or negative synergistic effects.

[3] – The estimated annual NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique.

[4] – The estimated annual NOx equipment auxiliary electrical power demand electricity cost is the estimated annual kW-hrs/yr for these alternatives resulting from the implementation of the individual NOx control technique multiplied by the incremental value of auxiliary electricity generation, assumed to be $38.00/MW-hr. All cost figures in 2005 dollars.

TABLE A.2-6 – Expected Auxiliary Electrical Power Demand and Usage for LOS Unit 2 NO_X Controls

		Estimated Annual Average NOx Equipment Auxiliary Electrical Demand & Usage		
Alt. #[1]	**NOx Control Technique**	**Total Net Demand[2] kW**	**Net Generation Reduction kW-hrs/yr[3]**	**Annual Cost, K$/yr[4]**
D	RRI+SNCR w/ ASOFA	285	2,464,270	94
C	SNCR w/ ASOFA	156	1,349,578	51
B	Coal Reburn w/ ASOFA	5,395	46,313,786	1,760
A	Advanced SOFA (ASOFA)	1	8,760	0.3

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.

[2] – The estimated NOx equipment gross auxiliary electrical power demand of alternatives is the sum of individual technologies combined by simple addition. Actual power demands may differ from this due to positive or negative synergistic effects.

[3] – The estimated annual NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique.

[4] – The estimated annual NOx equipment auxiliary electrical power demand electricity cost is the estimated annual kW-hrs/yr for these alternatives resulting from the implementation of the individual NOx control technique multiplied by the incremental value of auxiliary electricity generation, assumed to be $38.00/MW-hr. All cost figures in 2005 dollars.

TABLE A.2-7 – Expected NOx Reagent Usage and Cost Estimates for LOS Unit 1 NO_X Controls

Alt. #[1]	NOx Control Technique	NOx Reduction Reagent Urea Usage (undiluted, as delivered)			NOx Reduction Reagent Dilution Water Usage[3]	
		lbs/hr	tons/yr	$1000/yr	1000 gal/yr	$1000/yr
E	SNCR with boosted SOFA	637	2,764	1,050	2,645	1.1
D	SNCR with basic SOFA	765	3,345	1,270	3,175	1.3
C	SNCR with Close-Coupled SOFA	960	4,199	1,590	3,985	1.6

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.

[2] – Reagent consumption derived from vendor (Fuel Tech) December 2004 proposal for SNCR. Reagent usage for RRI is twice the amount of urea usage for comparable SNCR conditions and percent reduction. All cost figures in 2006 dollars.

[3] – Reagent dilution water usage assumes filtered steam turbine condenser recirculated cooling water is added to create a 10% urea concentration (4 parts water to 1 part aqueous urea at 50% concentration as delivered) prior to injection. Dilution water unit cost assumed to be $0.40 per thousand gallons.

TABLE A.2-8 – Expected NOx Reagent Usage and Cost Estimates for LOS Unit 2 NO_X Controls

Alt. #[1]	NOx Control Technique	NOx Reduction Reagent Urea Usage (undiluted, as delivered)			NOx Reduction Reagent Dilution Water Usage[3]	
		lbs/hr	tons/yr	$1000/yr	1000 gal/yr	$1000/yr
D	RRI+SNCR w/ ASOFA	5,550	24,000	9,100	23,100	9
C	SNCR w/ ASOFA	2,920	12,600	4,800	12,100	5

[1] – Alternative number has been previously assigned from least removal to highest removal percentage.

[2] – Reagent consumption derived from vendor (Fuel Tech) December 2004 proposal for SNCR. Reagent usage for RRI is twice the amount of urea usage for comparable SNCR conditions and percent reduction. All cost figures in 2006 dollars.

[3] – Reagent dilution water usage assumes filtered steam turbine condenser recirculated cooling water is added to create a 10% urea concentration (4 parts water to 1 part aqueous urea at 50% concentration as delivered) prior to injection. Dilution water unit cost assumed to be $0.40 per thousand gallons.

Appendix A.3 - U.S. Cyclone NOx Reduction Projects Summary

SEPARATED OVERFIRE AIR

Cyclone-Fired Boilers

Alliant Energy (formerly Wisconsin Power & Light)
Edgewater Unit 4 Crushed Coal, single-wall cyclone-fired 1969 vintage
330 MW B&W boiler PRB/Illinois Coal blend
Boiler has 7 cyclone burners, arranged "3 over 4" style, on front wall, and fired a blend of 80% western subbituminous (PRB) coal, with 20% Illinois bituminous coal sometimes amended with 3% tire-derived fuel. After cyclone barrel reentrant throat and damper modifications allow firing up 100% PRB coal.
A SOFA system began operation in mid-2001(1), which initially reduced NOx emissions approx. 40-50% reduction from 1.08-1.15 (assume average of 1.10) down to 0.3 to 0.5 lb/mmBtu (assume average of 0.39) with typical cyclone air-staging (cyclone SR not stated but believed to be around 0.90) (2). Subsequent testing and optimized full load SOFA operation at deeper cyclone air-staging (SRs believed to be ≤ 0.90) dropped NO_X to average of 0.27 lb/mmBtu in 2003(2).
Source: (1)EPA Acid Rain Program CAMD June 15, 2005 Technical Support Document.
(2)Alliant/RMT 2003 Technical Paper. Also listed in (3)B&W Sept. 2002 OFA port experience list.

Ameren UE (formerly Union Electric Co.)
Sioux Unit 1 Crushed Coal, opposed-wall cyclone-fired 1969 vintage
500 MW B&W boiler PRB/Illinois Coal blend
Boiler has 10 cyclone burners, arranged "2 over 3" style, on opposite walls, and fires a blend of 85% to 50% western subbituminous (PRB) coal, with Illinois bituminous coal, petroleum coke, and tire-derived fuel. A ten-port OFA system (five ports on each front and rear wall) began operation in mid-2001, which reduced NOx emissions approx. 53% reduction from 1.1-1.3 (assume average of 1.19) down to 0.55 lb/mmBtu with moderate cyclone air-staging (cyclone SR from 1.19 to 1.0) (4). Subsequent testing and full load operation at deeper cyclone air-staging has dropped NO_X with SOFA alone to 0.38 lb/mmBtu in 2002, around 0.3 lb/mmBtu in 2004(4), and as low as 0.20 lb/mmBtu in 2005 (SRs ≤ 0.90)(7).
Source: REI 2002(4), 2003(5), 2004(6), 2005(7) Technical Papers.

Ameren UE (formerly owned by Central Illinois Public Service)
Coffeen Unit 1 Crushed Coal, opposed-wall cyclone-fired 1965 vintage
600 MW B&W boiler Illinois Coal (midwestern bituminous)
Unit 2 boiler has 14 cyclone burners, arranged "3 over 4" style, on front and rear walls.
SOFA system began operation in early-2000; average annual NOx emissions approx. 1.03 lb/mmBtu down 27% to 0.75 lb/mmBtu average(1).
Source: EPA Acid Rain Program CAMD June 15, 2005 Technical Support Document(1). Also listed in B&W Sept. 2002 OFA port experience list(3).

Dominion Resources (formerly owned by Commonwealth Edison)
Kincaid Units 1 and 2 Crushed Coal, opposed-wall cyclone-fired 1967, 1968 vintage
660 MW B&W boilers PRB Coal
Boilers have 14 cyclone burners, arranged "3 over 4" style, on front and rear walls.
SOFA systems with 11 ports each began operation in mid-2000; avg. 1999 annual NOx emissions approx. 0.91 and 0.94 lb/mmBtu, decreasing 27% in 2001 to 0.66 and 0.69 lb/mmBtu avg (respectively)(1).
Source: EPA Acid Rain Program CAMD June 15, 2005 Technical Support Document(1). Also listed in B&W Sept. 2002 OFA port experience list(3).

Tennessee Valley Authority (TVA) Crushed Coal, cyclone-fired, 1959 vintage
Allen Station Units 2 & 3 (TN) (seven cyclones)
300 MW B&W boilers PRB & western bituminous coal blend
GE-EER Overfire air (duplicate of Allen 1), 1999 startup
GE-EER claimed to lower NOx with OFA alone up to 29% from baseline 1.20 lb/mmBtu to 0.85 lb/mmBtu on Units #2 and 3 at full load(8).
Source: GE-EER Sept. 2005 experience list(8).

TABLE A.3-1 – Cyclone-Fired Boiler Overfire Air Retrofit Installations(1)

Facility Name	Installation Date	Comments
Allen Station Unit 2	Installed 1999*	Similar to Unit 1, w/o CGR) have SCR
Allen Station Unit 3	Installed 1999*	Similar to Unit 1, w/o CGR) have SCR
Asbury Unit 1	Installed 5/10/1999	Empire District, BART-eligible
Bailly Unit 7	Installed 2003(9)	SCR to be installed in 2006-7
Bailly Unit 8	Installed 5/31/2000	SCR retrofit 5/11/2004
Baldwin Unit 1	Installed 12/31/1999	SCR retrofit 4/28/2003
Baldwin Unit 2	Installed 5/8/2000	SCR retrofit 4/12/2002
Big Stone Unit 1	Installed 10/22/1997	part of conversion to PRB
BL England Unit 2	Installed 1998*	previous SNCR retrofit in 1996
Coffeen Unit 1	Installed 2/1/2001	SCR retrofit 4/21/2003
Coffeen Unit 2	Installed 2/9/2000	SCR retrofit 4/09/2002
Edgewater Unit 3	Installed 11/2001(9)	
Edgewater Unit 4	Installed 6/19/2001	
Joliet 9 Unit 6	Installed 2000(9)	
Kincaid Unit 1	Installed 4/28/2000	SCR retrofit 12/17/2002
Kincaid Unit 2	Installed 5/24/2000	SCR retrofit 6/07/2002
Allen S. King Unit 1	Installed 11/30/1999	
LaCygne Unit 1	Installed 2/28/2000	
Lake Road Unit 6	Installed 6/01/2002	
Michigan City Unit 12	Installed 4/1998(9)	SCR retrofit 5/01/2003
Nelson Dewey Unit 1	Installed 2002(9)	
Nelson Dewey Unit 2	Installed 2002(9)	
Paradise Unit 1	Installed 11/14/1998	SCR retrofit 5/01/2001
Paradise Unit 2	Installed 12/8/1999	SCR retrofit 5/01/2000
Paradise Unit 3	Installed 5/4/2000	SCR retrofit 3/10/2004
Powerton Unit 5-1	Installed 6/1/2003	
Powerton Unit 5-2	Installed 6/1/2003	
Powerton Unit 6-1	Installed 6/1/2002	
Powerton Unit 6-2	Installed 5/4/1999	
Schahfer Unit 14	Installed early 2000(9)	SCR retrofit 5/11/2004
Sibley Unit 2	Installed 5/24/2002	
Sibley Unit 3	Installed 5/4/1999	
Sioux Unit 1	Installed 4/30/2001	SNCR demo May 2005
Sioux Unit 2	Installed 4/30/1997	
State Line Unit 4	Installed 11/2001(9)	Similar to Joliet 9 Unit 6
Tanners Creek Unit 4	Installed 5/12/2002	
Thomas Hill Unit 1	Installed June 2004(9)	
Thomas Hill Unit 2	Installed November 2000(9)	

Note: This table does not include every installed U.S. coal-fired cyclone boiler OFA retrofit project.

TABLE A.3-2 – Cyclone-Fired Boiler Reburn Overfire Air Retrofit Installations(1)

Facility Name	Installation Date	Comments
Allen Station Unit 1	Installed 1998*	OFA w/ CGR retrofit; has SCR
CP Crane Unit 1*	Installed 1999	OFA w/ CGR retrofit
CP Crane Unit 2	Installed 2/1/1999	OFA w/ CGR retrofit
Lakeside Unit 7†	Installed 1992*	OFA w/ CGR retrofit; DOE-NETL
Kodak Park #15 Boiler†	Installed 1997*	OFA w/ micronized coal retrofit; DOE-NETL
Kodak Park #43 Boiler	Installed 1995	OFA w/ CGR retrofit
Kodak Park #41 Boiler	Installed 1998	OFA w/ CGR retrofit
Kodak Park #42 Boiler	Installed 1998	OFA w/ CGR retrofit
Nelson Dewey Unit 2†	Installed 1991	OFA w/ pulverized coal reburn; DOE-NETL

Note: This table does not include every installed U.S. coal-fired cyclone boiler OFA retrofit project for reburn.

Source: (1) US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005 (except as noted below)

* Vendor experience list (GE Energy for Allen Station Units 1-3; RJM for BL England Unit 2)

† U.S. Department of Energy National Energy Technology Laboratory Clean Coal Technology Demonstration Program project (not commercially available at time of implementation)(11)

REBURN – GAS, CONVENTIONAL

Cyclone-Fired Boilers

Constellation Energy (formerly Baltimore Gas & Electric)
C.P. Crane Station, Units 1 & 2 (MD) Crushed Coal, cyclone-fired, eastern bituminous coal
2 x 200 MW B&W boilers (four cyclones each) 1961, 1963 vintage
GE-EER Conventional Gas Reburn, 1999 startup
Added gas supply piping, metering, hangers, supports; reburn injectors and cooling air ductwork, OFA ductwork, injection nozzles and wall ports, field (assume eastern bituminous coal)
GE-EER claimed Gas Reburn with OFA lowered NOx between 60% and 65% from baselines of 1.50 lb/mmBtu to between 0.60 and 0.52 lb/mmBtu, at full load with reburn operation(8). No claims of percent reburn fuel or percent OFA included in GE-EER's experience list.
Another technical paper showed this installation of CGR operated with 25 percent reburn fuel(11).
Source: Sept. 2005 GE-EER experience list(8); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

City Water, Light & Power
Lakeside Unit 7 Crushed Coal, front-wall cyclone-fired, midwestern bituminous coal
300,000 lb/hr steam B&W boiler (approx. 33 MWe equivalent, two cyclones) 1961 vintage
Springfield, IL DOE Clean Coal demonstration project (included sorbent injection)
GE-EER conventional gas reburn w/ OFA 1992 startup (CGR not currently operating)
Vendor claimed to lower NOx by 66% from 0.95 lb/mmBtu baseline to 0.32 lb/mmBtu(8). A GE-EER 2004 technical paper showed 25% reburn fuel yielded minimum NOx emissions(11).
A DOE NETL technical paper showed this demonstration of CGR from 5/93-10/94 (assume with OFA) with 23 percent reburn fuel reduced NOx 60% from 0.97 to 0.39 lb/mmBtu (10).
Source: Sept. 2005 GE-EER experience list(8); GE-EER 2004 Technical paper(11); DOE-NETL 2004 Reburn Conference Technical paper(10).

Eastman Kodak Company
Kodak Park Boilers 41 & 42 Crushed Coal, front-wall cyclone-fired, 1964 & 1966 vintage
400,000 lb/hr steam B&W boilers (approx. 50 MWe equivalent, two 8-ft dia. cyclones)
Rochester, NY eastern bituminous coal
B&W conventional gas reburn w/ OFA December 1998, July 1998 startups (still operating)
Commercial installation of CGR, with (1) gas burner added to each sidewall + (2) large and (2) small OFA ports added to front wall above cyclones, utilizing higher reburn gas pressure (vs. Boiler #43) requires no flue gas recirculation; {Very small furnace w/ cyclone SR believed not <1.0}.
B&W claimed reburn with OFA lowered NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu.
B&W graph shows 10-12% percent reburn fuel to achieve 0.6 lb/mmBtu and 23-24% reburn gas input to reach 0.33 lb/mmBtu NOx (73% reduction) (12).
Another technical paper showed NOx lowered by 52% from 1.25 lb/mmBtu baseline to 0.60 lb/mmBtu with 18 percent reburn fuel(10).
Source: B&W Technical Paper(12); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

REBURN – GAS, CONVENTIONAL, continued

Cyclone-Fired Boilers

Eastman Kodak Company
Kodak Park Boiler 43 Crushed Coal, front-wall cyclone-fired 1968 vintage
600,000 lb/hr steam B&W boiler (approx. 60 MWe equivalent, two cyclones)
Rochester, NY eastern bituminous coal

B&W conventional gas reburn 1995 startup (still operating)

Commercial installation of CGR, with flue gas recirculation (FGR) for injection mass momentum w/ (1) FGR fan; (1) gas burner added to each sidewall + (2) OFA ports added front wall above cyclones. {Very small furnace/low residence time w/ cyclone SR believed not <1.0}

B&W claimed reburn with OFA & FGR lowered NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. B&W graph shows 18% percent reburn fuel to achieve 0.6 lb/mmBtu and 29% reburn gas input to reach 0.36 lb/mmBtu NOx (70% reduction)(12).

Another technical paper showed NOx lowered by 56% from 1.35 lb/mmBtu baseline to 0.60 lb/mmBtu with 18 percent reburn fuel(10).

Source: 2004 B&W Technical Paper(12); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference)(10).

Tennessee Valley Authority (TVA)
Allen Station Unit 1 (TN) Crushed Coal, cyclone-fired (seven cyclones) 1959 vintage
300 MW B&W boiler PRB &western bituminous coal blend fired
GE-EER Conventional Gas Reburn, 1998 startup

Commercial installation added gas supply piping, metering, hangers, supports; reburn injectors and cooling air piping, OFA ductwork, injection nozzles and wall ports, field I&C devices.

Reburn with OFA claimed to lower NOx 65% from baseline 1.20 lb/mmBtu to 0.42 lb/mmBtu) at full load with reburn operation. No claims of percent reburn fuel included. (TVA also installed duplicate OFA systems on Allen Units 2 & 3 boilers)(8).

Another technical paper showed NOx lowered by 65% from 0.86 lb/mmBtu baseline (to 0.30 lb/mmBtu) with 7 percent reburn fuel(11).

Source: Sept. 2005 GE-EER experience list(8); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference)(10).

REBURN – COAL, CONVENTIONAL

Cyclone-Fired Boilers

Alliant Energy (formerly Wisconsin Power & Light)
Nelson Dewey Station Unit 2 Crushed Coal, cyclone-fired, PRB coal 1962 vintage
110 MW B&W boiler 3-cyclones across front wall, 4 reburn burners +
4 OFA ports across rear wall, aligned vertically in columns.

US DOE Clean Coal Demonstration project of B&W's Conventional Coal Reburn, 1991 startup (since discontinued) added coal supply piping, reburn burners with flue gas recirculation, OFA ductwork + dual zone ports; coal feeder, pulverizer & PA fan, tested with PRB and bituminous coals. (western subbituminous coal)

B&W claimed reburn operation lowered NOx by 57% from baseline of 0.83 mmBtu to 0.38 lb/mmBtu at full load(13). Approx. 30% percent of total fuel input supplied as reburn fuel. Increased unit output by 10 MW, increased flyash unburned carbon by 4% (13-22% vs 9-18%), decreased furnace exit gas temperature (FEGT). OFA ports listed in B&W experience list(3).

B&W shows full load NOx w/o reburn was 0.75 lb/mmBtu, and 0.29-0.32 lb/mmBtu w/ PRB fuel during reburn operation (57% decrease). At 75% load, 0.64 vs 0.29-0.32 lb/mmBtu. At 55% load, 0.62 vs 0.29-0.31 lb/mmBtu without and with reburn activated(13).

Another technical paper showed NOx lowered by 52-55% from 0.82 lb/mmBtu baseline (to 0.39-0.34 lb/mmBtu) with 25-30 percent reburn fuel(11).

Source: 2004 B&W Technical Paper(12); DOE-NETL 2004 Reburn Conference Technical paper(11); B&W case history (from website, dated 1997)(13).

REBURN – COAL, MICRONIZED, CONVENTIONAL

Cyclone-Fired Boilers

Eastman Kodak Company
Kodak Park #15 Boiler Crushed Coal, front-wall cyclone-fired, 1956 vintage
400,000 lb/hr steam B&W boiler (approx. 50 MWe equivalent, two cyclones)
Rochester, NY eastern bituminous coal
GE-EER micronized coal reburn1996 initial startup (operating since 1997)

Demonstration project performed with Dept. of Energy's US Clean Coal Technology Program. Project added flue gas recirculation for injection mass momentum, FGR fan and two micronized coal pulverizers; (6) reburn coal injectors added to rear wall + (1) reburn coal injector on each of the sidewalls, with (4) OFA ports added across front wall above cyclones(15). GE-EER designed and fabricated the coal injectors and OFA ports. {Extremely small furnace and low residence time}.

GE-EER claimed reburn + OFA w/ FGR reduced NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. No claims of percent reburn fuel included(8).

Another technical paper showed this demonstration of micronized coal reburn from 4/97-10/98 lowered NOx by 57% from 1.36 lb/mmBtu baseline (to 0.59 lb/mmBtu) with 17 percent reburn fuel(11).

Source: DOE Topical Report Number 14 (May 1999) (14); GE-EER experience list(8); DOE-NETL 2004 Reburn Conference Technical paper(10).

REBURN – FUEL LEAN GAS REBURN

Cyclone-Fired Boilers

Midwest Generation (formerly Commonwealth Edison)
Joliet Station 9, Unit 6 Crushed Coal, opposed-wall cyclone-fired (nine cyclones)
340 MW B&W boiler 1959 vintage, 1997 startup (FLGR has since been decommissioned)

Energy Systems Associates demonstrated 25-30% NOx reduction using 5-10% of total heat input as reburn natural gas injected (without OFA)(10).

Another technical paper showed this demonstration in collaboration with Gas Research Institute of FLGR lowered NOx by 28-43% from 1.36 lb/mmBtu baseline (to 0.59 lb/mmBtu) with 7 percent reburn fuel(15).

Source: DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10);
NGB Technologies Technical Paper (15).

REBURN – FUEL LEAN GAS REBURN w/ SNCR

Cyclone-Fired Boilers

Owensboro Municipal Utilities (KY) Crushed Coal, front-wall cyclone-fired
Elmer Smith Unit 1 (three cyclones) 1965 vintage
150 MW B&W boiler

CFD model study only predicted NOx reductions from 1.59 to 0.39 lb/mmBtu with OFA only (75% reduction, 0.90 SR); 25-30% NOx reduction using 6% of total heat input as reburn natural gas injected above OFA; 40-45% NOx reduction from SNCR with <5 ppm ammonia slip(16).

Source: REI 2001Technical paper(16).

SELECTIVE NON-CATALYTIC REDUCTION/ RICH REAGENT INJECTION

Cyclone-Fired Boilers

Conectiv (formerly Atlantic Electric)
BL England Unit 1 Crushed Coal, single-wall cyclone-fired 1962 vintage
138 MW B&W boiler aqueous urea SNCR, 1995 startup eastern bituminous coal
Boiler has only 3 cyclone burners, arranged “1 over 2” style.

RJM implemented commercial Fuel Tech urea-based SNCR system installation in 1995 after short-term (3-month demonstration test) in 1993-1994. 31 % NOx reduction claimed, from 1.31 lb/mmBtu NOx baseline[1] for SNCR only; RJM claimed 35% reduction from 1.31 lb/mmBtu down to 0.85 lb/mmBtu (without overfire air) with urea-to-NOx NSR = 0.85 [17].

Added eight temporary RRI ports (three nozzles on each lower sidewall, and two nozzles on the upper rear wall, and performed one month demonstration parametric testing of overfire air only (without SNCR or RRI), at 120 MW nominal boiler load and cyclone S.R. = 0.90 in 1999. REI claimed 55% NOx reduction from a 1.2 lb/mmBtu uncontrolled NOx baseline to 0.55 lb/mmBtu with OFA only, with stack CO emissions below 50 ppm. For Rich Reagent Injection; REI claimed 25-30% NOx reduction for RRI down to 0.38 lb/mmBtu from controlled baseline w/ OFA alone of 0.55 lb/mmBtu NOx and a RRI urea-to-NOx NSR = 2; also showed RRI+SNCR w/ OFA reduced NOx 55% to 0.25 lb/mmBtu (34% beyond RRI w/ OFA), for an overall 79% NOx reduction with a SNCR urea-to-NOx NSR = 1. Measured less than 1 ppm ammonia slip during RRI testing, < 5 ppm slip for RRI + SNCR. No significant increase in CO emissions during RRI testing[18].
Source: RJM experience list[17]; 2001 REI Technical Paper[18];
(Also listed in ICAC SNCR 2000 White Paper[19]).

Conectiv (formerly Atlantic Electric)

BL England Unit 2	Crushed Coal, cyclone-fired, single-wall-fired	1964 vintage
160 MW B&W boiler	SNCR, 1996 startup eastern bituminous coal	

RJM implemented commercial Fuel Tech urea-based SNCR system in 1996, claimed 36% reduction from 1.36 lb/mmBtu down to 0.85 lb/mmBtu, urea-to-NOx NSR = 0.85 (without overfire air) [17].
An OFA system was added in 1998, resulting in NOx emissions of 0.33 lb/mmBtu, for an overall NOx reduction of 76%[17].
Source: RJM experience list[17]. (Also listed in ICAC SNCR 2000 White Paper[19]).

AmerenUE (formerly Union Electric Co.)

Sioux Unit 1	Crushed Coal, opposed-wall cyclone-fired	1969 vintage
500 MW B&W boiler	Rich Reagent Injection demonstration testing in 2001	

Boiler has 10 cyclone burners, arranged “2 over 3” style, on opposite walls, and fires a blend of 85% to 50% western subbituminous (PRB) coal, with Illinois bituminous coal, petroleum coke, and tire-derived fuel.

Installed twenty temporary RRI ports (six nozzles on each lower sidewall, and four nozzles on each front and rear wall), and performed one month demonstration parametric testing of overfire air only and initial testing with RRI in August 2001, followed by additional testing in March 2002, and the second quarter of 2004. Added 8 RRI ports (1 in each sidewall, 4 in each front and rear wall) and 14 SNCR ports (5 on upper front wall, 9 on upper rear wall) to the furnace in early 2005, followed by three weeks of parametric testing and 3 days of continuous testing of RRI with SNCR and deeper-staged OFA.
Tested in August 2001 at lower furnace SR approx.=1.0, 0.55 lb/mmBtu w/ OFA only, only 15% NOx reduction w/ RRI, zero ammonia slip[4].
Tested in March 2002 at lower furnace SR approx.=0.95, from 0.38 lb/mmBtu baseline w/ OFA only, achieved 29% NOx reduction w/ RRI down to 0.27 lb/mmBtu, NSR=3, zero ammonia slip[4].
(assume blend of PRB and Illinois bituminous coal w/ tire-derived fuel and petroleum coke)[4].
Operation in the second quarter 2004 showed actual stack NOx averaged around of 0.30 lb/mmBtu with OFA only and lower furnace at a cyclone SR around 0.88 burning a 85% PRB, 15% Illinois #6 bituminous coal blend, presumably at 440 MW. This is a 75% NOx reduction from a 1.19 lb/mmBtu pre-control baseline. REI using CFD modeling predicted NOx down to 0.18 lb/mmBtu with RRI+OFA, and below 0.15 with RRI+SNCR under similar deep cyclone air-staging (1.19 to 0.28 lb/mmBtu is 76% reduction, 0.18 vs 0.28 is an additional 36% reduction w/ RRI, and 0.14 vs 0.28 is a 50% reduction w/ RRI+SNCR, for an overall reduction of 88%)[5,6].

Tested in May 2005 at 480 MWg with lower furnace SR approx. = 0.85-0.88, 76-83% reduction from 1.2 lb/mmBtu baseline down to as low as 0.20 lb/mmBtu w/ SOFA only firing 80% PRB, 20% Illinois #6 bituminous coal blend; additional 15-39% NOx reduction w/ RRI, to as low as 0.15 lb/mmBtu from 0.20-0.28 lb/mmBtu baseline w/ SOFA only at urea NSR varied between 1 and 4, with one ppm ammonia slip; achieved additional NOx reduction w/ RRI +SNCR down to 0.12 lb/mmBtu, NSR=4, ammonia slip10 ppm or less. RRI+SNCR w/ SOFA NOx reduction percentage varied from 15% to 50% below SOFA-only levels, with NSRs between 1 and 4.5. SNCR alone had 13% (NSR=1) to 32% (NSR=1) NOx reduction with ammonia slip around 1-2 ppm (7).
Source: REI 2002(4) and 2003(5) Technical Papers; REI 2004(6) Technical paper; REI 2005(7) Technical paper.

Coal burning cyclone-fired utility boilers in the United States that have been retrofitted with SCR technology are listed in Table A.3-3. This list includes at least eight cyclone-fired boilers burning western subbituminous coal (or PRB blended with midwestern bituminous coal). The highest emission reductions listed in Table A.3-3 for SCR systems are for clean reactor catalyst and ideal operating conditions.

TABLE A.3-3 – Cyclone-Fired Boiler High-Dust SCR Installations

[1] – original design fuel for all listed cyclone boilers was bituminous coal

[2] – Generator nameplate rating, March 2002 Energy Information Administration report DOE/EIA-0095(2000). Actual unit MW output rating may be higher or lower than nameplate.

[3] – Burns & McDonnell internal database.

[4] – as reported to US EPA, available from their website at http://cfpub.epa.gov/gdm/index.cfm

[5] – includes application of separated overfire air for combustion NO_X control

[6] – current fuel believed to be a blend of subbituminous and bituminous coals

[7] – NAD = no published data from SCR emission testing found on these units.

[8] – original air preheaters were tubular-type; changed to rotary-type during SCR retrofit

[9] – Design NO_X removal efficiency is higher, approx. 90%.

[10] – current fuel believed to be subbituminous coal

For Merrimack Unit 1's SCR, inlet (i.e. uncontrolled) NO_X was 1.34 lb/mmBtu, for a blend of high sulfur bituminous and medium or low sulfur bituminous coals, and requires year-round SCR operation for compliance. The catalyst was designed for 88.9% NO_X removal efficiency and 5 ppm ammonia slip. SCR commercial service date July 20, 1999(20).
Source: Babcock Borsig Power 2000 technical paper on SCRs(20).

For Merrimack Unit 2's SCR, inlet (i.e. uncontrolled) NO_X was 2.66 lb/mmBtu, for a blend of high sulfur bituminous and medium or low sulfur bituminous coals, and requires year-round SCR operation for compliance. Initial testing demonstrated 70% removal(21), which exceeded the 65% requirement to

achieve a 0.92 lb/mmBtu permit limit. The catalyst was designed for 85-95% NO_X removal efficiency and 5 ppm ammonia slip(22).

[1] – Burns & McDonnell internal database.

[2] – Current fuel is eastern or midwestern bituminous coal, except Havana

[3] – US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005, except where noted. Dates in () are believed to be accurate but have not been confirmed.

[4] – The three values are "Pre-control average", "2004 annual average", and "2003 ozone season average" NO_X emission rates, as reported to US EPA. Pre-control and year 2004 annual average data as shown in US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005, posted on their website: http://docket.epa.gov/edkpub/do/EDKStaffItemDetailView?objectId=090007d48084562b. Values shown in parentheses are year 2003 annual average where 2004 data is not available. Year 2003 and 2003 ozone season data is available from the EPA's website at http://cfpub.epa.gov/gdm/index.cfm, includes application of separated overfire air for combustion NO_X control where applicable.

[5] – Generator nameplate rating, March 2002 Energy Information Administration report DOE/EIA-0095(2000). Actual unit MW output rating may be higher or lower than nameplate.

[6] – This boiler has low-NOx burners for combustion controls.

[7] – Carolina Power & Light plants listed here have two boilers per unit, total nameplate for Mayo is 736 MW, Roxboro is 745 MW; emission numbers are the average of both boilers.

[8] – This boiler has low-NOx burners and overfire air for combustion controls.

[9] – This is preliminary data reported to the US EPA for 2004 ozone season average emission rate.

[10] – This boiler's current fuel is believed to be subbituminous coal.

[11] – Mercer boilers listed have low-dust SCR with flue gas reheat. Unit size is approximate, not nameplate.

N/A = complete 2004 ozone season data is not available, and 2003 ozone season data is not representative of the post-SCR installation emission rate.

LOW NO_x BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR

Pulverized coal-fired boilers

AEP Cardinal Unit 1 Pulverized Coal cell-burner, opposed wall-fired B&W boiler
600 MW (nominal) 1967 vintage; Low NO_x burners installed in October 1998
Produced 0.75 lb/mmBtu NOx post-LNB install baseline at full load.
LNBs reduced NO_X 57% from 1.20 down to 0.52(24), produce NO_X at approx. 0.57 lb/mmBtu at min. load w/o SNCR (range 0.51 to 0.65) and produce 0.75 lb/mmBtu NO_X at approx. 585 MW (top of load range tested, NO_X range 0.73 to 0.86 lb/mmBtu) (25).
(50) original B&W circular burners were recently replaced on Cardinal Units 2 & 3 by Buckeye Power with DB Riley (now Babcock Power) CCV type low NOx burners.
Source: Riley Power (Babcock Power Inc.) 8/16/04 experience list(24); 2000 Fuel Tech technical paper(25).
(Also see SNCR installation summaries for pulverized coal boilers).

Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 startup
Low NO_X burners were previously retrofitted in 1997 without separated overfire air(1). NOx reduction was 46% from pre-LNB installation baseline of 1.08 lb/mmBtu (1) down to 0.58 lb./mmBtu (26).
(Also see SNCR, and FLGR with SNCR installation summaries for pulverized coal boilers).
Source: 2005 US EPA Docket OAR-2002-0076-0446 Technical Support Document spreadsheet(1);
CP&L and Fuel Tech 2001 Technical paper(26).

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 5 1956 vintage; eastern bituminous coal
154 MW CE boiler ROFA startup in 2000
Mobotec USA's Rotating Opposed Fire Air (ROFA) is a high velocity boosted separated overfire air system claimed to lower NO_X without retrofitting low-NOx burners. This was the first U.S. installation of Mobotec USA's "Rotating Opposed Fire Air" (ROFA) on a utility boiler, which utilizes a booster fan.
CP&L technical paper claimed to lower NO_X 53% from full-load pre-ROFA baseline 0.60 lb/mmBtu to 0.28 lb/mmBtu with ROFA alone following the installation of ROFA in 2000(27).
Source: CP&L 2002 Technical paper(27).
(Also see SNCR installation summaries for pulverized coal boilers).

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 6 twin-furnace (eight corner), 1958 vintage; eastern bituminous coal
175 MW CE boiler ROFA startup in 2001
This unit's "ROFA" system was installed as part of a "Rotamix" SNCR + ROFA system.
CP&L technical paper shows ROFA alone reduced NOx 57% from full-load pre-ROFA baseline 0.54 lb/mmBtu to a NO_X emission rate of 0.23 lb/mmBtu. (27)
Source: CP&L 2002 Technical paper(27).
(Also see SNCR installation summaries for pulverized coal boilers).

Conectiv (formerly Delmarva Power & Light)
Indian River Units 3 & 4 (Millsboro, DE) Unit 3 is front wall-fired, 1974 vintage
178MW and 440 MW Unit 4 is turbo-fired opposed-wall, 1980 vintage
B&W, DB Riley boilers eastern bituminous coal
REI performed CFD modeling on both units for potential SNCR application.
Unit 3 has Riley Low NOx burners (16), (8) front wall and (8) rear wall OFA ports, (8) wall boundary air ports, (66) side wall OFA slots, claimed baseline NOx around 0.37 lb/mmBtu w/o SNCR (28).

Unit 4 has (24) front and rear wall down-fired burners, (28) front and rear wall SOFA ports, claimed NOx around 0.44 lb/mmBtu w/o SNCR (28) {furnace has "Mae West" belt}.
Riley provided 16 CCV low-NOx burners for Unit 3 in 1994, and claimed to reduce NOx emissions by 67% from pre-LNB baseline of 1.05 lb/mmBtu down to 0.34 lb/mmBtu(24).
Source: REI 1999 Technical Paper(28); Riley Power (Babcock Power Inc.) 8/16/04 experience list(24).
(Also see SNCR installation summaries for pulverized coal boilers).

LOW NO$_x$ BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued
Pulverized coal-fired boilers

Dayton Power & Light — Pulverized Coal, Tangentially-fired
Killen Station, Unit 2 — 1955 vintage
632 MW — CE boiler, bituminous Illinois coal
GE-EER provided low-NOx burners in 1999. Vendor claimed full load NO_X was reduced by 23% from a 0.57 lb/mmBtu baseline down to 0.44 lb/mmBtu(8).
Source: GE Energy (formerly GE-EER) experience list September 29, 2005(8).
(Also see low-dust SCR installation list for pulverized coal boilers)

Dynegy Midwest Generation (formerly Illinois Power) — Pulverized Coal, wall-fired
Havana Station, Unit 6 — 1978 vintage
460 MW — B&W boiler, bituminous Illinois coal
GE-EER provided modifications to the original B&W dual-register burners, and an OFA system in 2000. Vendor claimed full load NO_X was unchanged from 0.38 lb/mmBtu baseline(8).
Source: GE Energy (formerly GE-EER) experience list September 29, 2005(8). (Also see low-dust SCR installation list for pulverized coal boilers)

Dynegy Midwest Generation (formerly Illinois Power) — Pulverized Coal, Tangentially-fired
Vermillion Station, Unit 1 — 1955 vintage
82 MW — CE boiler, bituminous Illinois coal
This rotating opposed fire air (Mobotec USA ROFA) system was installed in July 2002, as part of a "Rotamix" SNCR + ROFA system, without low-NOx burners.
Mobotec 2004 technical paper claimed to lower full load NO_X by 62% from 0.58 lb/mmBtu baseline to 0.22 lb/mmBtu in July 2002 (without LNB or SNCR). (29)
Source: Mobotec 2004 technical paper(29).
(Also see SNCR installation summaries for pulverized coal boilers).

Georgia Power — Pulverized coal, opposed wall-fired,
Harlee Branch Unit 1 — 250 MW B&W boiler, 1965 vintage — 2003 startup
Harlee Branch Unit 2 — 359 MW Riley boiler, 1967 vintage — 1998 startup
B&W provided 24 DRB-4Z low NOx burners for Unit 1 B&W boiler, 24 DRB-XCL low NOx burners for Unit 2 Riley boiler(3) (believe southeast coast lignite is primary fuel).
Source: B&W's experience list(3). No NOx reduction claims.

Kansas City Power & Light — Pulverized coal, opposed wall-fired, 600 MW B&W boiler
Hawthorn Unit 5 — 30 burners, 2001 vintage, (Powder River Basin coal)
B&W provided 30 DRB-4Z low NOx burners and 11 OFA ports with the new boiler(3).
Source: B&W's experience list(3). No NOx reduction claims.

LOW NO$_x$ BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued

Pulverized coal-fired boilers

New England Power Company (NEPCO)
Salem Harbor Station Pulverized Coal, front wall-fired,
Units 1, 2 & 3 1952, 1952, 1958 vintage (eastern bit. coal)
84 MWe x 2, & 156 MWe B&W boilers LNBs startup in 1995, 1995, and 1993
Riley claimed Unit 1 LNBs reduced NOx emissions by 57% from baseline of 1.10 lb/mmBtu down to 0.42 lb/mmBtu; Unit 2's LNBs achieved 42% NOx reduction from a baseline of 0.95 lb/mmBtu down to 0.55 lb/mmBtu; Unit 3's LNBs achieved 60% NOx reduction from a baseline of 1.05 lb/mmBtu down to 0.42 lb/mmBtu$^{(24)}$.
Source: Riley Power (Babcock Power Inc.) 8/16/04 experience list$^{(24)}$.
(Also see SNCR installation summaries for pulverized coal boilers).

Northeast Utilities (formerly Public Service of New Hampshire)
Shiller Station Pulverized Coal/#6 Fuel oil, front-wall-fired
Units 4, 5, & 6 1952, 1955, 1957 vintage
50 MWe x 3 Foster Wheeler boilers
RJM provided (6) Low NO$_x$ burner modifications per boiler in 1994, 1992, & 1994 respectively; LNBs reduced NOx 43% from 0.85 to 0.48, 50% from 1.0 to 0.50, and 51% from 0.82 to 0.40 lb/mmBtu$^{(17)}$.
Source: RJM experience list September 3, 2004$^{(17)}$

Potomac Electric Power (formerly West Pennsylvania Power)
Chalk Point Station Pulverized Coal opposed wall-fired
Units 1 & 2 1964, 1965 vintage eastern bituminous coal
360 MW (nominal) B&W boilers
DB Riley (now Babcock Power) CCV type low NOx burners retrofitted in 1993 and 1994, respectively. Vendor claimed to lower NOx up to 52% and 50% from 1.35 and 1.40 lb/mmBtu baselines (to 0.65 and 0.70 lb/mmBtu$^{(24)}$, assumed at full load).
Source: Riley Power (Babcock Power Inc.) 8/16/04 experience list$^{(24)}$.
(Also see Conventional Gas Reburn installation summaries for pulverized coal boilers).

Xcel Energy (formerly Public Service Company of Colorado)
Cherokee Unit 3 Pulverized coal, wall-fired, B&W boiler, 16 burners, 1962 vintage
175 MW October 1992 baseline testing started (western bituminous coal)
Installed (16) Foster Wheeler Controlled Flow/Split Flame low NO$_x$ replacement burners as part of a DOE Clean Coal Technology gas reburn demonstration performed with Gas Research Institute 1992-1995.
Uncontrolled NOx w/ original B&W flare-type burners was 0.73 lb/mmBtu. Replacement LNBs (assuming OFA included) reduced NO$_X$ 37% to 0.46 lb/mmBtu$^{(30)}$.
Source: DOE NETL 2001 Technical paper$^{(30)}$.

REBURN – GAS, CONVENTIONAL

Pulverized coal-fired boilers

Allegheny Power (formerly West Pennsylvania Power) Pulverized Coal, opposed wall-fired
Hatfield's Ferry Station cell-burner, 1969 & 1972 vintage
Units 2 & 3, 600 MW (nominal) each (B&W boilers) eastern bituminous coal
GE-EER Gas Reburn; 1999 startup (Unit 2) & 2003 (Unit 3)
GE-EER Low NOx burners, boosted OFA, gas reburn system.

GE-EER claimed to lower NOx up to 67% from baseline of 0.60 lb/mmBtu to 0.20 lb/mmBtu at full load with reburn operation on Unit 2, 68% from 0.62 lb/mmBtu to 0.20 lb/mmBtu on Unit 3. No claims of percent reburn fuel included(8).
GE-EER technical paper shows approx. 35% NOx reduction at 600 MW load with LNB + OFA w/o reburn fuel, and an additional 50% reduction to 0.20 lb/mmBtu with reburn fuel(31).
B&W added 20 OFA ports in 1994 per B&W's experience list. No NOx reduction claims.(3)
Source: Sept. 2005 GE-EER experience list(8); GE-EER 2004 Technical paper(31). Unit 2 and Unit 3 listed in (10) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Conectiv (formerly Delmarva Power & Light)   Pulverized Coal, Tangentially-fired
Edgemoor Unit 4   1966 vintage, eastern bituminous coal
160 MW CE boiler   1999 startup
GE-EER Gas Reburn project added gas supply piping, metering, hangers, supports, reburn injectors and cooling air piping; OFA ductwork, injection nozzles and wall ports, field instrumentation. No FGR or OFA booster fans.
Vendor claimed to lower NOx up to 48% from baseline of 0.32 lb/mmBtu to 0.16 lb/mmBtu) at full load with reburn operation. No claims of percent reburn fuel included(8).
GE-EER technical paper shows approx. 32% NOx reduction for gas reburn with 4-mill operation at 160 MW load from 0.31 lb/mmBtu LNB + OFA baseline w/o reburn fuel (down to 0.21 lb/mmBtu), and 48% NOx reduction for gas reburn with 3-mill operation, to 0.16 lb/mmBtu (31).
Source: Sept. 2005 GE-EER experience list(8); GE-EER 2004 Technical paper(31). Listed in (10) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference)

Dynegy (formerly Illinois Power)   Pulverized Coal, Tangentially-fired
Hennepin Unit 1   1966 vintage
71 MW CE boiler   eastern bituminous coal
GE-EER Gas Reburn, 1990 startup (not currently operating); GE-EER Orimulsion Reburn, 1997.
DOE Clean Coal demonstration project (included sorbent injection).
Vendor claimed gas reburn w/ OFA lowered NOx up to 67% from baseline of 0.75 lb/mmBtu to 0.25 lb/mmBtu) at full load; 65% reduction from baseline of 0.75 lb/mmBtu down to 0.26 lb/mmBtu with subsequent Orimulsion reburn operation(8).
GE-EER 2004 technical paper shows 18% gas reburn fuel yielded minimum NOx emissions(11).
Another technical paper showed this 80 MW US DOE Clean Coal demonstration project in January 1991-January 1993 lowered NOx by 67% from 0.75 lb/mmBtu baseline (to 0.25 lb/mmBtu) with 18 percent reburn fuel(11).
Source: Sept. 2005 GE-EER experience list(8); GE-EER 2004 Technical paper(11); DOE-NETL 2004 Reburn Conference technical paper, and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).
(Also see Conventional Oil reburn installation summaries for pulverized coal boilers).

AES (formerly New York State Gas & Electric (NYSEG)
Greenidge #6 (NY)   Pulverized Coal, Tangentially-fired,   1953 vintage
100 MW CE boiler   GE-EER Conventional Gas Reburn, 1996 startup
Vendor claimed to lower NOx 55% from 0.63 lb/mmBtu baseline to 0.28 lb/mmBtu at full load with reburn operation burning eastern bituminous coal. Gas Research Institute predicted would achieve 76% (down to 0.15 lb/mmBtu) w/ advanced gas reburn(8).
GE-EER 2004 technical paper shows 23% reburn fuel yielded minimum NOx emissions around 0.23 lb/mmBtu(11).

EPA's "Scorecard on Reburning 6/1/2004" shows a 109 MW t-fired boiler (listed as Greenidge Unit 4) lowered NOx by 50% from 0.50 lb/mmBtu baseline (to 0.25 lb/mmBtu) with 10 percent reburn fuel (no longer operating) (10).
Source: Sept. 2005 GE-EER experience list(8); GE-EER 2004 Technical paper(11); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

REBURN – GAS, CONVENTIONAL continued
Pulverized coal-fired boilers)

Potomac Electric Power (formerly West Pennsylvania Power)

Chalk Point Station	Pulverized Coal	opposed wall-fired B&W boilers
Units 1 & 2	1964, 1965 vintage	eastern bituminous coal
360 MW (nominal)	GE-EER Gas Reburn, 2000 startup	

Vendor claimed to lower NOx up to 43% and 45% from 0.60 lb/mmBtu baseline to 0.34 and 0.33 lb/mmBtu) at full load with reburn operation, respectively. No claims of percent reburn fuel included(8).
Source: Sept. 2005 GE-EER experience list(8). Listed in DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

Xcel Energy (formerly Public Service Company of Colorado)

Cherokee Unit 3	Pulverized coal, wall-fired, 1962 vintage
175 MW B&W boiler	western bituminous coal
DOE Clean Coal demonstration project	November 1992-January 1995

Gas reburn demonstration performed with Dept. of Energy and Gas Research Institute 1992-1995. Existing boiler with 16 burners was retrofitted with low NO$_X$ burners and GE-EER gas reburn OFA, FGR, and reburn injectors. Added OFA booster fan, 800 hp flue gas recirculation fan for injection mass momentum, for increased gas injection mass momentum (which was subsequently removed). The CGR installation portion has since been decommissioned.
Vendor claimed to lower NOx up to 64% from baseline of 0.73 lb/mmBtu to 0.26 lb/mmBtu) at full load with reburn operation(8).
GE-EER 2004 technical paper shows 15-20% reburn fuel yielded minimum NOx emissions(11).
A 2004 DOE-NETL technical paper showed this project achieved 0.46 lb/mmBtu NO$_X$ emissions with low NO$_X$ burners alone (37% reduction), further reduced NO$_X$ by 44% with 12.5 percent reburn fuel(10).
A 2001 DOE-NETL technical paper claimed a NOx reduction of 65% at an average reburn gas heat input of 18% of total boiler fuel input, with and without FGR. Demonstrated 70% NOx reduction at higher reburn input rates. Referred to technology as GR-LNB. FGR was added for gas injection momentum but was subsequently removed to reduce fuel input. (30)
Source: Sept. 2005 GE-EER experience list(8); GE-EER 2004 Technical paper(11); DOE-NETL 2004 Reburn Conference technical paper and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10); DOE-NETL 2001 Technical paper(30); also in DOE 1999 Topical Report Number 14(14).

REBURN – OIL, CONVENTIONAL
Pulverized coal-fired boilers

Dynegy (formerly Illinois Power)	Pulverized Coal, Tangentially-fired	
Hennepin Unit 1	1966 vintage, eastern bituminous coal	
71 MW	CE boiler	1997 startup

GE-EER Orimulsion Reburn system w/ OFA, claimed orimulsion reburn lowered NOx up to 65% from baseline of 0.75 lb/mmBtu to 0.26 lb/mmBtu at full load with Orimulsion reburn operation (installed after gas reburn was demonstrated in early 1990's). No claims for percent reburn fuel included(8).
GE-EER 2004 technical paper shows 60% reduction with subsequent Orimulsion reburn (11).

Source: Sept. 2005 GE-EER experience list(8); GE-EER 2004 Technical paper(11). Orimulsion not mentioned in DOE-NETL 2004 Reburn Conference technical paper or DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).
(Also see Conventional Gas Reburn installation summaries for pulverized coal boilers).

New Brunswick Power
Coleson Cove, Bunker C/Orimulsion–fired, opposed-wall
St. John, New Brunswick, Canada
3x 350 MW B&W Boilers
Sixteen new low-NO_X oil/Orimulsion burners, eight reburn burners, nine SOFA ports, two combustion air booster fans, reburn and OFA wall penetration openings, OFA windboxes, ductwork, dampers, and accessories were added(12).
Another technical paper showed this reburn system lowered NOx by 78% from 1.0 lb/mmBtu baseline to 0.22 lb/mmBtu at 25 percent reburn fuel input(10).
Source: B&W 2004 Technical Paper(12); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

Georgia Power Pulverized Coal, Tangentially-fired
Scherer Unit 1 1982 vintage
887 MW CE boiler 2000 oil reburn startup
GE-EER Oil Reburn system, claimed to lower NOx from baseline of 0.36 lb/mmBtu.
GE-EER 2004 Technical paper shows reduction up to 48% (to 0.19 lb/mmBtu) at 800 MW load with oil reburn operation. No claims of percent reburn fuel included(11).
Source: Sept. 2005 GE-EER experience list shows this as a coal reburn project with eastern bituminous coal, reducing NO_X emissions 33% from 0.36 to 0.24 lb/mmBtu; GE-EER 2004 Technical paper(31).
Not listed in DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

REBURN – COAL, MICRONIZED, CONVENTIONAL

Pulverized coal-fired boilers

AES (formerly New York State Electric and Gas Milliken Station Unit 1)
Cayuga tangentially-fired, pulverized coal, 1956 vintage
148 MWe, CE boiler eastern bituminous coal
GE-EER micronized coal reburn system 1996 startup (still operating)
US DOE Clean Coal demonstration project from March 1997-April 1999 lowered NOx with this reburn system by 29% from 0.35 lb/mmBtu baseline to 0.25 lb/mmBtu at 14 percent reburn fuel input(10).
Not listed in GE-EER's experience list nor in their 2004 technical paper.
Source: DOE-NETL 2004 Reburn Conference technical paper and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

E. ON US Holdings (formerly Louisville Gas and Electric)
R.D. Green Station Units 1 & 2 (KY) wall-fired, pulverized coal, vintage unknown
293 MWe, 2 boilers eastern bituminous coal
GE-EER coal reburn system Startup dates: 2003 & 2002, respectively
Vendor claimed to lower NOx up to 57% from baseline of 0.45 lb/mmBtu to 0.20 lb/mmBtu at full load with reburn operation(8).
Reburn system listed on EPA's "Scorecard on Reburning 6/1/2004" shows NOx lowered by 44% from baseline of 0.45 lb/mmBtu down to 0.25 lb/mmBtu (with unknown reburn fuel input(10)).
Another technical paper showed baseline NOx with existing low-NOx burners was 0.45 lb/mmBtu, and reduced NOx emission 40% to 0.27 lb/mmBtu with OFA, and further reduced NOx emissions 22% down to 0.21 lb/mmBtu with the coal reburn system in operation[32].

Source: Sept. 2005 GE Energy (formerly GE-EER) experience list(8); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10); March 2004 Modern Power Systems issue article (32).

REBURN – COAL, MICRONIZED, CONVENTIONAL continued

Pulverized coal-fired boilers

Cheng Loong (not in United States)
Unit #1, 250 MWe   wall-fired, bituminous pulverized coal, vintage & mfr unknown
GE-EER coal reburn system   2000 Startup (still operating)
Vendor claimed to lower NOx 44% from baseline 0.45 lb/mmBtu to 0.25 lb/mmBtu) at full load with OFA alone; further reduced NOx 28% to 0.18 lb/mmBtu, for 60% overall reduction. Recent (2004) data shows NOx down to 0.14 lb/mmBtu (69% overall) with up to 30 percent reburn fuel(8).
Source: Sept. 2005 GE Energy (formerly GE-EER) experience list(8); Listed in DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

REBURN – GAS, CONVENTIONAL w SNCR

Pulverized coal-fired boilers)

NRG Somerset   Pulverized Coal, Tangentially-fired,   vintage unknown
Unit 6 Boiler 8 (NY)   GE-EER Conventional Gas Reburn,
120 MW CE boiler   Fuel Tech SNCR, 2003 startup
Reburn vendor claimed to lower NOx 55% from 0.45 lb/mmBtu baseline to 0.20 lb/mmBtu at full load with reburn operation burning Venezuelan coal. The SNCR system further reduced NOx emissions 45% down to 0.11 lb/mmBtu, for an overall reduction of 77%(32).
Source: Sept. 2005 GE Energy experience list(8); March 2004 Modern Power Systems issue(32).

REBURN – FUEL LEAN GAS REBURN (FLGR)

Pulverized coal-fired boilers

Duke Power Company   tangentially-fired, pulverized coal
Riverbend Unit 7   eastern bituminous coal   1954 vintage
140 MWe, CE boiler   1998 FLGR startup, gas reburn decommissioned since then
Previously installed ABB/CE's Low NOx Concentric Firing System (LNCFS-1) with Close-Coupled Overfire Air (CCOFA); (pre-mod NOx + combustion mods date not known).
Commercial FLGR installation claimed 34% NOx reduction from full-load baseline of 0.42 lb/mmBtu down to 0.29 lb/mmBtu w/ the combustion modifications and FLGR gas reburn fuel at 7% of total boiler heat input. CO emissions were above 1000 ppm corrected to 3% O_2.(33)
Vendor claimed to lower NOx 57% from 0.47 lb/mmBtu baseline to 0.20 lb/mmBtu) at full load with separated OFA alone; further reduced NOx 45% to 0.11 lb/mmBtu with low-NOx burners, OFA, gas reburn, and SNCR, for 77% overall reduction; no claims for amount of reburn fuel(32).
EPA's "Scorecard on Reburning 6/1/2004" showed this reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input(10).
Source: ESA, GRI, NGB 1998 Technical paper(33); GE Energy 2004 Technical paper(32); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

Wisconsin Electric Power Company (WEPCO)
Pleasant Prairie Unit 1   DB Riley, turbo-fired PC, Powder River Basin coal
620 MWg   1980 vintage   1999 startup
Fuel Tech listed FLGR installation and claimed 20% NOx reduction from baseline of 0.45 lb/mmBtu (to 0.36 lb/mmBtu). No claims of percent reburn fuel input included(23).

Source: Fuel Tech experience list dated 1/28/2005(23). Also listed in DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).
(Also see FLGR + SNCR installation summaries for pulverized coal boilers).

REBURN – FUEL LEAN GAS REBURN w/ SNCR (Amine-Enhanced FLGR)

Pulverized coal-fired boilers

Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 startup
Commercial urea-based Fuel Tech SNCR +FLGR installation claimed 50% NOx reduction from baseline(19) of 0.58 lb/mmBtu (426 ppm) down to 0.29 lb./mmBtu w/ 5 ppm ammonia slip(23). Low NO_X burners were previously retrofitted in 1997 without separated overfire air(26). This is 33 % lower than 0.44 lb/mmBtu baseline for SNCR alone. (Also see SNCR installation summaries for pulverized coal boilers). Urea-to-NOx NSR not stated.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(10).
Another technical paper showed 52% NOx reduction down to 0.28 lb/mmBtu at all loads, from 99 MWg to 207 MWg (48% to 100% MCR) with an average NH_3 slip of 3 ppm. FLGR alone achieved 23% NOx reduction with 6% reburn fuel and < 400 ppm CO at full load. (26)
Source: Fuel Tech experience list 1/28/05(23); ICAC SNCR 2000 White Paper(19); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10); CP&L and Fuel Tech 2001 Technical paper(26).
(Also see SNCR installation summaries for pulverized coal boilers).

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Hudson Station, Unit 2 Pulverized Coal, opposed-wall-fired, 1968 vintage
660 MWe Foster Wheeler boiler eastern bituminous coal March 1999 startup
Commercial SNCR + FLGR urea-based Fuel Tech installation claimed 40% NOx reduction from baseline of 0.65 lb/mmBtu (down to 0.39 lb/mmBtu) w/ 10 ppm ammonia slip(19). This is 20 % lower than 0.49 lb/mmBtu baseline for SNCR alone. Urea-to-NOx NSR not stated.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(10).
Source: Fuel Tech experience list 1/28/05(23), ICAC SNCR 2000 White Paper(19); DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).
(Also see SNCR installation summaries for pulverized coal boilers).

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Mercer Station (2) twin-furnace boilers, 320 MWe each, DB Riley turbo-fired
Unit 1 and Unit 2 front wall PC, wet-bottom (slagging ash) eastern bituminous coal
Furnace #11 & #12 1960 vintage May 1999 startup
Furnace #21 & 22 1961 vintage May 1999 startup
Commercial urea-based Fuel Tech SNCR + FLGR installation claimed 60% NOx reduction from baseline of 1.4 lb/mmBtu (down to 0.56 lb/mmBtu) w/ 5 ppm ammonia slip (19). This is 72 % lower than 2.0 lb/mmBtu baseline without control. Initial demonstration of AEFLGR coinjected amine-enhanced natural gas into Furnace 22 in 1998. Subsequently installed AEFLGR on both units to reduce NOx starting in May 1999 using (2) levels of AEFLGR retractable gas injectors and (2) levels of SNCR injectors(34). Urea-to-NOx NSR not stated, goal was NSR < 1.25.

{Note both units have since been retrofitted with low-dust tail-end SCRs in 2004; SNCR systems are still capable and operated as needed, mostly for flyash conditioning to aid ESP performance}
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 1999, but not currently operating(10).
Source: Fuel Tech experience list 1/28/05 (23), ICAC SNCR 2000 White Paper(19); PSE&G, FT and ESA 2000 Technical paper(34); DOE-NETL Scorecard on Reburning 6/1/2004 (2004 Reburn Conference). (10)

REBURN – FUEL LEAN GAS REBURN w/ SNCR (Amine-Enhanced FLGR) continued
Pulverized coal-fired boilers

Wisconsin Electric Power Company (WEPCO)
Pleasant Prairie Unit 1 DB Riley, turbo-fired PC, Powder River Basin coal
620 MWg 1980 vintage 1999 startup
Fuel Tech urea-based SNCR +FLGR demonstration installation claimed 56% NOx reduction from baseline of 0.45 lb/mmBtu to 0.20 lb/mmBtu w/ 5 ppm ammonia slip(19). This is 44 % lower than 0.36 lb/mmBtu baseline for FLGR alone.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(5).
Source: Fuel Tech experience list 1/28/05(23), ICAC SNCR 2000 White Paper(19) ;
DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference) (10).

SELECTIVE NON-CATALYTIC REDUCTION
Pulverized coal-fired boilers

American Electric Power (AEP) Pulverized Coal, cell-burner, opposed wall-fired B&W boiler
Cardinal Unit 1 1967 vintage; Low NO_x burners installed in October 1998
600 MW (nominal) Brilliant, Ohio
Fuel Tech urea-based SNCR installed in October 1998.
Fuel Tech, DOE, EPRI-member utilities SNCR demonstration project. Tested in March-April 1999, claimed 65% reduction with LNBs + SNCR w/ 5 ppm NH_3 slip, (from pre-LNB retrofit baseline of 1.20 lb/mmBtu(24)) down to 0.52 lb/mmBtu at 620 MW (100% MCR). SNCR reduced NO_X 31% below LNBs alone (0.75 lb/mmBtu baseline), at 620 MWg (100% MCR), 34% reduction at 75% MCR (450 MWg), and 42% reduction at minimum load (340 MWg, 55% MCR) ≤ 5% ammonia slip(25), burning eastern bituminous coal. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23); ICAC SNCR 2000 White Paper(19), 2000 Fuel Tech technical paper(25), Riley Power (Babcock Power Inc.) experience list 8/16/04(24).

Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 SNCR startup
Fuel Tech commercial SNCR installation claimed 25% NOx reduction from low-NO_X burner w/o OFA baseline of 0.58 lb/mmBtu (down to 0.44 lb/mmBtu on SNCR alone)(23). Urea-to-NOx NSR not stated. (Also see FLGR + SNCR installation summaries for pulverized coal boilers).
Source: Fuel Tech experience list dated 1/28/2005(23).

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 5 1956 vintage; eastern bituminous coal
154 MW CE boiler SNCR startup in 2002
Mobotec USA "Rotamix" ammonia-based SNCR system injects aqueous ammonia liquid into a high velocity boosted separated overfire air (ROFA) system at the boiler.
CP&L technical paper claimed to lower NO_X from 0.28 lb/mmBtu baseline by 43% to 0.16 lb/mmBtu in 2002 with 5 ppm NH_3 slip following the installation of ROFA in 2000.

Overall reduction 73% from full-load pre-ROFA baseline 0.60 lb/mmBtu to 0.16 lb/mmBtu(27).
Mobotec claimed further NO_X reduction was possible by injecting urea in place of ammonia, achieving 0.13 lb/mmBtu instead of 0.18 lb/mmBtu, which would be 54% decrease from 0.28 lb/mmBtu with ROFA alone, or 78% overall decrease(35). Ammonia-to-NOx NSR not stated.
Source: CP&L 2002 Technical paper(27); Mobotec 2003 technical paper(35).

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 6 twin-furnace (eight corner), 1958 vintage; eastern bituminous coal
175 MW CE boiler SNCR startup in 2001
Mobotec USA "Rotamix" ammonia-based SNCR system, injects aqueous ammonia liquid into a high velocity boosted separated overfire air ("ROFA") system at the boiler.
CP&L technical paper claimed to lower NO_X from 0.23 lb/mmBtu baseline by 22% to 0.18 lb/mmBtu with 5 ppm NH_3 slip following the installation of ROFA+SNCR in 2001(27). Presentation slide graph shows no reduction for Rotamix beyond ROFA alone at full load NO_X emission rate of 0.23 lb/mmBtu. Ammonia-to-NOx NSR not stated.
Overall reduction 67% from full-load pre-ROFA baseline 0.54 lb/mmBtu to 0.18 lb/mmBtu.
Mobotec claimed further NO_X reduction was possible by injecting urea in place of ammonia, achieving 0.10 lb/mmBtu instead of 0.18 lb/mmBtu, which would be 56% decrease from 0.23 lb/mmBtu with ROFA alone, or 81% overall decrease(35). Urea-to-NOx NSR not stated.
Source: CP&L 2002 Technical paper(27); Mobotec 2003 technical paper(35).

Cinergy (formerly Cincinnati G&E) Pulverized Coal, Tangentially-fired,
Miami Fort Unit 6 (Ohio) 1960 vintage; startup prior to 2000
163 MW CE boiler
Fuel Tech urea-based SNCR system, claimed to lower NOx by 35% from 0.55 lb/mmBtu baseline(20).(assume eastern bituminous coal). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23), ICAC SNCR 2000 White Paper(19).

Conectiv (formerly Delmarva Power & Light)
Edgemoor Unit 3 Pulverized Coal, Tangentially-fired, 1954 vintage
84 MW CE boiler mid-March 1996 startup; (assume eastern bituminous coal)
Hamon Research-Cottrell supplied a urea-based SNCR system. HRC claimed 35% NOx reduction with less than 10 ppm ammonia slip. Urea-to-NOx NSR not stated.
Another source shows a 30% reduction from 0.54 lb/mmBtu baseline(20).
Source: Hamon experience list (not listed by Fuel Tech)(36); ICAC SNCR 2000 White Paper(19).

Conectiv (formerly Delmarva Power & Light) Pulverized Coal
Indian River Units 3 & 4 (Millsboro, DE) Unit 3 is front wall-fired, 1974 vintage
178MW and 440 MW Unit 4 is turbo-fired opposed-wall, 1980 vintage
B&W, DB Riley boilers Spring 2000 startup (eastern bituminous coal)
Hamon Research-Cottrell supplied a urea-based SNCR system (not listed by Fuel Tech) on both units. HRC claimed 35% NO_X reduction with less than 5 ppm ammonia slip(36). Urea-to-NOx NSR not stated.
An REI 1999 technical paper shows a pre-SNCR baseline of 0.37 and 0.44 lb/mmBtu, respectively(28).
Another source listed these units as having a pre-control NO_X baseline of 0.97 and 0.57 lb/mmBtu, and 2004 post-SNCR startup average of 0.32 and 0.33 lb/mmBtu, respectively(1).
Source: Hamon experience list (not listed by Fuel Tech)(36); REI 1999 technical paper(28);
US EPA Docket OAR-2002-0076-0446 Excel Spreadsheet 6/15/2005(1).

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Dominion Generation (Virginia E&P Co.)
Clover Station, Units 1 & 2 (VA)
2 x 465 MW
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, Tangentially-fired
ABB/CE boilers, 1995, 1996 vintage
(eastern bituminous coal)
1995, 1996 startup (initial commercial)

Fuel Tech claimed NOx reduced by 25% from 0.32 lb/mmBtu baseline (to 0.24 lb/mmBtu)(23).
Source: Fuel Tech experience list dated 1/28/2005(23). Urea-to-NOx NSR not stated.

Dynegy Midwest Generation (formerly Illinois Power)
Vermillion Station, Unit 1
82 MW

Pulverized Coal, Tangentially-fired
1955 vintage
CE boiler, bituminous Illinois coal

Mobotec USA "Rotamix" urea-based SNCR system with rotating opposed fired air (ROFA).
Mobotec 2004 technical paper claimed to lower NO_X by 55% from 0.22 lb/mmBtu baseline to 0.10 lb/mmBtu in April 2004 with urea-based Rotamix SNCR and < 5 ppm CO. NH_3 slip not mentioned. Overall reduction 83% from full-load pre-ROFA baseline 0.58 lb/mmBtu to 0.10 lb/mmBtu (29). Urea-to-NOx NSR not stated.
Source: Mobotec 2004 technical paper(29).

Eastern Utilities Associates,
Montaup Electric Company
Somerset Unit 8 (Massachusetts)
112 MW CE boiler

Pulverized Coal, Tangentially-fired
1959 vintage
Summer 1995 startup
(eastern bituminous coal)

Hamon Research-Cottrell supplied a urea-based SNCR (Fuel Tech system), claimed to lower NOx below 0.38 lb/mmBtu (Mass. RACT)(36). Urea-to-NOx NSR not stated.
Another source listed 28-60% NOx reduction from a 0.49-0.89 lb/mmBtu baseline(19).
Source: Hamon experience list 4/26/04(36), Fuel Tech experience list dated 1/28/2005(23), ICAC SNCR 2000 White Paper(19).

First Energy
Eastlake Unit 3 (Ohio)
130 MW CE boiler (w/ division wall)
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, Tangentially-fired,
1954 vintage
(eastern bituminous coal)
SNCR startup prior to 2000

Fuel Tech claimed to lower NOx from 20-32.5% from 0.34-0.40 lb/mmBtu baseline(23). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23); ICAC SNCR 2000 White Paper(19).

First Energy
Sammis Unit 2 (Ohio)
180 MW Foster Wheeler boiler
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, wall-fired,
1960 vintage
SNCR startup Fall 1999
(eastern bituminous coal)

Fuel Tech claimed to lower NOx from 25-30% from 0.45 lb/mmBtu baseline (23). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23), ICAC SNCR 2000 White Paper(19).

First Energy
Sammis Units 6 & 7 (Ohio)
680 MW B&W Universal Pressure boilers
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, wall-fired,
1969 & 1971 vintage
(eastern bituminous coal)
SNCR startup after 1999

Fuel Tech claimed to lower NOx from 25% from 0.38 lb/mmBtu baseline(23). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23).

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

New England Power Company (NEPCO)
Salem Harbor Station
Units 1, 2 & 3
84 MWe x 2, & 156 MWe B&W boilers
Urea-based SNCR (Fuel Tech system)
Pulverized Coal, front wall-fired,
1952, 1952, 1958 vintage (eastern bit. coal)
SNCR startup prior to 2000
Fuel Tech claimed 66% (50-75%) NOx reduction from baseline of 1.0 ± 0.1 (range 0.85-1.12) lb/mmBtu(23), (which would lower NOx to around 0.34±0.07 lb/mmBtu). Urea-to-NOx NSR not stated.
{These NOx reduction percentages may include impact of low-NOx burners}.
Source: Fuel Tech experience list dated 1/28/2005(23), ICAC SNCR 2000 White Paper(19).
(Also see LNB installation summaries for pulverized coal boilers).

Northeast Utilities (formerly Public Service of New Hampshire)
Schiller Units 4, 5, & 6
50 MWe x 3Foster Wheeler boilers
Urea-based SNCR (Fuel Tech system)
Pulverized Coal/#6 Fuel oil, front-wall-fired
1952, 1955, 1957 vintage
Colombian bituminous coal
August 1999 startup
RJM implemented Fuel Tech urea-based commercial SNCR installation on all three boilers.
RJM claimed 50% reduction from 0.50 lb/mmBtu pre-SNCR baseline to 0.25 lb/mmBtu for SNCR coal-firing operation; NO_X baseline 0.82 lb/mmBtu prior to RJM's LNB modifications installed in 1994, 1992, & 1994 (39% reduction)(17); Urea-to-NOx NSR not stated.
Fuel Tech claimed 30% NO_X reduction for SNCR from baseline of 153 ppm firing #6 fuel oil on Units 4 & 6 only(23).
Source: RJM experience list 9/3/04(17), Fuel Tech experience list dated 1/28/2005(23).

Owensboro Municipal Utilities (KY)
Elmer Smith Unit 2
300 MW CE boiler
Pulverized Coal, Tangentially-fired,
1974 vintage
eastern bituminous coal
Hamon Research-Cottrell supplied an ammonia-based SNCR system but stated no claims for NOx reduction(36); (this project is not listed in ICAC SNCR 2000 White Paper(19)). Ammonia-to-NOx NSR not stated.
Source: Hamon experience list 4/26/04(36).

PECO Energy (formerly Philadelphia Electric Company)
Cromby Unit 1
160 MWe B&W boiler 1954 vintage
Pulverized Coal, front wall-fired divided furnace
eastern bituminous coal
RJM installed Fuel Tech urea-based SNCR with low NO_X burner modifications & OFA in 1999, June 1999 startup.
RJM claimed 29% SNCR NO_X reduction from baseline of 0.35 lb/mmBtu, down to 0.25 lb/mmBtu with urea NSR = 0.8; RJM provided burner modifications of B&W XCL low-NOx burners installed in 1994 + OFA; this reduced NO_X from 0.50 to 0.35 lb/mmBtu (30% reduction) without SNCR(17). Urea-to-NOx NSR not stated.
Source: RJM experience list9/3/2004(17); ICAC SNCR 2000 White Paper(20).

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Exelon (formerly PECO Energy/ Pennsylvania Electric Company)
Eddystone Units 1 & 2 Pulverized Coal Tangentially-fired, 1954 vintage
318, 333 MW each CE boilers 1999 SNCR startup, eastern bituminous coal
Fuel Tech claimed 30% NOx reduction from baseline of 0.26 lb/mmBtu(23).
Source: Fuel Tech experience list dated 1/28/2005(23).

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Hudson Station, Unit 2 Pulverized Coal, opposed-wall-fired, 1968 vintage
660 MWe Foster Wheeler boiler eastern bituminous coal March 1999 startup
Fuel Tech urea-based commercial SNCR installation claimed 25% (initial) NOx reduction for SNCR alone from baseline of 0.65 lb/mmBtu (down to 0.49 lb/mmBtu)(23). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23), also listed in ICAC SNCR 2000 White Paper(19).
(Also see FLGR+SNCR installation summaries for pulverized coal boilers).

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Mercer Station (2) twin-furnace boilers, 320 MWe each, DB Riley turbo-fired
Unit 1 and Unit 2 front wall PC, wet-bottom (slagging ash) eastern bituminous coal
Furnace #11 & #12 1960 vintage April 1999 startup
Furnace #21 & 22 1961 vintage May 1999 startup
Fuel Tech urea-based commercial SNCR installation claimed 30-35% NOx reduction from baseline of 2.0 lb/mmBtu on SNCR alone, down to 1.4 lb/mmBtu(23). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23), also listed in ICAC SNCR 2000 White Paper(19).
(Also see FLGR+SNCR installation summaries for pulverized coal boilers).

Reliant Energy (formerly GPU Genco) Pulverized Coal
(formerly Sithe, formerly Penelec) Tangentially-fired
Seward # 15 (PA) mid-1990's SNCR startup
Units 4 & 5 eastern bituminous coal
62 & 156 MW CE boilers 1950 & 1957 vintage
Urea-based SNCR (Fuel Tech system), later installed an in-duct SCR to reduce NH_3 slip.
Fuel Tech claimed to lower NOx 35% for SNCR only (55% for combined SNCR/SCR from 0.78 lb/mmBtu baseline)(23). Boilers have since been demolished and replaced with CFBs. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23), ICAC SNCR 2000 White Paper(19).

Rochester Gas & Electric Pulverized Coal, Tangentially-fired
Russell Station, Units 1-4 (NY) 1948, 1950, 1953, 1957 vintage
1 x 50 MW, 2 x 65 MW, 1 x 85 MW CE boilers eastern bituminous coal
Urea-based SNCR (Fuel Tech system) SNCR startup prior to 2000
Vendor claimed to lower NOx by 15-27.5% from 0.28 – 0.42 lb/mmBtu baselines(23). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005(23).

HYDROCARBON-ENHANCED AMMONIA SNCR (NOxStar™)

Pulverized coal-fired boilers

Tennessee Valley Authority (TVA)	Pulverized Coal twin-furnace, tangentially-fired,
Kingston Power Station (TN)	1955 vintage eastern bituminous coal
Unit 9, 200 MWe CE boiler	NOxStar™ startup January 2002

Demonstration of NOxStar™ hydrocarbon-enhanced ammonia-based SNCR installation.
Mitsui Babcock claimed 68% NOx reduction from baseline of 0.55 lb/mmBtu down to 0.17 lb/mmBtu with boosted OFA and NOxStar™ with < 5 ppm ammonia slip; NOxStar™ alone reduced NOx by 53%(37); boosted OFA only reduced NOx from 0.55 to 0.45 lb/mmBtu (18% reduction). Ammonia-to-NOx NSR not stated.
TVA's website reported that "an earlier version of NOxStar was installed at Kingston Fossil Plant Unit 9 in 2002 with mixed results. NOx reductions were achieved, but the boiler was damaged" (http://www.tva.gov/environment/repotrs/envreports/aer/2003/env_compliance.htm)
Source: Mitsui Babcock Technical paper, October 2003(37).

Tennessee Valley Authority (TVA)	Pulverized Coal, wall-fired
Colbert Station (AL)	1955 vintage
Unit 4, 192 MWe twin-furnace B&W boiler w/ FGR	eastern bituminous coal

First commercial installation of NOxStar™ hydrocarbon-enhanced ammonia-based SNCR technology.
Mitsui Babcock showed 80% NOx reduction from baseline of 0.50 to 0.10 lb/mmBtu; using < 0.1% of total boiler heat input for propane input and 1% of total steam flow generated in the boiler for lance cooling(38); 2004 SNCR system startup. Ammonia-to-NOx NSR not stated.
Source: Mitsui Babcock 2004 Technical paper(38).

ASH IMPACTS ON SCR CATALYST PERFORMANCE

EXECUTIVE SUMMARY

The ash deposition behavior of the lignites from North Dakota is the most complex and severe of any coals in the world, and installation of catalysts for NO_x reduction is going to be plagued with problems. The Center lignite fired at the Milton R. Young (MRY) Power Station is highly variable in abundance of various types of ash/slag-forming components. Ash-forming components consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with oxygen functional in the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. The alkali and alkaline-earth elements combine with minerals during combustion, resulting in low-melting-point phases that cause a wide range of fireside deposition problems. In addition, the alkali and alkaline-earth elements also form very small particles that are carried into the backpasses of the combustion system and react with flue gas to form sulfates that can cause deposition, blinding, and plugging problems in selective catalytic reduction (SCR) systems. This report analyzes these problems, and concludes that SCR is not a feasible option to control NOx emissions at MRY Power Station because of the high sodium levels present in the coal.

Following is a list of the key problems that are associated with Center lignite which have not been overcome and, in our opinion, make the installation of SCR at the MRY plant technically infeasible for NO_x control.

- Blinding of Catalyst Pores by High Sodium Compounds

  X High levels of alkali and alkaline-earth elements present in the coal fired at the MRY plant produce small particles that react to form sulfates that blind the catalyst pores. The high levels of sodium in the coals combined with calcium will produce low-melting-point eutectic sulfate compounds that will form and melt inside the pores of the catalyst.
  - Alkali and alkaline earth sulfates are enhanced by cyclone fired system. The cyclone firing results in partitioning of the ash between bottom slag and the body of the boiler. The sulfate forming materials are more concentrated in the ash as a a result of cyclone firing.

  - Sulfate formation is enhanced by the presence of an SCR catalyst; this accelerates the sulfation reactions, causing blinding of the catalyst.

  - The sulfate reactions are more severe at MRY because of the high temperature where an SCR would be installed. The higher temperature increases the rate of formation of sulfates and rate of pore plugging.

  - The testing conducted by the Germans found catalyst deactivation and blinding occurs when firing coals with lignite or brown coals that have ashes that are rich in alkali and alkaline-earth elements. .

- The findings by the Germans were confirmed by recent SCR catalyst slipstream testing that showed significant evidence of sodium and calcium-rich sulfate formation that fill and plug the catalyst at both lignite- and subbituminous-coal-fired power plants. The results of this recent testing showed that the presence of sodium significantly enhanced the formation of bonding of particles and more rapid sulfation, filling of pores, and rapid increase in pressure drop across the catalyst.

- Deposit carryover, or "popcorn ash," plugging the top of the SCR catalyst is a significant problem because of the extremely high deposition rates of the Center coal. When firing Center coal, deposits form on various parts of the boiler requiring continuous sootblowing. The sootblowing of upstream heat-exchange equipment will cause deposit fragments to be carried back to the SCR catalyst, resulting in plugging. In addition, during sootblowing of the SCR catalyst, the entrainment of deposit fragments along with the sootblowing media will result in significant erosion of the catalyst surfaces.

- Recent testing with subbituminous and lignitic coals indicated a significantly higher level of pore filling and plugging in the catalyst exposed to lignite ash as compare to subbituminous coal ash. The catalyst pores as well as the catalyst surface in the lignite tests were completely coated with a sodium calcium sulfate material, while only pore filling was found in the subbituminous coal testing. The pressure drop across the catalyst exhibited for lignite was 4 to 5 times greater than that found for a catalyst exposed to subbituminous coal ash. The plugging occurred over a 1000 hour test period.

➢ Cold Side SCR Installation

- High-sodium lignite coal from the Center Mine Hagel A and B seam coal produces significant levels of homogeneously condensed sodium sulfate that pass through the ESP and wet scrubber.

- These small particles have been shown to pass through a wet scrubber and will accumulate on surfaces of tail-end SCR systems. The accumulated materials require sootblowing to remove the particulate and will result in increased opacity.

- Liquid pyrosulfate materials at temperatures as low as 535°F from sodium sulfate materials occurs in coal-fired power systems and is well documented. Pyrosulfates will form and cause blinding of tail-end SCR devices. In addition, SCR systems are known to catalyze the formation of SO_3 from SO_2. The presence of SO_3 significantly enhances the formation of the pyrosulfates.

ASH IMPACTS ON SCR CATALYST PERFORMANCE

INTRODUCTION

Ash produced during combustion of coal in conventional power systems is a major problem that results in decreased efficiency, unscheduled outages, equipment failures, and increased cleaning. The many ways in which the detrimental effects of ash manifest themselves in a boiler system include fireside ash deposition on heat-transfer surfaces, corrosion and erosion of boiler parts, poor slag flow, and production of fine particulates that are difficult to collect. Decades of research have been conducted to develop a better understanding of the chemical and physical processes of ash formation and deposition in combustion systems. Overviews of ash-related issues and compilations of work by many investigators can be found by referring to the work of Mehta and Benson (1), Schobert (2), Baxter and DeSollar (3), Couch (4), Williamson and Wigley (5), Benson and others (6), Benson (7), Bryers and Vorres (8), Raask (9, 10), and Benson (11). This work has led to a detailed understanding of ash formation and behavior in combustion systems as well as the development of predictive methods (12, 13).

The chemical composition and physical characteristics of ash-forming or inorganic components (mineral and organically associated elements) of the fuel(s) fired have an influence on the following processes in the combustion systems:

- Firing conditions such as cyclone, pulverized coal, and low-NO_x burners
- Transformations of coal inorganic components to ash particulate and vapor-phase species
- Boiler design characteristics, including number of burners, radiant section area, tube bank spacing, access for cleaning, and number of sootblowers
- Ash transport to heat-transfer surfaces in utility boilers
- Erosion wear and sticking
- Ash deposit growth and impact on heat transfer
- Ash blinding and plugging of selective catalytic reduction (SCR) catalysts
- Ash deposit removability

The ash deposition in North Dakota lignite-fired power plants is a major problem that impacts all fireside surfaces of the power plant. The ash problems are due to the variable and complex nature of inorganic components associated with lignite coals (2). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. During the gas-cooling processes in the boiler, the gas-phase species condense and the liquid-phase materials solidify. The abundance of these gas-phase and liquid materials entrained in the bulk gas flow is highly dependent upon coal composition and system operating conditions. The inorganic materials are transported to heat-transfer and catalyst surfaces by diffusion, electrophoresis, thermophoresis,

and inertial impaction. The particle sticking and accumulation rates are dependent upon the quantity of ash and the abundance and viscosity of the liquid-phase components. In high-temperature regions of the boiler, high-temperature sodium–calcium–aluminosilicate liquid phases act as the sticky material, causing deposit initiation, growth, and development of deposit strength. As the temperature of the flue gases decreases, the condensation and reaction of flame-volatilized species play a more significant role in the formation of deposits from lignite coals. The formation of sodium and/or calcium magnesium sulfates dominates the deposit accumulation mechanisms at lower temperatures. The aluminosilicate phases are dominant above about 1800°F. Below about 1800°F, the sulfate phases become stable, with an optimum temperature of formation of about 1400°F, and can form at temperatures as low as 300°F.

The most significant problems that prohibit the successful operation of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates and phosphates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency (14–16).

INORGANIC COMPOSITION OF LOW-RANK COALS

Inorganic elements in coal occur as discrete minerals, organically associated cations, and cations dissolved in pore water. The fraction of inorganic components that are organically associated varies with coal rank. Lower-ranked subbituminous and lignitic coals have high levels of oxygen, which act as bonding sites for cations such as sodium, magnesium, calcium, potassium, strontium, and barium (other minor and trace elements may also be present in this form). In higher-ranked coals, bituminous and anthracite, inorganic components consist mainly of minerals. Mineral grains are usually the most abundant inorganic component in coal. The major mineral groups found in coals include silicates, aluminosilicates, carbonates, sulfides, sulfates, phosphates, and some oxides.

The behavior of ash produced during coal combustion is related to the abundance, size, and association of mineral grains in the coal. In addition, the association of the mineral grain with the coal matrix influences the temperature and gaseous environment the mineral is exposed to during combustion. A mineral associated with the organic part of a coal particle is said to be included. A mineral that is not associated with organic material is referred to as excluded. The behavior of the organically associated elements, those elements that are atomically dispersed in the coal matrix, must also be measured as to their abundance in the coal. The organically associated elements will react and interact with the other ash-forming constituents during combustion.

The Center lignite is highly variable in abundance of various types of ash/slag-forming constituents. Ash-forming components in the Center lignite are of two types. The first form may constitute up to 50% of the ash and is derived from inorganic elements (sodium, magnesium, calcium, and potassium) associated with oxygen functional in the organic matrix of the coal. The second type consists of mineral grains (sand, clay, limestone, and pyrite). The minerals are discrete particles of ash-forming species and the sources of silicon, aluminum, iron, titanium, and minor amounts of the calcium and potassium. The Center lignite fired at the Milton R. Young (MRY) plant has been examined extensively because of its problem with ash behavior. Analyses

of as-fired and drill core samples have been conducted. The mean and the range of selected components are shown in Figure 1. The results indicate that both the abundance of ash and the abundance of major oxides in the ash vary significantly. In addition, the abundance of alkali and alkaline-earth elements (Na and Ca) varied dramatically. Variations in Si were found to be the most significant. High levels of Ca and/or Na were found for lower-ash coals as compared to high levels of Al and Si associated with higher-ash coals (17, 18).

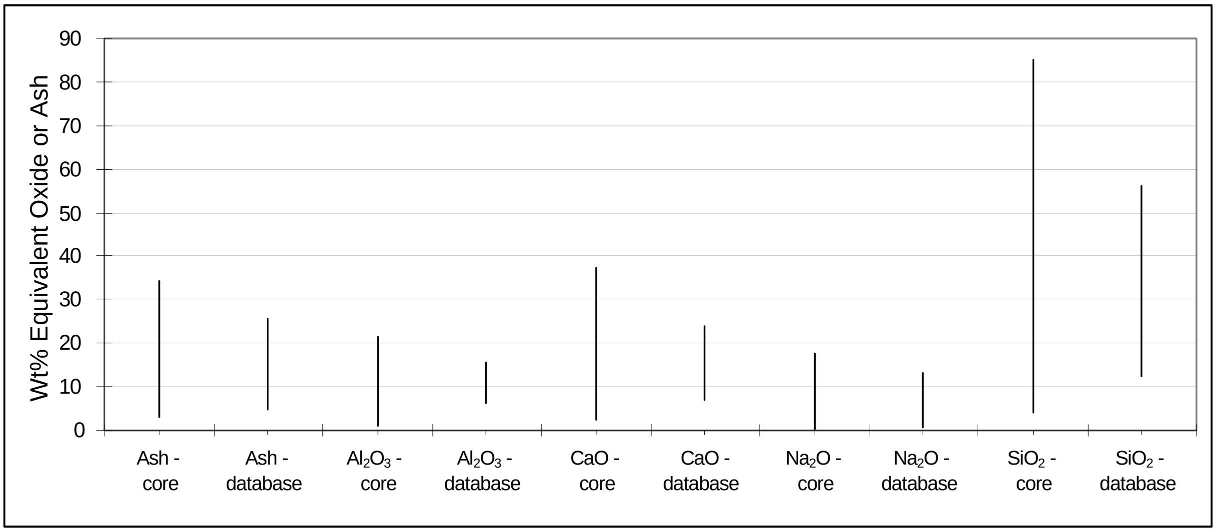

Figure 1. Variability of ash and selected constituents in core analysis database provided by BNI Coal, Ltd. and Minnkota as fired coal analysis database.

The variability of the ash-forming components has been examined for the approximately 5000 samples characterized to date. Wide variations in ash contents and the major ash-forming constituents are observed. During the mining processes, the inorganic components are mixed, and some of the extreme characteristics are diluted (17).

INORGANIC TRANSFORMATIONS AND ASH FORMATION

The inorganic coal components undergo complex chemical and physical transformations during combustion to produce intermediate ash species. The inorganic species consist of vapors, liquids, and solids. The partitioning of the inorganic components during combustion to form ash intermediates depends upon the association and chemical characteristics of the inorganic components, the physical characteristics of the coal particles, the physical characteristics of the coal minerals, and the combustion conditions.

The physical transformation of inorganic constituents depends on the inorganic composition of the coal and combustion conditions. The inorganic components can consist of organically associated cations, mineral grains that are included in coal particles, and excluded mineral grains. There is a wide range of combinations of mineral–mineral, mineral–coal,

mineral–cation–coal, and mineral–mineral–cation–coal associations in coal. These associations are unique to each coal sample.

The physical transformations involved in fly ash formation include 1) coalescence of individual mineral grains within a char particle, 2) shedding of the ash particles from the surface of the chars, 3) incomplete coalescence due to disintegration of the char, 4) convective transport of ash from the char surface during devolatilization, 5) fragmentation of the inorganic mineral particles, 6) formation of cenospheres, and 7) vaporization and subsequent condensation of the inorganic components upon gas cooling. As a result of these interactions, the ash has a bimodal size distribution. The submicron component is largely a result of the condensation of flame-volatilized inorganic components. The mass mean diameter of the larger particles is approximately 12 to 15 μm, depending upon the coal and combustion conditions. The larger-size particles have been called the residual ash by some investigators (19) because these ash particles resemble, to a limited degree, the original minerals in the coal. Processes such as ash mineral coalescence, partial coalescence, ash shedding, and char fragmentation during char combustion and mineral fragmentation, all play an important role in the size and composition of the final fly ash. Loehden and others (20) and Zygarlicke and others (21) indicate that three potential modes for fly ash generation can be used to describe fly ash particle-size and composition evolution. The first, “fine limit,” assumes that each mineral grain forms a fly ash particle and that the organically associated elements form fly ash particles of less than 2 μm. The second, “total coalescence,” assumes one fly ash particle forms per coal particle. The third, “partial coalescence,” suggests that the fly ash composition and particle size evolve because of partial coalescence.

The transformations of excluded minerals are dependent upon the physical characteristics of the mineral. Excluded minerals such as quartz (SiO_2) can be carried through the combustion system with its angular structure still intact. Excluded clay minerals can fragment during dehydration, melt, and form cenospheres. The behavior of excluded pyrite depends upon its morphology. Some of the pyrite may be present as framboids. Framboidal pyrite may fragment more easily than massive pyrite particles. In addition, the decomposition of pyrite is very exothermic, and it transforms to pyrrhotite and oxidizes to FeO, Fe_3O_4, and Fe_2O_3 during combustion.

ASH DEPOSITION ON HEAT-TRANSFER AND OTHER SURFACES EXPOSED TO ASH AND FLUE GAS

The characteristics of a deposit depend upon the chemical and physical characteristics of the intermediate ash species, geometry of the system (gas flow patterns), gas temperature, gas composition, and gas velocity. Figure 2 illustrates the ash deposition phenomena in utility boilers. Ash particle accumulations occur via transport of particles to the fireside surfaces (heat transfer, ceramic materials, support materials, SCR catalysts, baghouse materials, and ESP wires and plates) and sticking of the particles. The transport mechanisms important for ash deposition include small-particle mechanisms for particles less than 10 μm that involve thermophoresis, electrophoresis, and vapor-phase and small-particle diffusion; and large-particle mechanisms for particles greater than 10 μm that involve inertial impaction. The ability of larger particles to stick depends upon the quantity and viscosity of the liquid phase on the particle surface.

Thermophoresis is a phenomenon that involves the transport of very small particles as a result of a thermal gradient from hot gases to cooler surfaces. Electrophoresis is the transport of particles because of a difference in charge. Vapor-phase and small-particle diffusion occurs in the boundary layer next to the surface and results in transport of ash to the surface. Inertial impaction is a larger-particle phenomenon where the particles are of a sufficient size and density to leave airflow patterns around the tube and impinge upon the surface of a tube or deposit. Deposits that form in high-temperature regions of the boiler, such as the radiant section, are called slag deposits. Deposits that form in lower-temperature regions of the boiler, such as in the convective pass on steam tubes and lower-temperature surfaces such as SCR catalysts, are called fouling deposits. Slag deposits are usually associated with a high level of liquid-phase components and are exposed to radiation from the flame. This is a description that many researchers use to aid in classification of deposits since some engineers call any type of deposit "slag". Slag deposits are typically dominated by silicate liquid phases, but may also contain moderate to high levels of reduced iron phases such as FeO and FeS. The liquid characteristics of the silicates are highly dependent upon the quantities of Na, Mg, Ca, K, and Fe ash on the silicates. In addition, the initiating layers of slag deposits may consist of very fine particulate and can produce a reflective ash layer. This phenomenon is especially evident when high organically associated calcium subbituminous coal is fired. These coals produce small CaO particles that usually form the initiating layers.

Fouling deposits form in the lower-temperature regions of the boilers and, in most cases, do not contain the high levels of liquid phases that are usually associated with slagging-type deposits. Fouling deposits contain lower levels of liquid phases as compared to slag deposits. The fouling deposit liquid phases usually consist mainly of sulfates that bind the particles together. Fouling deposits typically form as a result of the reaction of gas-phase sulfur oxide species with particles rich in alkali and alkaline-earth elements.

ASH-RELATED EXPERIENCES AT MRY FACILITY

The MRY is a minemouth electrical generating plant located near Center, North Dakota. The station consists of two units: Unit 1, rated at 276 MWg, began production in 1970; Unit 2, rated at 506 MWg, began production in 1977. Both Units 1 and 2 are equipped with B&W cyclone-fired boilers; the Unit 1 boiler has seven cyclones, and the Unit 2 boiler has twelve cyclones. Annual station gross generation is approximately 5.5 million MWh.

BNI Coal Ltd. is the sole coal supplier for the MRY Station. Coal is mined from the nearby Center mine, which consists of three distinct seams varying from 2½–9 feet thick. Coal is strip-mined using two draglines and is loaded with front-end loaders and delivered to the plant with bottom-dump haul trucks. Annual coal production is 4.3 million tons per year.

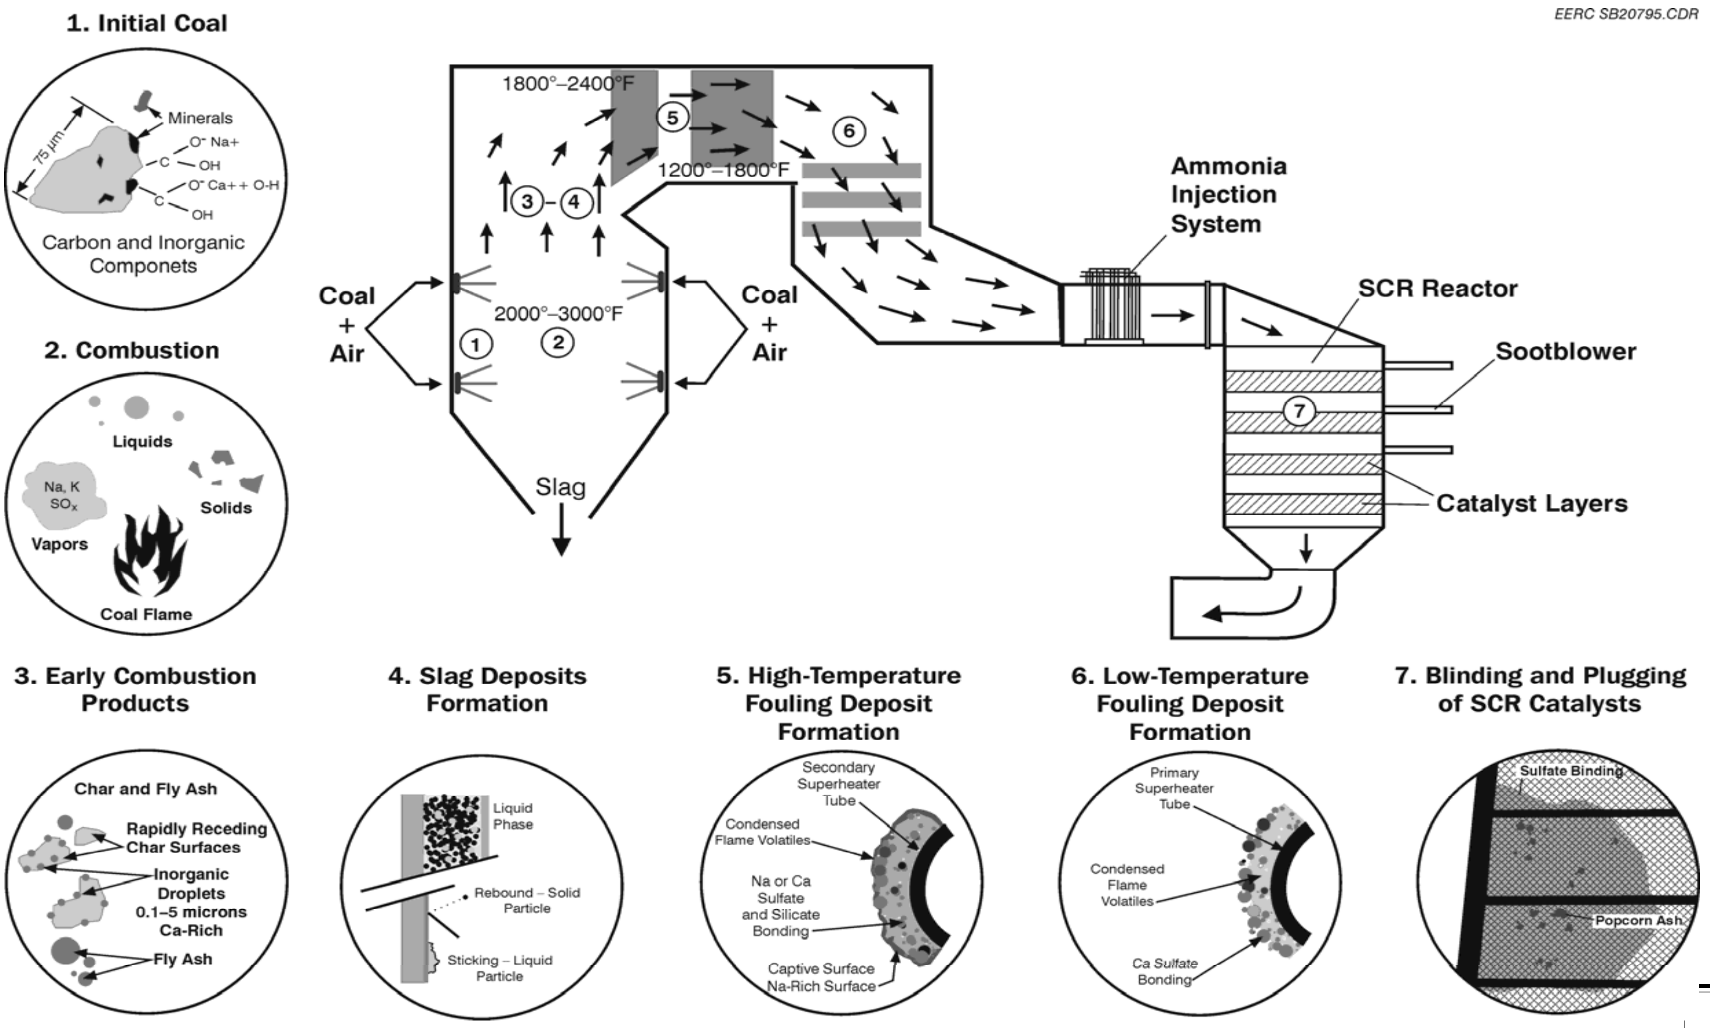

Figure 2. Overall processes of ash deposition typical of a lignite- or subbituminous-fired boiler.

History of Furnace Slagging/Fouling

Prior to 1991, besides annual maintenance outages, load reductions and forced outages due to furnace slagging/fouling were the largest cause of production loss. In 1985, operating guidelines were established that reduced furnace slagging/fouling, including deslagging outages scheduled every six months.

In 1991, a 3-month boiler cleaning cycle was proposed and initiated. The goal of this program was to increase annual generation by running the units at higher sustained loads and scheduling boiler-cleaning outages at 3-month intervals. However, furnace slagging/fouling continued to have a significant impact on plant operations. Success was measured in the number of production days between boiler-cleaning outages.

During the mid-1990s, a major outage every third year was scheduled for each unit. In addition, Unit 1 cleaning outages were scheduled for 80–90-day runs (four cleaning outages per year), and Unit 2 cleaning outages were scheduled for 65–75-day runs (five cleaning outages per year). The problem was that furnace and convection-pass surfaces gradually become coated with ash deposits, which, over time, sootblowers cannot remove. Some of the contributors to the ash deposits were as follows:

- Organically associated sodium is a primary contributor to deposition problems. Sodium is vaporized in the cyclones and condenses on other ash particles, causing them to become sticky and deposit at the furnace exit. The problem is associated with sulfate formation and occurs in the convective pass, including the economizer. Samples show that sodium in the ash varies from 0.6%–13.0%.

- Organically associated calcium is another component that causes deposition problems. Unlike sodium, calcium does not produce a vapor-phase component. Calcium does react with silicate (derived from clays) to cause low-melting-point phases that produce wall deposits and deposits in the high-temperature regions of the convective pass. Calcium also produces very small particles that will be transported to heat-transfer surfaces, resulting in the formation of thin, light-colored layers called reflective ash. These small particles of ash are carried through to the back passes where they are sulfated and can combine with sodium to cause the formation of strongly bonded sulfate-based deposits. Samples show that calcium in the ash varies from 6.8%–24.0%.

- Clay minerals and quartz – Center lignite can contain high levels of illite, which has a 1:3 Al:Si ratio and high levels of potassium, both of which cause wall slagging and high-temperature fouling. Quartz and other clays can significantly contribute to the mass of the deposits. Samples show that ash content varies from 5.0%–25.5%.

Advanced Boiler Performance Indices

Advanced indices are used to relate the coal characteristics as determined by computer-controlled scanning electron microscopy (CCSEM) and chemical fractionation to ash behavior in a coal-fired utility boiler (12). Fuel performance is estimated in terms of slag flow behavior,

abrasion and erosion wear, wall slagging, high-temperature silicate-based convective pass fouling, and low-temperature sulfate-based convective pass fouling. The following indices are used to assess the effects of ash behavior on utility boiler performance:

- Convective-Pass Fouling Indices

  Sulfation Index: Indicates the propensity of deposit to form in the convective pass of the utility boiler in the temperature range from 1000°–1750°F. This index is based on the availability of alkali (Na and K) and alkaline-earth (Ca and Mg) elements to react with SO_2 and SO_3 to form sulfates. The sulfates are the primary materials that cause particle-to-particle bonding in high-calcium coals. The sulfates are thermodynamically stable at temperatures below about 1650°F. Index values range from 1 (low) to 10 (severe).

  Silicate Index: Indicates the propensity of deposits to form from 1600°–2400°F. This index is related to the formation of deposits in which the silicate material is the primary component that bonds the deposits together. The information used to derive the index includes the size of the minerals such as quartz and clay minerals, availability of alkali and alkaline-earth elements, and viscosity of the silicate liquid phase. Index values range from 1 (low) to 200 (severe).

- Waterwall Slagging

  Slagging Index: Indicates the propensity of a deposit to form on the radiant walls from 2000°–3000°F. The basis of the slagging index is the size of the minerals (especially the illite, quartz, and pyrite), association of the calcium (calcite can contribute to slagging), and viscosity of the silicate-based liquid phase. Index values range from 1 (low) to 20 (severe).

- Wear Indices

  Abrasion Index: This index indicates the potential for wear of fuel preparation and handling equipment. The wear is related to the hardness of minerals in the coal. The primary minerals of concern include quartz and pyrite. The index values range from 0.1 (low) to 10 (severe).

  Erosion Index: This index indicates the potential for wear of boiler parts due to the impaction of fly ash particles. The erosion index is dependent upon the size of the ash/mineral particle, size of the particle, and velocity of the particle. The index values range from 0.1 (low) to 1.0 (severe).

- Cyclone Slagging Index: This index provides information on the slag flow behavior in cyclones. The factors that are included in this index include the partitioning of the ash in the cyclone based on size and association of the ash-forming components in the coal. The partitioning of the ash between the slag and entrained ash can significantly influence the flow behavior of the slag. Standard partitioning criteria have been developed to provide the composition of the slag. The composition is used to estimate the viscosity of the slag as a function of temperature. The index values have several ranges as follows: 1 (low viscosity), 1.5–2.5 (optimum viscosity), >3.0 (slag freezing).

- Strength Development Index: The strength index is based on the ability of the deposited material to develop strength. Strength development is primarily dependent upon the abundance and viscosity of the liquid-phase components in the deposits. Index values less than 0.25 indicate that the material will produce weak deposits; index values of 0.25–0.34 indicate weak-to-moderate-strength deposits; index values of 0.34–0.41 indicate high-strength deposits; and index values >0.41 indicate flowing slag.

Indices were calculated for a range of coals from the Center mine, and the propensity for ash deposition in various portions of the boiler indicates wide variations, as shown in Table 1. The BNI numbers indicate the location in the seams where the coal originated: Kinneman Creek seam (KC), Hagel A (HA), and Hagel (HB). Each seam has a different distribution of minerals and organically associated elements that can have a significant impact on the formation of deposits in the system. Comparison of Center lignite to subbituminous and bituminous coals from other regions of the United States, shown in Table 2, indicates significant differences in the potential to form deposits in the boilers. In all cases, the lignite (not the worst coal from Center mine) from the Center mine has a high propensity to produce deposits as compared to the other coals.

Another indication of the variability of lignites can be illustrated based on the calculation of the temperature where the slag flow would occur. This is defined as the T250 temperature, where the slag viscosity is 250 poise. Frequency distributions of the T250 values for all the data for coals analyzed are illustrated in Figure 3. Calculations of T250 values for 1212 samples obtained from the Center mine database (17) were made using empirical relations derived from CCSEM and chemical fractionation data and knowledge of how ash partitions in the cyclone. Figure 3 shows a bimodal distribution in the T250 based on the Urbain equation calculations. The primary mode was at a value of 2000°F. The secondary mode was at about 2700°F. The results indicate that many of the coals have a sufficiently low T250 for good slag flow. However, coals with T250 at 2700°F are not suitable for maintaining good slag flow.

Figures 4 through 6 illustrate the variations in T250 for the various seams of coals characterized. The HA and HB seam coals appear to have large numbers of samples, with T250 values at or near 2000°F. The KC seam coal, as illustrated in Figure 6, has extremely high T250 values. Based on these data, the KC coals are not favored relative to the slag flow behavior of the ash.

Frequency distributions of cyclone slagging index values indicated significant variations in slagging potentials of coals mined from the three seams, KC, HA, and HB. This information proved particularly useful in planning the mining and firing of coal from the KC seam.

During a July 1999 test burn, the composition of the cores was used to examine and illustrate the variability of the delivered coal quality based on base-to-acid ratio calculated from the ash composition. Figure 7 shows the variation in the base-to-acid-ratio and the seam where the coal was loaded. The base-to-acid ratios were calculated from core data that corresponded to the location in the seam where the coal was mined. There is a significant variation in the base-to-acid ratio for the coals. The coals that have the highest base-to-acid ratio are typically from the HA seam. HB seam coals generally have an intermediate base-to-acid ratio. KC or top-seam coal has the lowest base-to-acid ratio. Lower base-to-acid-ratio coals typically produce slag with high viscosities.

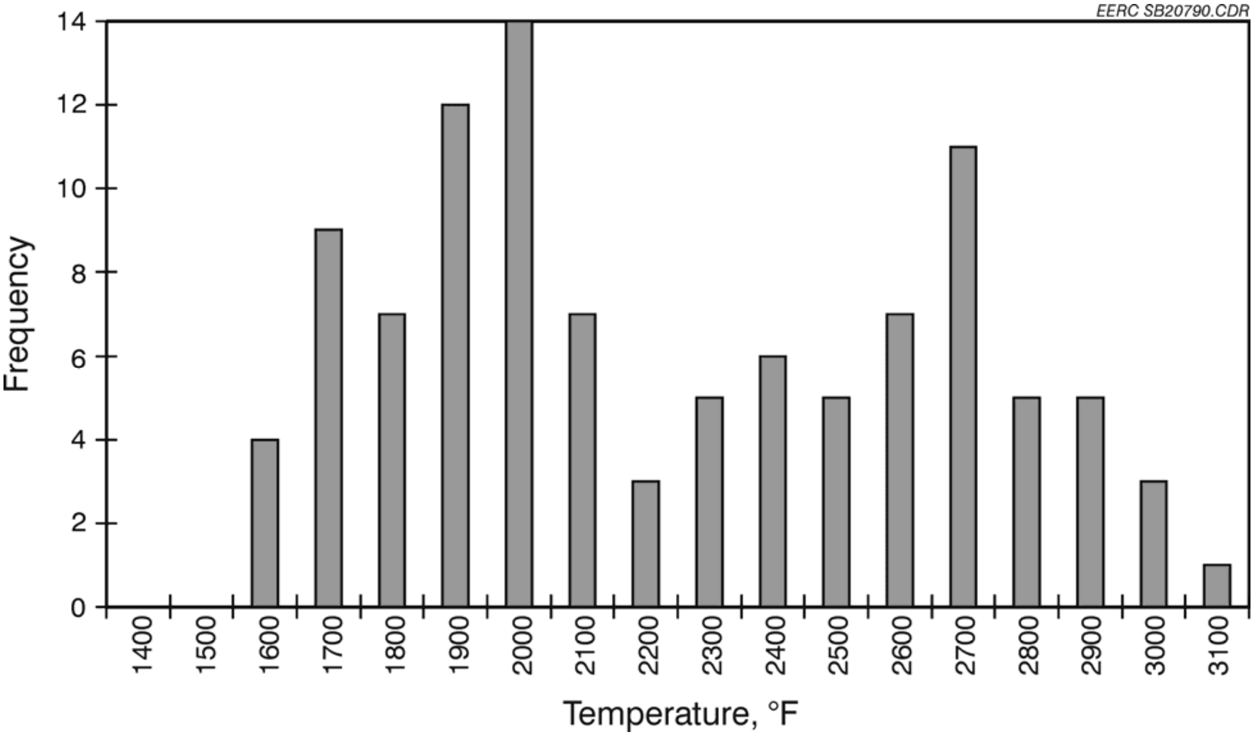

Figure 3. T_{250} frequency distribution for all Coal Quality Management System (CQMS) data, °F.

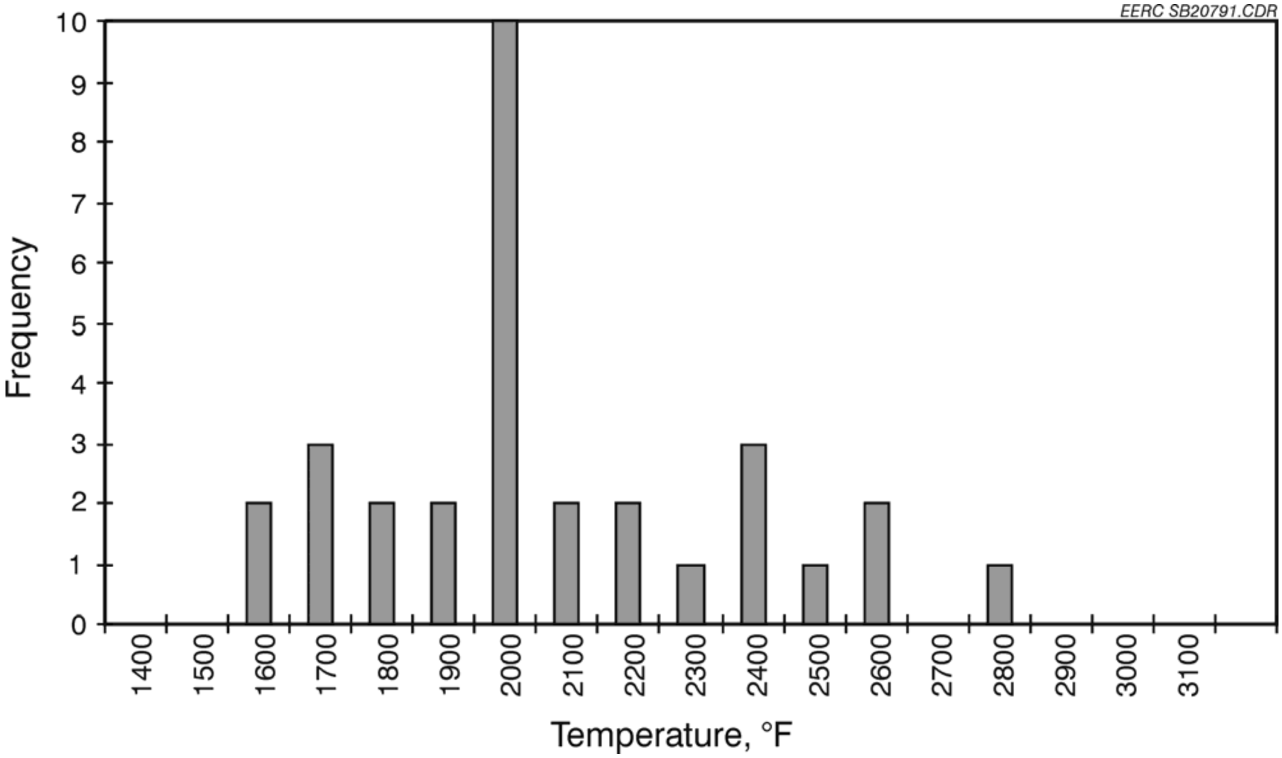

Figure 4. T_{250} distribution for HA seam coal.

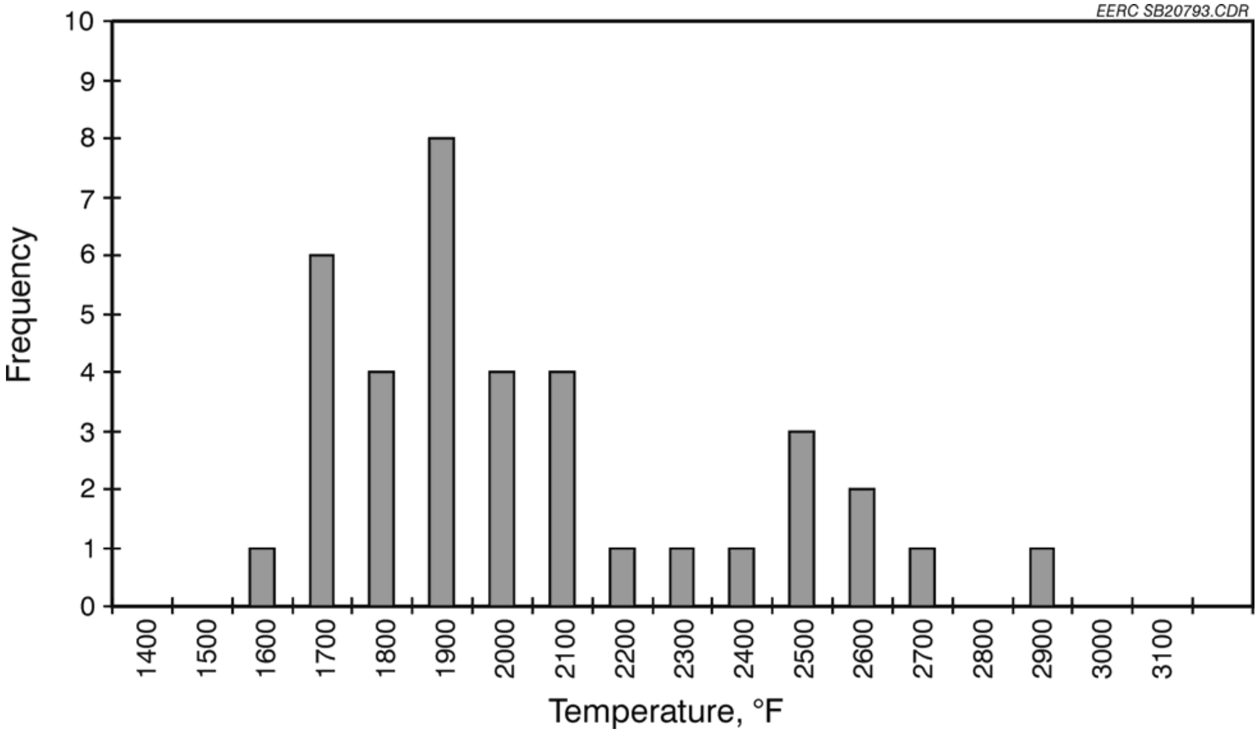

Figure 5. T_{250} distribution for HB seam coal.

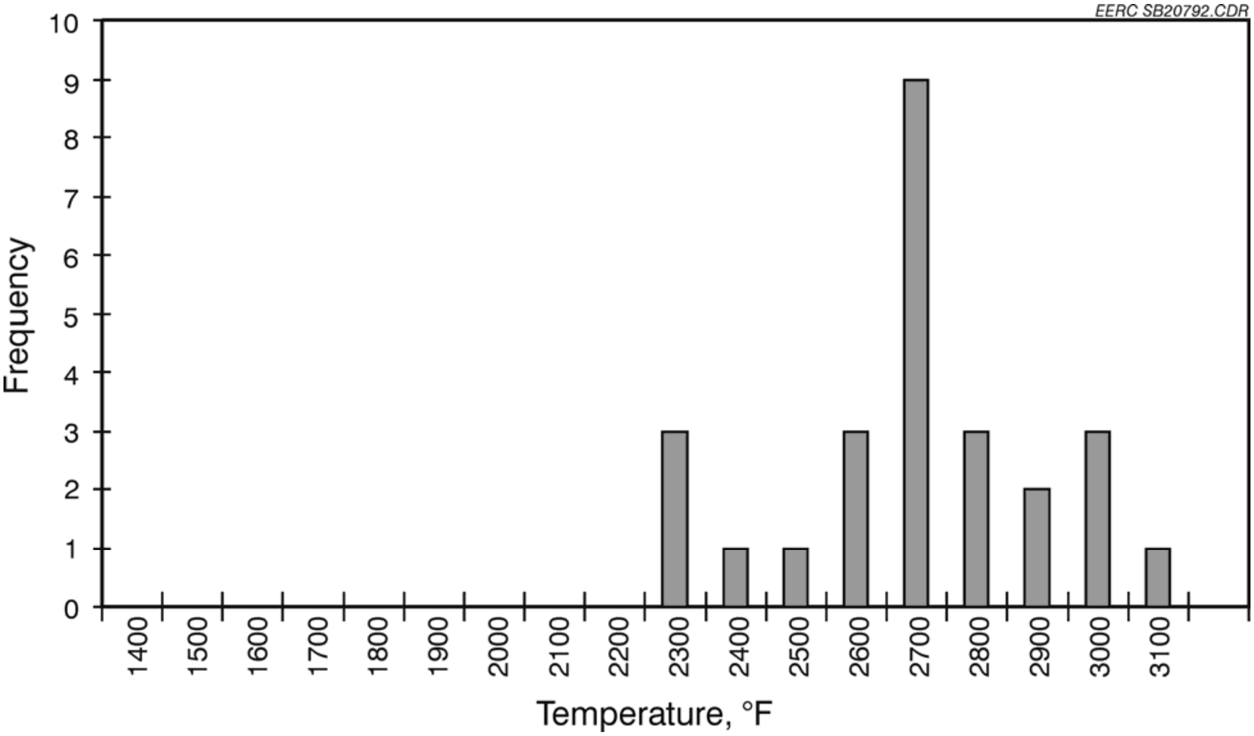

Figure 6. T_{250} distribution for KC seam coal.

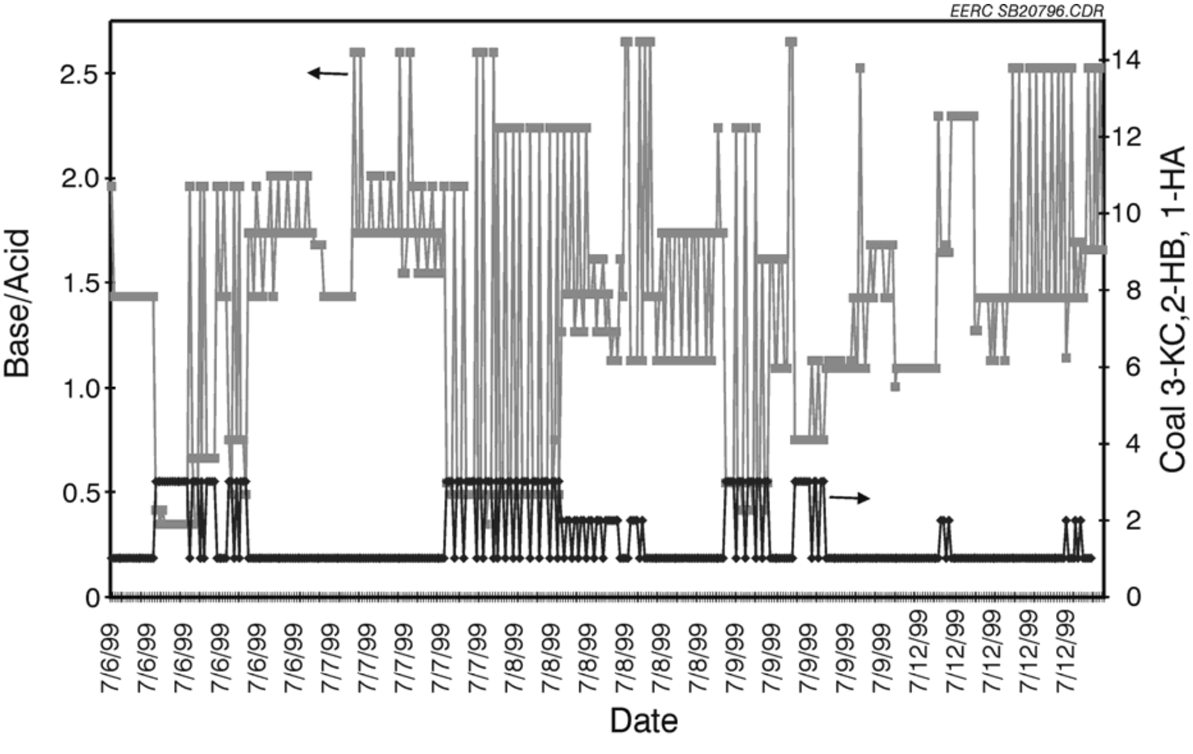

Figure 7. Variations in the delivered coal quality during a test burn period.

Figure 7 shows the sequence of deliveries beginning on July 6 and ending on July 12, 2004. During this period, the majority of the coal delivered was from the HA seam, followed by KC, and HB. Most of the deliveries alternated between KC and HA. Figure 6 shows several instances where significant quantities of KC coal were delivered, on July 6 through July 9. The quantity of KC coal delivered will have the potential to increase the viscosity of the slag and result in poor slag flow from the cyclones.

ASH-RELATED IMPACTS ON SCR CATALYST PERFORMANCE

Ash-related impacts on SCR catalyst performance will depend upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design (14–16, 22). The problems currently being experienced on SCR catalysts include the following:

- Formation of sulfate- and phosphate-based blinding materials on the surface of catalysts.
- Carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing on top of the SCR catalysts.

Licata and others (14) conducted tests on a South African and German Ruhr coal and found that the German Ruhr coal significantly increased the pressure drop across the catalyst because of the accumulation of ash. They found that the German coal produced a highly adhesive ash consisting of alkali (K and Na) sulfates. In addition, they reported that the alkali elements are in a water-soluble form and highly mobile and will migrate throughout the catalyst material, reducing active sites. The water-soluble form is typical of organically associated alkali elements in coals. The German Ruhr Valley coal has about 9.5% ash and 0.9 % S on an as-received basis, and the ash consists mainly of Si (38.9%), Al (23.2%), Fe (11.6%), and Ca (9.7%), with lower levels of K (1.85%) and Na (0.85%) (15). Cichanosicz and Muzio (16) summarized the experience in Japan and Germany and indicated that the alkali elements (K and Na) reduced the acidity of the catalyst sites for total alkali content (K+Na+Ca+Mg) of 8%–15% of the ash in European power plants. They also found that alkaline-earth elements such as calcium react with SO_3 on the catalyst, resulting in plugging of pores and a decrease in the ability of NH_3 to bond to catalyst sites. The levels of calcium in the coals that caused blinding ranged from 3%–5% of the ash.

The mechanisms for this type of low-temperature deposition have been examined and modeled in detail at the Energy & Environmental Research Center (EERC) in work termed Project Sodium and Project Calcium in the early 1990s; however, the focus of those projects was specific to primary superheater and economizer regions of boilers and not SCR systems (22, 23). Deposit buildup of this type can effectively blind or mask the catalyst, diminishing its reactivity for converting NO_2 to N_2 and water and potentially creating increased ammonia slip (14). Arsenic and phosphates, which are not uncommon in low-rank coals, may also play a role in catalyst degeneration. Arsenic is a known catalyst poison (14) in applications such as catalytic oxidation for pollution control. Phosphates can occur in low-temperature ash deposits to create blinding effects, and they also occur with arsenic and can cause catalyst poisoning (23).

Lignite and subbituminous coals produce ash that plugs and blinds catalysts (25–28). The problems currently experienced with SCR catalysts include the formation of sulfate- and phosphate-based blinding materials on the surface of catalysts and the carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing them on top of the SCR catalysts (14). The most significant problem that limits the successful application of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates, phosphates, and possibly carbonates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency (14–16, 27–28). The degree of the ash-related impacts on SCR catalyst performance depends upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design (15–16, 24, 27–28).

In studies (7) the impacts of temperature and the presence of catalyst on the ability of ash to sulfate were examined. The tests were conducted using a thermogravimetric analyzer (TGA). TGA testing was conducted using a <5-µm-size fraction of ash produced from Powder River Basin (PRB) coals and lignites and exposing them to vapor-phase sulfur dioxide with and without catalyst at several temperatures. The aim of the testing was to determine the potential of the formation of sulfates to cause particle-to-particle bonding that leads to the formation of deposits in the temperature range where SCR catalysts are used. The TGA testing is focused on determining the reactivity of the <5-µm ash produced from selected PRB and blends to sulfur dioxide and gas-phase phosphorus species as a function of temperature. Testing was conducted to determine the weight gain with flue gas containing ammonia. The impact temperature on the weight gain due to the formation of sulfates for a PRB blend is shown in Figure 8. The rates of sulfation were found to increase with increased temperature. The results show an increase in the weight gains when ammonia and phosphorus were added. Ground catalyst was mixed with PRB and placed in the TGA. Increases in weight gain were observed when catalyst was added as compared to baseline cases for 100% PRB, as shown in Figures 8 and 9, respectively. The presence of catalyst enhances the formation of sulfates.

Full-Scale Slipstream Testing

More recently (8), the behavior of ash and mercury in flue gas produced from the combustion of lignite and subbituminous coals from the United States of America in selective catalytic reduction (SCR) systems for nitrogen oxide removal has been examined. Typically, these coals contain ash-forming components that consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, these coals produce ash that has an abundance of alkali and alkaline-earth-rich oxide particles (<5 µm) that are carried into the backpasses of the combustion system and react with flue gas to form sulfates and possibly carbonates. The forms of mercury in the flue gas produced from the lignite and subbituminous coals are dominated by the elemental form. Slipstream testing was conducted at two subbituminous-fired power plants and one lignite-fired power plant to determine the impacts of ash on SCR plugging, blinding, and mercury oxidation.

The SCR slipstream system consists of two primary components: the control room and the SCR reactor. The reactor section consists of a catalyst section, an ammonia injection system, and sampling ports for NO_x at the inlet and exit of the catalyst section. The control room houses a computer system that logs data and controls the gas flow rates, temperatures, pressure drop across the catalyst, and sootblowing cycles. The computer is programmed to maintain constant temperature of the catalyst, gas flow rates, sootblowing cycles, and ammonia injection. The computer is equipped with a modem that allows for downloading of data and modification of the operation of the reactor from a remote computer located at the EERC.

Flue gas is isokinetically extracted from the convective pass of the boiler upstream of the air heater. The temperature is typically about 790°F. The flue gases pass through a 4-inch pipe equipped with sampling, thermocouple, and pressure ports. Ammonia is injected into the piping upstream of the reactor section. The reactor consists of a steel housing that is approximately 8.5 inches square and 8 feet long. The reactor section has three components, including a flow straightener, a pulse section or sootblower, and a catalyst test section. A metal honeycomb is used as a flow straightener upstream of the catalyst section and is about 6 inches long. A purge section was installed ahead of the catalyst test section to remove accumulated dust and deposits. The catalyst test section is located downstream of the purge section. The entire catalyst section is insulated and equipped with strip heaters for temperature control. The catalyst test section is 3.28 ft (1 m) in length and houses three catalyst sections. Thermocouple and pressure taps are located in the purge sections for measurements before and after each section.

The induced-draft fan is used to extract approximately 400 acfm (200 scfm) of flue gas from the convective pass of the utility boiler to achieve an approach velocity of 5.2 m/s (17.0 ft/s). The gas velocity is similar to that found in full-scale applications. The total gas flow through the reactor represents a thermal load of approximately 300 kW.

The range of operating conditions for the reactor is listed below:

- Gas temperature: ~700°–800°F
- Gas flow rate: 400–500 acfm
- Approach velocity range: 5.0–5.5 m/sec
- Ammonia injection rate: 0.5:1 with NO_x level
- Tempering air for fan: ~ 50–200 scfm
- Catalyst dP: 0.5–1.0 inches water column
- Fan sized for up to 30 inches water column

The catalyst installed at the Baldwin and Coyote Stations was the Haldor Topsoe catalyst. Topsoe's DNX-series of catalysts comprises SCR DENOX catalysts tailored to suit a comprehensive range of process requirements. DNX-series catalysts are based on a corrugated, fiber-reinforced titanium dioxide (TiO_2) carrier impregnated with the active components vanadium pentoxide (V_2O_5) and tungsten trioxide (WO_3). The catalyst is shaped to a monolithic structure with a large number of parallel channels. The unique catalyst design provides a highly porous structure with a large surface area and an ensuing large number of active sites. The pitch of the catalyst was approximately 6 mm.

The catalyst installed at the Columbia Station was a Babcock Hitachi plate-type catalyst. This catalyst is a TiO_2-based plate catalyst, developed and manufactured by Hitachi. The pitch of the catalyst was approximately 10 mm.

The coals produced ash that had significant accumulations of ash on the catalyst on both macroscopic and microscopic levels. On a macroscopic level, there were significant observable accumulations that plugged the entrance as well as the exit of the catalyst sections. On a microscopic level, the ash materials filled pores in the catalyst and, in many cases, completely masked the pores within 4 months of operation.

The deposits on the surfaces and within the pores of the catalyst consisted of mainly alkali and alkaline-earth element-rich phases that have been sulfated. The results of this testing found that the <5-µm ash rich in alkali and alkaline-earth elements is captured on the surface and within the catalyst pores. These materials react with SO_2/SO_3 in the flue gas, resulting in the formation of a continuous phase that blinds the catalyst. The ability of elemental mercury to be oxidized across the SCR catalyst was investigated at a North Dakota lignite-fired plant. These results showed no oxidation of mercury across the SCR catalyst.

The reactor was installed at the Baldwin Station and operated for a 6-month time period on the Haldor Topsoe catalyst. The information obtained from testing included pressure drop, sootblowing cycles, and reactor temperatures. Figure 10 show the pressure drop across the catalyst test periods from 0 to 2 months. During the first two months of operation, the pressure was about 0.5 inches of water; at the end of two months, the pressure drop was about 0.8 inches of water, indicating plugging had occurred. The air was pulsed a minimum of every 8 hours in an attempt to maintain cleanliness. The reactor was monitored on a daily basis, and adjustments in pulsing cycles were made in order to minimize deposit accumulation. However, for the first two months, the pressure drop steadily increased. There are several periods where the unit was taken off-line; during those times, the temperature of the catalyst was maintained. At 2-month intervals, a section of catalyst was removed and replaced with a new one.

For Months 2 through 4, the pressure drop was highly variable initially but was about 0.8 inches of water. From Months 4 through 6, the pressure drop was maintained between 0.6 and 0.8 inches of water. This is due to the installation of a fresh catalyst section and leaving two thirds of the catalysts in place that were partially plugged. The gas velocity in the single section of new, clean catalyst was high because of channeling, and the result of the high gas flow was less deposition and accumulation. Gas velocity has a significant impact on the potential for deposits to form. However, at high gas velocity, low NO_x conversion is likely.

The reactor was installed at the Columbia Station and operated for a 6-month period of time with the Babcock Hitachi catalyst. The information obtained from the testing included pressure drop information, sootblowing cycles, and reactor temperature. Figure 11 shows the test periods from 0 to 2 months. The pressure drop across the SCR upon installation was about 0.4 inches of water and increased to an average of about 0.5 inches of water, but ranged from less than 0.4 to greater than 0.8 inches of water. The pressure drop for Months 2 to 4 increased from about 0.5 to 0.7 inches of water because of accumulation of ash. After cleaning the reactor and replacing one catalyst section, the pressure drop was about 0.3 but increased to over 0.6 inches of water up to about 4100 hours. There was an outage at the plant, and aggressive pulsing of the reactor was conducted; the pressure drop was brought back down to 0.3 but rapidly increased to over 0.5 inches of water within 500 hours.

The same reactor that was installed at the Baldwin Station was moved and installed at the Coyote Station. In addition, the same Haldor Topsoe catalyst type was used in the reactor. The reactor was operated for a 6-month period of time. Figure 12 shows the test periods from 0 to 2 months. As this paper is being prepared, the reactor is still operating on-site. The pressure drop across the catalyst upon installation was about 0.4 inches of water. After only 750 hours, the pressure drop was 1.5 inches of water, indicating significant plugging and blinding. Very aggressive air pulsing was conducted, with little success in removing the deposits. The pressure drop for the catalyst was over two times greater than the pressure drop observed for the Baldwin Station utilizing the same reactor and same catalyst. At about 1700 hours, the reactor was cleaned, and a section of catalyst was removed for characterization. The pressure drop after cleaning was about 0.8 to 1.0 inches of water. The pressure drop did not increase as rapidly because of the higher velocities through the clean section of the catalyst.

The tops of the catalysts were photographed during inspection and sampling of the catalyst sections. Figure 13 shows the ash materials that accumulated on the catalyst inlet after 2 months of operation. The most significant accumulation was noted for the Coyote Station, followed by Columbia and Baldwin. The Coyote Station had some larger pieces of ash deposit material on the surface as well as plugging of the catalyst passages. The Baldwin Station showed some obvious deposition along the walls of the reactor and some accumulation on the inlet sections. The Columbia Station showed more significant accumulation and plugging than the Baldwin Station.

After 4 months, the tops of the catalysts were photographed during inspection and sampling of the catalyst sections, as shown in Figure 14. The most significant accumulation was noted for the Coyote Station and some accumulation for the Baldwin Station.

SCR Ash Deposit Characterization

The characteristics of the ash materials that collected on the catalyst surfaces and pores were characterized by SEM and x-ray microanalysis and, in selected cases, XRD was used to determine the crystalline phases present. The catalysts were sampled after 2, 4, and 6 months. The sections were sampled, and approximately 2.5-cm squares were mounted for SEM analysis on double-stick tape and in epoxy resin. The double-stick tape samples allowed for characterization of the external morphology of the particles and catalyst surface. The samples mounted in resin were cross-sectioned and polished, which allowed for more detailed and quantitative analysis of the bonding materials and materials that accumulated in the pores of the catalyst. Detailed information on all the samples can be found elsewhere (add FPT reference). Examples of two deposit and catalyst analysis are presented here.

The 6-month sample from the Baldwin Station showed extensive sulfation of the alkaline-earth elements present in the deposits. Figures 15a and 15b show regions of the catalyst where all the pores were blocked and a minimal amount of deposit on the surface of the catalyst. Figure 15c shows a higher-magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The chemical compositions of selected points that indicate the presence of high levels of calcium and sulfur are listed in Table 3. There is much more extensive bonding of the materials with the sulfate matrix as compared to the 2-month sample. In addition, there are some regions of high levels of calcium, aluminum, and sulfur present. The calcium aluminum materials are likely derived from the calcium aluminum phosphate minerals found in the coal fired at this plant.

The 4-month sample from the Coyote Station showed particles adhering to the surface and filling pores in the catalyst. Figure 16 shows the 4-month sample from the Coyote Station. The catalyst showed particles adhering to the surface and completely filling and masking the pores in the catalyst. The external morphology of the catalyst surface shows the masking of the catalyst surface. Chemical compositions of selected points are shown in Table 4. The 4-month sample shows more sulfation than the two months of exposure samples. Figures 16b and 16c shows a higher-magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of sodium-, calcium-, and sulfur-rich material, likely in the form of calcium sulfate. Significant sodium was found in the deposits, as shown in Table 4. The sample shows significant evidence of sulfation after 4 months of exposure and was much more pronounced than the samples for the Baldwin and Columbia Stations that are fired on PRB coals. The presence of sodium enhances the bonding and sulfation of the particles to form a strongly bonded matrix (22).

SCR Deposit Formation Mechanisms

The mechanism for the formation of deposits that blind SCR catalysts involves the transport of very small particles rich in alkali and alkaline-earth elements, the surface of the catalyst, and reactions with SO_2/SO_3 to form sulfates. The formation of SO_3 from SO_2 is catalyzed by the SCR; this, in turn, increases the reaction rate of SO_3 to form sulfates. In some cases, the alkali and alkaline-earth elements will also react with CO_2 to form carbonates. XRD analysis identified $CaSO_4$ as a major phase and $Ca_3Mg(SiO_4)_2$ and $CaCO_3$ as minor phases.

Lignite and subbituminous coals contain high levels of organically associated alkali and alkaline-earth elements including sodium, magnesium, calcium, and potassium, in addition to mineral phases. The primary minerals present in these coals include quartz, clay minerals, carbonates, sulfates, sulfides, and phosphorus-containing minerals (6).

During combustion, the inorganic components in the coal are partitioned into various size fractions based on the type of inorganic component, their association in the coal, and combustion system design and operating conditions. Significant research has been conducted on ash formation mechanisms and relationships to impacts on power plant performance (1–6, 9–13, 19–21, 29). During combustion, the inorganic components associated with western subbituminous and lignite coal typically are distributed into various size fractions of ash. The smaller size fractions of ash are dominated by partially sulfated alkali and alkaline-earth elements. These ash particles are largely derived from the organically associated cations in the coal. The larger size fraction has higher levels of aluminum and silicon derived from the mineral fraction of the ash-forming component of the coal. Entrained ash was extracted from the Columbia Station at the point of the inlet to the SCR reactor and was aerodynamically classified and analyzed. The composition of the size fractions was compared to the chemical composition of the ash deposited on and in the catalyst, as shown in Figure 17. The comparison shows that the composition of the particle captured in the SCR catalyst is very similar to the <5-µm size fraction. The deposited material shows significantly more sulfation than the entrained-ash size fraction, indicating that the sulfation process occurs after the particles are deposited in the catalyst.

The mechanism of SCR catalyst blinding when firing lignite or subbituminous coals is shown in Figure 18 (30). The requirements for the formation of deposits that blind SCR catalyst include firing a coal that produces significant levels of <5-µm-sized particles. The particles are transported into the pores of the catalyst and subsequently react with SO_3 to form sulfates. The sulfate forms a matrix that bonds other ash particles. The SCR catalyzes the formation of SO_3 and thereby increases the rate of sulfation (24, 25). The sulfation of CaO increases the molar volume, resulting in the filling of the pore. For coals that have high sodium contents, formation of low-melting-point phases such as pyrosulfates is possible (31). Pyrosulfate materials can melt at temperatures as low as 535°F in coal-fired power systems.

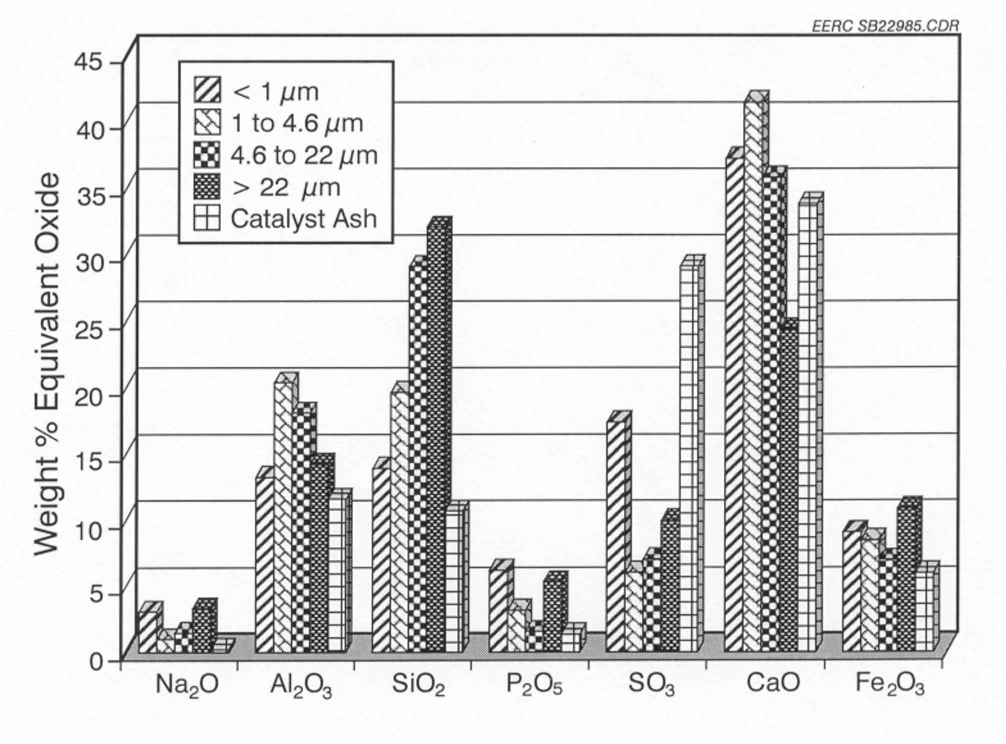

Figure 17. Comparison of entrained ash and deposited ash on catalyst for Columbia Station.

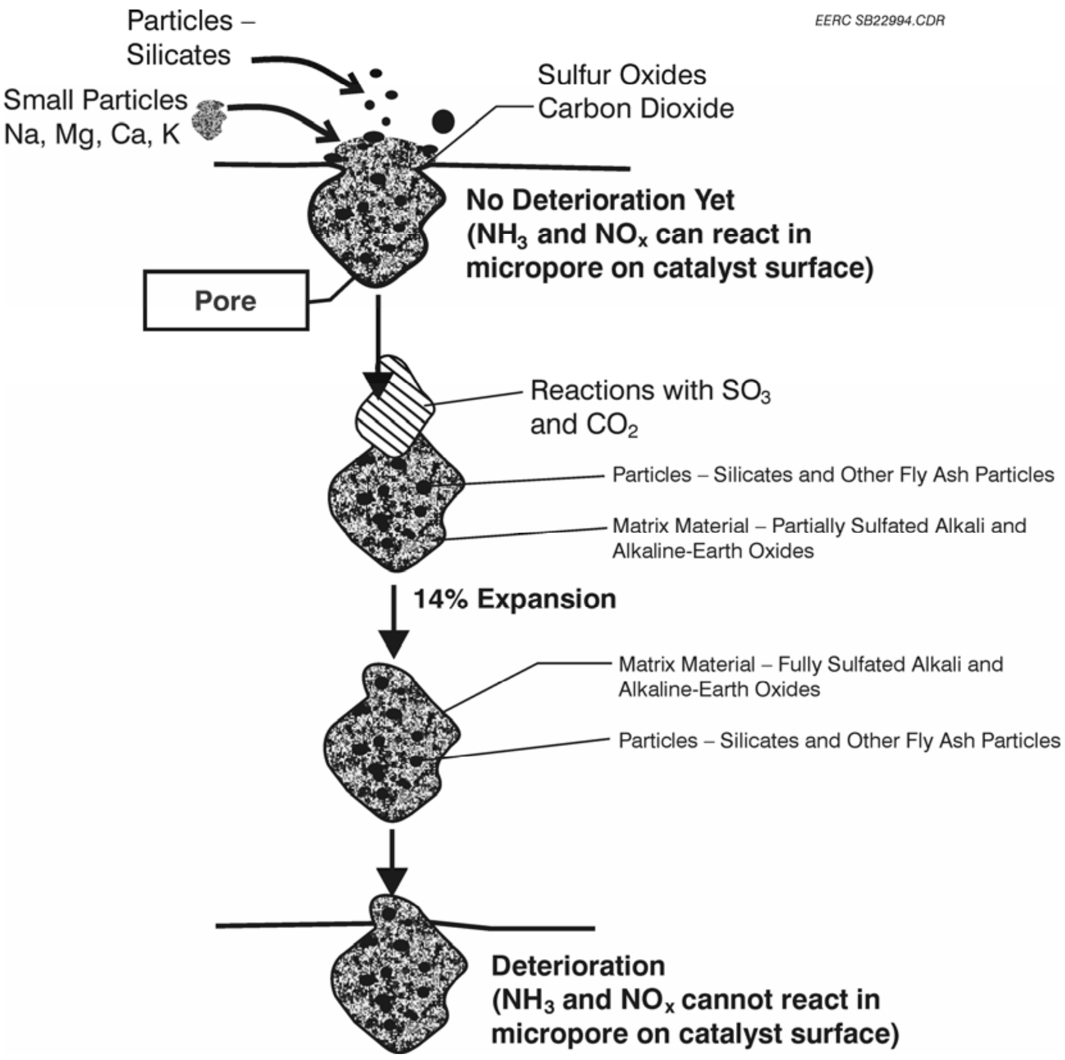

Figure 18. Mechanism of SCR catalyst blinding via the formation of sulfates and carbonates (modified after Pritchard and others [30]).

Low-Temperature Pyrosulfates

The presence of sodium sulfate in the flue gas exiting a scrubber will cause problems to low-dust and tail-end devices such as selective catalytic reduction (SCR) systems for NO_x reduction. There are two problems associated with the fine particulate rich in sodium sulfate on downstream devices. These include accumulation of fine particles on the SCR that, when sootblown, will cause opacity problems, and that the fine particles on the SCR will form pyrosulfates such as $(K_{1.5}Na_{0.5})S_2O_7$ that have melting points as low as 535°F (31) that will blind the catalyst. The presence of these compounds in low-temperature corrosion deposits is well known (32). In addition, the presence of SO_3 enhances the formation of the low-melting-point pyrosulfates (31). The sodium sulfate materials will cause opacity and SCR catalyst blinding problems that limit the feasibility of the low-dust or tail-end SCR technology for use with high-sodium lignite coals.

The sodium sulfate materials will be transported to the catalyst surfaces by diffusion, electrophoresis, and, possibly, inertial impaction. The particles are held in place by weak electrostatic and van der Waals forces. Once accumulation takes place, the sodium sulfate particles will react with flue gas components, resulting in the formation of pyrosulfates. The formation of pyrosulfates involves the following processes (31):

1. Formation of sulfates such as Na_2SO_4 and K_2SO_4
2. Conversion of SO_2 to SO_3 in the bulk gas phase – catalytically active surface such as an SCR catalyst – $SO_2 + \frac{1}{2} O_2 \rightarrow SO_3$
3. Pyrosulfate formation – $Na_2SO_4 + SO_3 \rightarrow Na_2S_2O_7$

The melting points of selected pyrosulfate phases are shown in Table 5.

Table 5. Melting Points of Selected Pyrosulfate Compounds

Compound	Temperature, °C	Temperature, °F
$K_3Fe(SO_4)_3$	618	1144
$K_3Al(SO_4)_3$	654	1209
$KFe(SO_4)_2$	694	1281
$Na_3Fe(SO_4)_3$	624	1155
$Na_3Al(SO_4)_3$	646	1195
$NaFe(SO_4)_2$	690	1274
$Na_2S_2O_7$	401	754
$K_2S_2O_7$	300	572
$(K_{1.5}Na_{0.5})S_2O_7$	279	535

Melting points for pyrosulfates between 535° and 770°F have been reported in the literature. Much of the past work has focused on the formation of these phases on tube surfaces. These species contribute to the corrosion of heat-transfer surfaces in coal-fired power plants. The exact melting point depends on the relative amounts of sodium and/or potassium.

There is significant evidence for the formation of sodium-rich fine particulate in full-scale power plants when firing high-sodium-containing coals. For example, Minnesota Power's Boswell Energy Station found that when it fired high-sodium, lower-ash subbituminous coal, it experienced increases in opacity. Hurley and Katrinak (33) conducted a field-testing project on Unit No. 4, a pulverized coal-fired boiler equipped with an electrostatic precipitator and a wet scrubber, to better understand the reasons for the opacity problems. During the field testing, sampling of the coals, flue gases, and scrubber materials was conducted. The particulate in flue gases downstream of the scrubber was aerodynamically classified using an impactor and multicyclone. The sized fractions were analyzed to determine the composition of the submicron-sized fraction.

The results of the study indicated that the particulate collected downstream of the scrubber was coal-related and caused by the high sodium content of one of the coals. Vapor-phase sodium condenses in the convective pass to form fine sodium sulfate particles or other Na species that later react with ash particles. Pure Na_2SO_4 particles are too small to be removed by scrubbing.

CONCLUSION: SCR IS NOT FEASIBLE FOR NO_X REDUCTION AT MILTON R. YOUNG

The ash deposition behavior of the lignites from North Dakota is the most complex and severe of any coals in the world, and installation of catalysts for NO_x reduction is going to be impossible because of the formation of sodium calcium sulfates in the pores of the catalyst. Following is a list of the key roadblocks associated with lignites which have not been overcome and, in our opinion, make the installation of SCR catalyst at the MRY plant technically infeasible for NO_x control.

- High alkali and alkaline-earth elements present in the coal fired at the MRY plant form sulfates that blind the catalyst.
    - Cyclone-firing partitions the ash during combustion. As a result the level of sodium and calcium in the fly ash is enhanced and will increase the SCR catalyst blinding.
    - Sulfate reactions increase with increasing temperature, and the suggested temperature of installation at the MRY facility is higher than typical installations; therefore, sulfation problems are enhanced.
    - Sulfate formation is also enhanced by the presence of an SCR catalyst; this accelerates the sulfation reactions, causing blinding of the catalyst.
    - The high levels of sodium in the coals combined with calcium produces low-melting-point eutectic compounds that will melt on the surface.
    - Sulfates form on the surfaces of catalysts firing PRB coals. Lignites will be several orders of magnitude worse because of the higher levels of sodium.

- The ash components to impact SCR performance in Japan and Europe (14–16) include alkali and alkaline-earth elements that result in sulfate formation. The total calcium content and the sum of the calcium, magnesium, potassium, and sodium provide an indication of the problems that occur. For the coals fired at the MRY power plant, the CaO content ranges from 6.8%–19.99%, and the sum of the alkali and alkaline-earth elements range from 9.33%–29.87% of the ash. The levels of calcium in Center lignite are 2 to 4 times higher than the problematic coals in Japan and Europe.

- The finding or work conducted in Germany and Japan were confirmed by recent SCR catalyst slipstream testing that showed significant evidence of sodium and calcium-rich sulfate formation that fill and plug the catalyst at both lignite (North Dakota)- and subbituminous-coal-fired power plants. The results of this recent testing showed that the presence of sodium significantly enhanced the formation of bonding of particles and more rapid sulfation, filling of pores, and rapid increase in pressure drop across the catalyst.

- Deposit carryover, or popcorn ash, plugging the top of the SCR catalyst with deposit fragments, is a significant problem because of the extremely high deposition potential of the coal. The formation of deposits in various parts of the boiler requires continuous sootblowing. The deposit fragments are likely going to be carried with the bulk gas flow to the SCR catalyst, resulting in plugging.

- The variability of the lignite is a problem of unique concern at MRY. The deposition potential of the coal is always changing rapidly, resulting in rapid growth and formation of deposits in various sections of the boiler. Aggressive sootblowing of all fireside surfaces is already required to maintain full-load operation. The sootblowing of upstream heat exchange equipment will cause deposit fragments to be carried back to the SCR catalyst, and during sootblowing of the SCR catalyst, the entrainment of deposit fragments along with the sootblowing media will result in significant erosion of the catalyst surfaces.

The ash-related impacts of the lignites from North Dakota are the most complex and severe of any coals in the world, and installation of tail-end SCR systems for NO_x reduction will not be possible. The key problems associated with lignites that have not been overcome and, in our opinion, make the installation of tail-end SCR systems at the MRY plant technically infeasible for NO_x control at MRY's Units 1 and 2 are listed below:

X High-sodium lignite coal from the Center Mine Hagel A and B seam coal produces extreme levels of homogeneously condensed sodium sulfate that pass through the wet scrubber. In addition, the cyclone-firing system captures much of the ash as slag, resulting in a decrease in ash that is available for providing condensation sites for vapor-phase sodium compounds upon gas cooling. This results in an increased homogeneous condensation of sodium sulfate.

X These small particles pass through a wet scrubber and will accumulate on surfaces of tail-end SCR systems. The accumulated materials cannot feasibly be resolved through conventional sootblowing and cleaning technologies to remove the particulate.

X Recent testing with subbituminous and lignitic coals indicated a significantly higher level of pore filling and plugging in the catalyst exposed to lignite ash as compare to subbituminous coal ash. The catalyst pores as well as the catalyst surface in the lignite tests were completely coated with a sodium calcium sulfate material, while only pore filling was found in the subbituminous coal testing. The pressure drop across the catalyst exhibited for lignite was 4 to 5 times greater than that found for a catalyst exposed to subbituminous coal ash. The plugging occurred over a 1000 hour test period.

The formation of liquid pyrosulfate materials at temperatures as low as 535°F from sodium sulfate materials occurs in coal-fired power systems and is well documented. Pyrosulfates will form and cause blinding of tail-end SCR devices. In addition, SCR systems catalyze the formation of SO_3 from SO_2. The presence of SO_3 significantly enhances the formation of the pyrosulfates at MRY to an extreme level that cannot be dealt with effectively using cleaning technologies that exist today.

APPENDIX B

Technical Description of SO_2 Controls (B1)

Coal Data for Future PTE Case (B2)

B1 Technical Description of SO_2 Controls

B1.0 Fuel Switching

Fuel switching can be a viable method of fuel sulfur content reduction in certain situations. Often, coal combustion facilities are constructed to take maximum advantage of the particular combustion characteristics of a specific fuel. One such fuel is lignite, which is a low Btu content, high ash, high moisture, medium sulfur content fuel. A typical lignite boiler is physically larger than a similarly rated unit designed for bituminous or sub-bituminous fuel due to the lower heat content of the lignite. The lignite fueled boiler must burn a greater mass of coal each hour to achieve the same heat input due to the lower heat content of the lignite fuel. Therefore, ancillary equipment such as coal crushers/dryers and conveyors, ductwork, etc. are designed larger to handle the greater quantities of coal and flue gas. For this analysis, fuel switching would consist of changing from North Dakota lignite to Powder River Basin (PRB) sub-bituminous.

Firing sub-bituminous fuels such as PRB coal in boilers designed for lignite fuel results in a significantly lower coal feed rate for the same heat input, and lower flue gas quantities. If a lignite fired boiler is switched to PRB coal, gas velocities would slow approximately 20% in the boiler for similar heat inputs. Slowing the flue gas velocity affects heat transfer characteristics and steam generation capabilities. While the slower gas velocities may seem to enable additional heat extraction due to a lengthier gas residence time in the boiler, this is somewhat counterbalanced by the fact that the boiler operator must also maintain a minimum outlet temperature. Lower flue gas velocity, with the same flue gas heat capacity (PRB flue gas approx. 1.5% less than lignite), also translates into higher initial flue gas temperatures in the combustion zone, which might mean greater heat absorption in the waterwall portion of the furnace. However, an actual test burn is required to determine the exact effects.

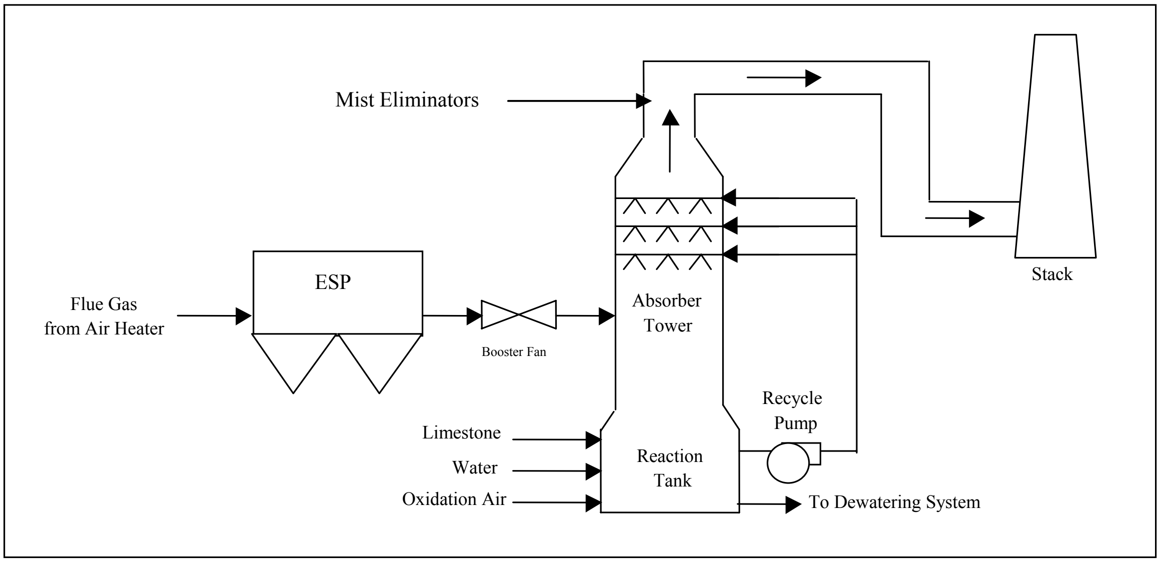
Switching to a fuel such as PRB coal will achieve significant SO_2 emission reductions. However, additional SO_2 control measures, such as post combustion controls might be required to achieve BART. Unfortunately, the removal efficiency of the post combustion technologies would be negatively affected by lower inlet flue gas SO_2 content. While a modern wet FGD system may readily achieve 95% SO_2 control on a medium or high sulfur fuel, when coupled with lower sulfur western fuels, the problem becomes one of diminishing returns. This should be easily understandable as one of the principal process variables affecting the performance of these systems is the inlet SO_2 concentration.

B2.0 Wet Flue Gas Desulfurization

Wet FGD technology utilizing lime or limestone as the reagent and employing forced oxidation to produce gypsum (calcium sulfate dihydrate, $CaSO_4{\cdot}2H_2O$) as the byproduct, is commonly applied to coal-fired boilers. The gypsum byproduct is either landfilled or sold for commercial reuse.

A flow diagram of the wet FGD process is provided in Figure B-1. In the wet FGD process, a slurry of finely ground limestone ($CaCO_3$) in water is recirculated through an absorber tower where it is brought into turbulent contact with the flue gas. The contact between the flue gas and the slurry cools and saturates the gas via evaporation of water from the slurry. SO_2 is simultaneously absorbed into the slurry where it forms sulfurous acid which reacts with the limestone, forming calcium sulfite hemihydrate ($CaSO_3{\bullet}½H_2O$) which can then be disposed of as a waste product or oxidized to calcium sulfate dihydrate or gypsum ($CaSO_4{\bullet}2H_2O$) before disposal or for commercial reuse. No commercial uses for sulfite waste products have been identified.

Figure B-1. Wet FGD Process Flow Diagram



Chemical reactions between the limestone and the absorbed SO_2 take place within the slurry in the absorber, and in the absorber reaction tank, resulting in the formation of particles of $CaSO_3{\cdot}½\,H_2O$. Some of the oxygen in the flue gas may participate in the reaction, resulting in the formation of particles of $CaSO_4{\bullet}2H_2O$ as well. Air may be injected into the absorber sump to promote the formation of gypsum and minimize the formation of calcium sulfite solids where a gypsum product is desired, either for ease of disposal or commercial use. The resultant slurry is then processed in a dewatering system prior to disposal or commercial use.

As the limestone reagent in the recirculating slurry is depleted, it is replenished with fresh slurry prepared by wet grinding of crushed limestone using reclaimed liquid from the dewatering system. Fresh water is also required to replace water lost to evaporation in the flue gas cooling process. Fresh water is often used to wash the mist eliminators, devices located at the scrubber exit to capture slurry droplets entrained in the exiting flue gas stream and return them to the scrubber. The mist eliminator wash removes accumulated materials from the mist eliminator chevrons, thus preventing solids buildup and pluggage. In addition, depending upon the mineral content of the coal, a portion of the reclaimed liquid from the dewatering process may be blown down, or disposed of, to prevent excessive accumulation of mineral salts in the slurry which could result in mineral scaling within the absorber equipment. The blow down rate varies with each plant. Fresh water makeup, both through the mist eliminator wash system and in the limestone grinding process, replaces the blow down and evaporative losses.

Lime scrubbers are very similar to limestone scrubbers. The use of lime rather than limestone can reduce the liquid-to-gas ratio and/or absorber size required to achieve a given SO_2 removal rate. Lime is sometimes used in wet FGD systems where extremely high SO_2 removal rates are desired or where limestone is not readily available. However, since lime is more expensive than limestone, the reagent cost is much higher for a lime system. Therefore, the vast majority of wet FGD systems are designed to use limestone as the neutralizing reagent.

Advantages of the wet FGD systems include lower operating costs, primarily due to the ability to use limestone instead of lime as a reagent, the production of a salable by-product and high removal efficiency. Also, wet FGD systems have a high turndown capability and plant operational flexibility is not hindered to the same degree as the semi-dry, CFB and FDA processes. This last advantage is important where wet FGD systems are applied to load following units. Disadvantages of wet FGD systems include corrosion due to a wet environment with corrosive chemicals including salts of sulfurous and sulfuric acid and hydrochloric acid. Also, because the wet systems are more mechanically complex, they typically require larger maintenance staff than the semi-dry, CFB and FDA alternatives. The greater mechanical complexity also contributes to a greater capital cost for wet FGD systems. Finally, because wet FGD systems completely saturate the flue gas stream, nearly all the SO_3 or H_2SO_4 vapor in the entering flue gas is condensed into aerosol droplets which are too small to be efficiently captured in the scrubber. Fifty percent or more of these droplets pass right through the scrubber. Where units are burning high sulfur fuels, this can cause a plume opacity problem. Wet FGD systems commonly achieve 95% percent SO_2 removal efficiencies in commercial applications.

B3.0 Semi-Dry Flue Gas Desulfurization
