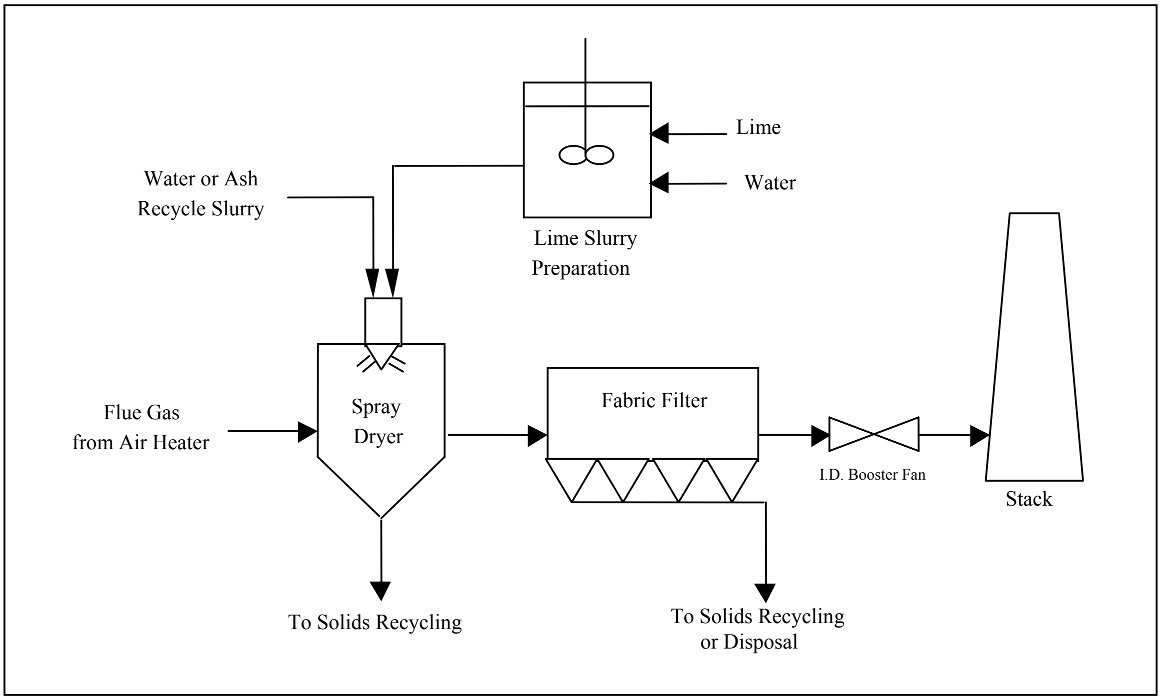
As an alternative to wet FGD technology, the control of SO_2 emissions can be accomplished using semi-dry FGD technology. The most common semi-dry FGD system is the lime Spray Dryer Absorber (SDA) using a fabric filter for downstream particulate collection. The semi-dry FGD process became popular in the U.S. beginning in the late 1970s as a way to comply with the New Source Performance Standards (NSPS) for electric utility steam generating units for which construction commenced after September 18, 1978 (40 CFR Part 60, Subpart Da). These standards require that all new coal-fired electric utility boilers be equipped with a “continuous system of emission reduction” for SO_2. However, the standards allowed SO_2 removal efficiency as low as 70 percent for facilities burning low-sulfur coal. The semi-dry FGD process could meet this requirement, and was often selected as the SO_2 control technology for many new coal-fired power plants that were built in the 1970s and 1980s and designed to burn low-sulfur western coal. In the late 1980s and through the 1990s, most of the new coal-fired boilers built in the U.S. were for small Independent Power Producer (IPP) projects, and many of these also selected the semi-dry/lime FGD process.

There are several variations of the semi-dry process in use today. This section addresses the spray dryer FGD process. Two other variations, the Flash Dryer Absorber and Circulating Fluidized Bed absorber are addressed in following sections. They primarily differ by the type of reactor vessel used, the method in which water and lime are introduced into the reactor and the degree of solids recycling.

A schematic diagram of the spray dryer FGD process is provided in Figure B-2. In the spray dryer FGD process, boiler flue gas is introduced into a Spray Dryer Absorber (SDA) into which hydrated lime (calcium hydroxide, $Ca(OH)_2$) and water are added as dispersed droplets. The $Ca(OH)_2$ reacts with SO_2 that has been absorbed into the water to form primarily calcium sulfite and some calcium sulfate. The heat from the flue gas causes the water to evaporate, cooling the gas and drying the reaction products. Because the total water feed rate is much lower than that of the wet FGD process, the reaction products are dried in the SDA and the flue gas is only partially saturated. The amount of water added to the process is carefully controlled so that the flue gas temperature is maintained well above the saturation, or dewpoint, temperature (typically 30-40 ^{0}F above saturation) to avoid corrosion problems. Cooling the gas to this point significantly increases the SO_2 control efficiency over injection into hot, dry flue gas. The reaction product leaves the SDA as fine dry particles entrained in the flue gas. The flue gas enters the SDA at the top and flows downward, cocurrent with the introduced neutralizing agent. This characteristic is the opposite of the wet FGD system which introduces flue gas into the bottom of the absorber, countercurrent to the falling slurry spray.

Figure B-2 Spray Dryer FGD Process Flow Diagram



In the lime spray drying process, quicklime (CaO) is slaked with water to form lime slurry which is then injected into the SDA along with additional water through a rotary atomizer or dual fluid nozzle or similar apparatus. Recycled PM from the PM control equipment downstream of the SDA is often mixed with the lime slurry before injection into the SDA to provide additional surface area for SO_2 absorption. The flue gas is introduced into the SDA in a manner designed to maximize the contact between the gas and the droplets and to prevent slurry impingement on the walls of the SDA. The turbulent mixing of the flue gas and the slurry droplets promotes rapid absorption of SO_2 into the water of the slurry droplets. The chemical reactions between the absorbed SO_2 and the calcium hydroxide take place within the droplet as the flue gas moves through the SDA. The flue gas is cooled and partially humidified as the water evaporates, leaving a mixture of fly ash and dry powdered reaction product entrained in the flue gas. Some of the solid particles fall to the bottom of the reactor and are collected by a waste handling system. Entrained particles are collected in an electrostatic precipitator (ESP) or fabric filter (FF) downstream of the SDA.

An additional distinguishing characteristic of the SDA is that it must be located upstream of a particulate control device, as opposed to the wet FGD process which is normally the last flue gas treatment process before discharge to the stack. For new plants, this point is not of such great importance. However, when retrofitting FGD equipment to an existing coal-fired plant, which already has particulate control equipment installed, this becomes an important point. If a suitable location exists for the insertion of a new SDA upstream of an existing PM control device, and if the performance of the existing PM control device would not be overly degraded by the additional PM loading, then the retrofit process would consist only of installation of the SDA, reagent preparation and waste handling systems. However, many times one, or both, of these conditions do not exist and the choice to utilize an SDA requires the installation of a new PM control device, such as an ESP or fabric filter. Where this situation exists, the capital cost of the SDA option increases significantly.

Semi-dry processes have some notable advantages compared to wet FGD processes including a dry byproduct which can be handled with conventional ash handling systems. Because the semi-dry system does not have a truly wet zone, corrosion problems in the SDA are eliminated, or significantly reduced, to the point exotic materials of construction are not required. Spray dryer systems utilize less complex equipment resulting in a reduced capital cost and allowing somewhat smaller operations and maintenance staff. Where a fabric filter is utilized as the downstream particulate control device for a semi-dry process, the lime content of the filter cake on the fabric filter reacts with condensed SO_3 in the flue gas stream capturing and neutralizing the acid aerosol. Consequently, semi-dry FGD options, paired with a fabric filter for PM control, have virtually zero emissions of acid aerosols.

The primary disadvantages of the lime spray dryer process make it less likely to be applied to large power plant boilers, especially those firing high-sulfur coal. The lime spray dryer requires the use of lime, which is much more expensive than limestone. While lime contains approximately 1.8 times more calcium than limestone on a mass basis, lime can cost up to five times more than limestone on a mass basis. Therefore, reagent costs for a lime based process are typically higher than a limestone-based process for a given application.

Wastes from semi-dry processes have very limited possibility for reuse due to fly ash contamination. Also, where fly ash might be sold for other uses, contamination with the semi-dry FGD reaction products typically eliminates commercial options for reuse. Where fly ash sales are to be maintained, a second PM control device would be required for the semi-dry FGD system exhaust stream, increasing both capital and O&M costs.

SDAs have much more stringent size limitations than wet FGD scrubbers. Typically units larger than 250 to 300 MW will require at least two SDAs, thus driving up capital costs and system complexity for larger units, while wet FGD systems can handle up to 1000 MW in a single absorber module. SDAs do not have the same turndown capabilities as wet FGD absorbers, further limiting applicability for load following units. Finally, lime spray dryer systems do not have the same level of experience with high SO_2 removal requirements in high sulfur applications that wet FGD systems have.

No variation of semi-dry FGD systems has clearly demonstrated the ability to achieve SO_2 removal levels similar to wet FGD systems in the U.S. Table B-1 lists many of the recent lime spray dryer system installations in the U.S. The information in Table B-1 was obtained from the RACT/BACT/LAER Clearing House. As can be seen in the column titled Efficiency, two units were permitted with an SO_2 removal efficiency of 94.5% and one with 95%. However, these units typically use a lower sulfur fuel and achieve an emissions limit in the range of 0.12 to 0.17 lb SO_2/mmBtu.

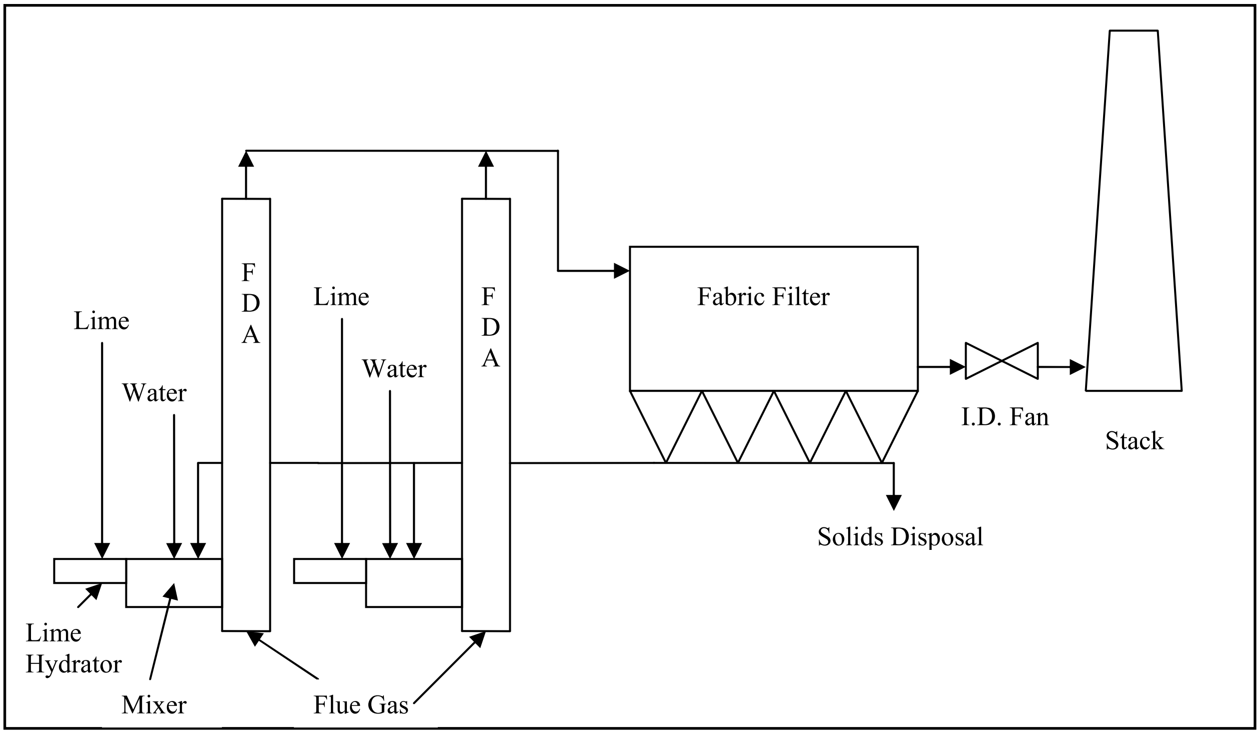
B4.0 Flash Dryer Absorber Flue Gas Desulfurization

The Flash Dryer Absorber (FDA) is a further development of the lime spray dryer process. The approach is similar in that the flue gas is only partially saturated during the process and thus corrosion problems are either reduced or eliminated. Like the SDA, waste solids from the particulate control process are added to the reagent feed stream to the reactor. Similar to the SDA, the FDA mixes lime, water and recycled PM for enhanced surface area. Recycled PM, along with absorption products and unreacted lime, are collected downstream of the FDA and a sizable fraction recycled to the FDA. Unlike the SDA, the FDA recycles a very high fraction of the captured PM. Because of this, the ratio of solids to liquid in the reagent stream injected into the FDA reactor is much higher than the SDA. The ratio is so much higher that the wetted recycled solids are still a relatively dry free flowing stream after wetting in the mixing stage[2]. Because the reagent stream starts off much higher in solids, the liquid film thickness on the wetted solids is much thinner and the drying time for the injected solids is much shorter than a typical SDA. This allows the FDA to function with a significantly smaller reactor compared to the typical SDA absorber vessel. Like the SDA, the water injection rate of the FDA is controlled to lower the flue gas temperature to optimize the SO_2 control efficiency while avoiding saturation and the accompanying corrosion problems. Unlike the SDA, the flue gas is flows vertically upward in the FDA. Figure B-3 is a schematic presentation of the FDA design.

The FDA utilizes quicklime (CaO) instead of hydrated lime as a reagent. The reasoning given for this by the designers is that when purchasing lime, although the price per ton is similar, the quicklime has 32% more calcium (SO_2 neutralization component) per ton than hydrated lime. Also, because quicklime is denser (900-1,200 kg/m^3 for quicklime vs. 450-640 kg/m^3 for hydrated lime), both transport and onsite storage capacity requirements can be smaller. However, direct injection of quicklime has resulted in less efficient reagent utilization compared to hydrated lime use. This is theorized to be due to hot spots created in the reaction zone by the hydration of the quicklime. The heat of hydration of quicklime is approximately 1.1 mmBtu/ton, so there is considerable heat evolved during the hydration step. To avoid adding this heat to the flue gas or creating hot spots that could reduce lime utilization, the FDA design incorporates a separate lime hydration stage where more than the stoichiometrically required amount of water is added to the quicklime in stages. The super stoichiometric water is heated during the slaking process and evaporates, leaving dry hydrated lime. The hydrated lime, recycled solids and water are then combined in a mixing vessel just prior to injection into the reactor.

Figure B-3 Flash Dryer Absorber FGD Process Flow Diagram



Like the SDA, the FDA must be followed by a PM control device to capture the dry solids in the FDA exhaust. The great majority of these solids are recycled back to the FDA. The non recycled fraction is a mixture of calcium sulfite/sulfate solids and fly ash for which limited possibilities for reuse exist. Also, in those instances where fly ash sales produce an income for the power plant, addition of the FDA solids to the fly ash will likely render the waste solids stream valueless. Where the plant receives revenue from fly ash sales, the lost revenue would be an additional cost of FDA implementation because the fly ash is used as a surface area enhancer in FDA operation.

The FDA is a relatively recent modification of the semi-dry FGD concept and as such, has not established a significant field record at this time. In their paper on FDA technology in 2002[3], Alstom cited a 280 MW plant in China with an 85% SO_2 removal efficiency. This plant had an FDA installed upstream of an ESP. Dry and semi-dry scrubbers installed upstream of a fabric filter have been consistently shown to achieve approximately 5-10% greater acid gas removal efficiency due to absorption and neutralization taking place in the filter cake of the fabric filter. Typically ESPs downstream of an FDA or other dry or semi-dry SO_2 scrubbing system are attributed no more than 5% SO_2 removal efficiency.

Advantages of the FDA over wet FGD systems are similar to those described for the semi-dry process described previously, including ease of byproduct handling, much less aggressive corrosion conditions allowing the use of more common, less expensive materials of construction, less complex equipment, and potentially enhanced SO_3 control when combined with a fabric filter. FDA advantages also include a significantly smaller reactor/absorber which translates into a lower area requirement than either wet or semi-dry FGD systems, though manufacturers often provide multiple FDA's, even on smaller units.

Disadvantages of the FDA, when compared to the wet FGD system are similar to those described for the semi-dry process, including reactor size limitations, lower turndown ratio, more expensive reagent, and lack of byproduct market value.

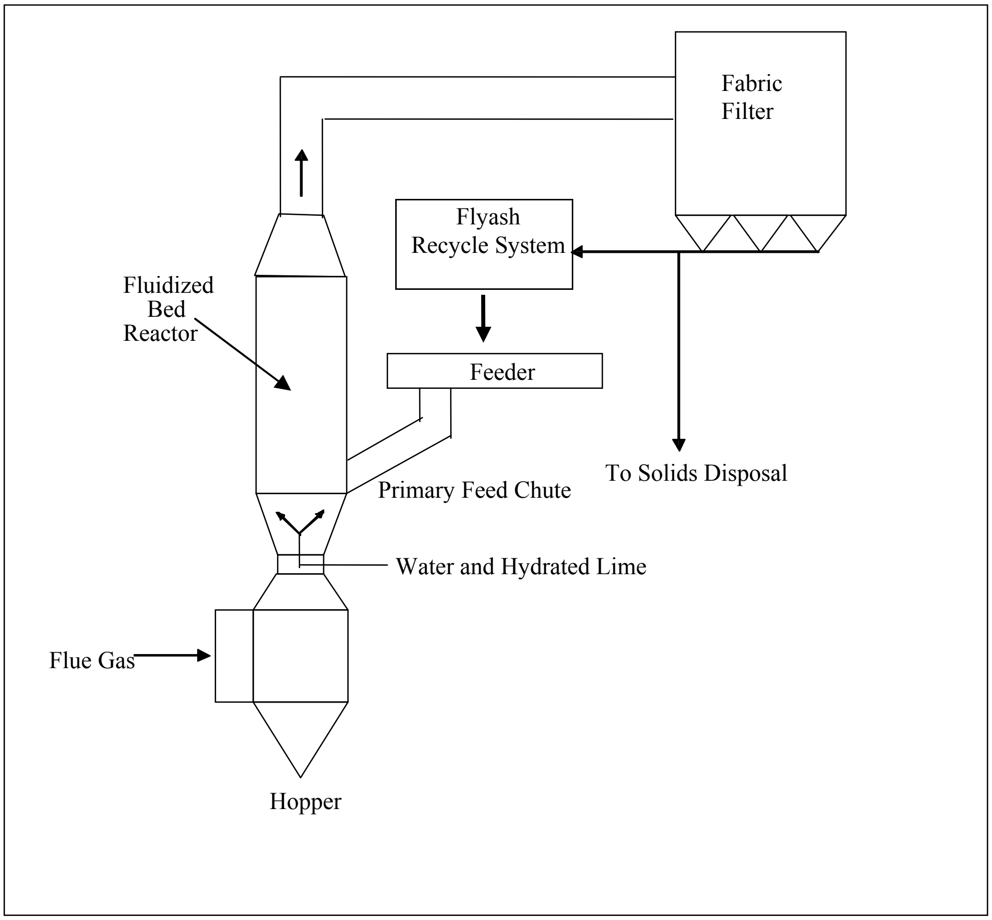
B5.0 Circulating Fluidized Bed Absorber Flue Gas Desulfurization

In the fluidized bed dry scrubbing process, the flue gas is introduced into the bottom of a reactor vessel at high velocity through a venturi nozzle, and mixed with water, hydrated lime, recycled flyash and FGD reaction products. High velocity movement of the gas through the reactor suspends the solids creating a fluidized bed. A CFB absorber vessel would be a smaller diameter than the SDA discussed previously in this report. A schematic representation of the CFB process is shown in Figure B-4. The smaller diameter absorber helps maintain higher flue gas velocities required to maintain the fluidized bed. Water injected into the venturi throat cools the flue gas and wets the recycled solids similar to the process described previously for the FDA. Dry, powdered, hydrated lime is injected into the bed near the bottom of the absorber vessel, above the venturi and dissolves in the thin water film on the recycled solids. SO_2 from the flue gas is also absorbed into the evaporating water film and reacts with the lime to produce both calcium sulfite and sulfate reaction products. Flue gas temperatures are typically reduced from 300 ^{0}F to approximately 160 ^{0}F to optimize SO_2 removal efficiency. The evaporation of the water cools and partially humidifies the flue gas and maintains the bed in a slightly moist, powdery condition. The continuous motion of the bed helps prevent solids deposition inside the absorber and promotes regeneration of the particle surfaces, exposing additional lime to react with absorbed SO_2. Particles that are entrained in the flue gas leaving the top of the reactor are collected in an ESP or fabric filter downstream of the CFB absorber. A large portion of the collected particles is recycled to the reactor, sustaining the bed and improving lime utilization. CFB absorbers have been installed with both fabric filters and ESPs for particulate control.

The CFB absorber dry scrubbing process utilizes a bed of fluidized particles to provide an extended surface area for wetting, evaporation and SO_2 absorption. The extended surface decreases the time required for SO_2 absorption. Even though the gas velocity is higher than a wet FGD absorber or an SDA, the CFB absorber is not taller than either of these vessels.

The CFB has many of the same advantages of the SDA and FDA such as a dry byproduct, simplified waste handling systems and conventional materials of construction.
CFBs also have less rotating equipment than wet FGD or SDA systems, thus simplifying maintenance requirements somewhat. Like the SDA and FDA, the CFB application with a fabric filter for particulate collection will also achieve very good acid aerosol control. Unlike the SDA the CFB does not require dual fluid nozzles or atomizers in the absorber. This feature simplifies the absorber maintenance of a CFB over that of the SDA. Also, because lime and water are injected separately into the CFB, increased reagent requirements can be met without increasing saturation of the flue gas.

Figure B-4 – Circulating Fluidized Bed FGD System



Disadvantages of the CFB process include higher reagent cost and lower utilization than SDAs in similar applications and more limited turndown capability. In a recent study[2] the National Lime Association determined that compared to CFB's in similar applications, the SDA achieved slightly lower SO_2 removal with slightly better reagent utilization. Because CFBs must maintain gas velocities within a fluidizing range, a recycle duct from the absorber exhaust to the inlet is sometimes included to allow for partial recycle of flue gas to maintain bed velocity and improve the turndown ratio. Similar to the SDA and FDA processes, CFBs are size limited and multiple absorbers are required for applications larger than 250-300 MW.

An additional disadvantage the CFB has over the SDA is pressure drop. Because the CFB must maintain the fluidized bed condition, the pressure drop over the absorber is typically 8-10 in. w.g. compared to an SDA at 6-8 in. w.g. and a wet FGD system at approximately 6.0 in. w.g.

B6.0 Powerspan Electro Catalytic Oxidation (ECO™) Technology

The Powerspan Electro-Catalytic Oxidation (ECO™) system is a multipollutant control technology designed to control emissions of NO_X, SO_2, fine particulate, mercury and certain Hazardous Air Pollutants (HAPs). The ECO™ process has two main process vessels, a barrier discharge reactor and a multi-level wet scrubber. The barrier discharge reactor utilizes an electrical discharge to create oxygen and hydroxide radicals which then react with NO_X, SO_2, and mercury to produce sulfur trioxide (SO_3), sulfuric acid (H_2SO_4), nitric acid (HNO_3) and oxidized metallic species (e.g., mercury). The flue gas stream then enters the bottom of the ECO™ scrubber where the lower loop cools the flue gas and removes a portion of the SO_2, acid gasses produced in the barrier reactor (H_2SO_4 & HNO_3) and oxidized metals such as mercury, with a low pH aqueous ammonia reagent. A second scrubbing loop is then entered where additional SO_2, NO_2, acid gases and oxidized metals are removed with an aqueous ammonia reagent, though at a higher pH. Above the second scrubber loop is an absorber section for absorbing fugitive ammonia from the first and second scrubbing loops. The final step in the ECO™ process is a wet electrostatic precipitator (WESP) which collects fine particulate matter, aerosols generated in the scrubber and additional mercury.

As a reagent the system utilizes aqueous ammonia in two scrubber loops, with varying pH to control collection efficiency in the lower and upper loops. The ammonia reacts with the collected SO_2 in aqueous solution to produce ammonium sulfate as a byproduct. The ammonium sulfate is then salable as fertilizer, thus turning byproduct disposal into a profitable venture for system operators. Captured mercury and other oxidized metals are removed from the scrubber bleed stream with activated carbon and disposed of as a hazardous waste. Ash and insoluble metals are filtered from the scrubber bleed stream before fertilizer production and disposed of with other particulate wastes from upstream particulate control equipment. The ammonium sulfate can be either, sold as an aqueous product, or crystallized, granulated and sold.

In addition to high removal efficiencies for SO_2, NO_X, and mercury, the ECO™ process claims to achieve high levels of fine particulate control in the WESP. Powerspan claims a routine SO_2 removal efficiency of >98% with inlet concentrations up to approximately 2,000 ppm. SO_2 levels at LOS Unit 2 are commonly about 1,399 parts per million. NO_X removal is stated to be up to 90% with a 0.05 lb NO_X/mmBtu outlet condition achievable. Mercury removal of 75-85% is also reported by Powerspan for the ECO™ process.

Powerspan performed an extended pilot plant demonstration at R.E. Burger Station Units 4&5. The pilot demonstration project treated a slipstream of approximately 110,000 scfm and demonstrated performance, reliability and economics. The demonstration program started in January, 2004. Powerspan recently indicated that they are scaling the reactor and scrubber for optimum cost and space arrangement and incorporating lessons learned from the pilot plant operation. It is important for the purposes of this BART study to note that coproduct crystallization and granulization equipment was not included in the pilot plant operation. The coproduct stream that would normally feed into the crystallization and granulation processes was collected and transported offsite for this process step during pilot plant operation. Because crystallization and granulation of ammonium sulfate from an ammonia scrubber solution is not a new technological process, this was not considered a deficiency in the pilot plant program. For instance, the Dakota Gasification Company (DGC) in Beulah, ND currently operates an SO_2 scrubber utilizing ammonia as a reagent. Following the generation of ammonium sulfate, DGC crystallizes and granulates a fertilizer product on site. No full size commercial scale ECO™ systems have been installed or operated at the time of this report.

APPENDIX C

Technical Description of Particulate Matter Controls (C1)

Appendix C1 – Technical Description of Particulate Matter Controls

C1.0FUEL SWITCHING

Fuel switching along with flue gas conditioning is a viable method of reducing particulate matter emissions in certain situations. Often, coal combustion facilities are constructed to take maximum advantage of the particular combustion characteristics of a specific fuel. One such fuel is lignite, which is a low Btu content, high ash, high moisture, and medium sulfur content fuel. A typical lignite boiler is physically larger than a similarly rated unit designed for bituminous or sub-bituminous fuel due to the lower heat content of the lignite. The lignite fueled boiler must burn a greater quantity of coal per hour to achieve the same heat input due to the lower heat content of the lignite fuel. Therefore, ancillary equipment such as pulverizers, coal conveyors, ductwork, etc. are designed larger to handle the greater quantities of coal and flue gas.

Firing sub-bituminous fuels such as PRB in boilers designed for lignite fuel result in a significantly lower coal feed rate for the same heat input, and lower flue gas quantities. If a lignite fired boiler is switched to PRB coal, gas velocities would slow approximately 20% in the boiler for similar heat inputs. Lower flue gas velocity, with the same flue gas heat capacity (PRB flue gas is approximately 1.5% less than lignite), also translates into higher initial flue gas temperatures in the combustion zone, which might mean greater heat absorption in the waterwall portion of the furnace. However, an actual test burn is required to determine the exact effects.

Fly ash conditioning methods installed upstream of an ESP usually involve the injection of a chemical into the flue gas stream to control the electrical resistivity of the fly ash. Conditioning systems can also be used to cause coagulation of the dust particles, agglomeration, and improve the cohesiveness of the fly ash in order to improve the collection efficiency of an ESP. Two of the main factors that determine the resistivity are the sulfur content of the coal and the elemental composition of the ash. Low amounts of sulfur in the coal will limit the concentration of sulfur dioxide in the flue gas and thus the extent of its oxidation to sulfur trioxide. The low sulfur PRB coal limits the amount of available sulfur trioxide and water vapor that can be absorbed on a non-conductive fly ash particle, which would lower the resistivity of the fly ash. The low sulfur content and the high alkaline ash both contribute to high resistivity. The low sulfur content limits the amount of sulfur trioxide that is formed while the calcium oxide will preferentially react with the acid and form a non-conducting ash.

The most common types of flue gas conditioning systems for this application include humidification of the flue gas, sulfur trioxide injection, ammonia injection, or a combination of these conditioning methods. Humidification of the flue gas was one of the first methods used to lower the resistivity of the fly ash. However, many of these systems have been replaced with sulfur trioxide and/or ammonia conditioning systems. It is common for facilities with flue gas conditioning systems to utilize sulfur trioxide and/or ammonia injection. Ammonia injection is typically used in retrofits where an existing ESP is undersized and sulfur trioxide alone is not able to effectively reduce the resistivity. However, if sulfur trioxide can effectively reduce the resistivity, then ammonia injection and thus ammonia storage on-site is avoided. Switching to a fuel such as PRB and adding a flue gas conditioning system to achieve lower PM emission rates will achieve significant PM emission reductions assuming that the control efficiency of the existing ESP can be restored.

C2.0FABRIC FILTER (FF)

A fabric filter or baghouse removes particulate by passing flue gas through filter bags. A pulse-jet fabric filter (PJFF) unit consists of isolatable compartments with common inlet and outlet manifolds containing rows of fabric filter bags. The filter bags are made from a synthetic felted material that are suspended from a tube sheet mounted at the top of each fabric filter compartment. The tube sheet separates the particulate laden flue gas from the clean flue gas. This tube sheet is a flat sheet of carbon steel with holes designed to accommodate filter bags through which the bags are hung. The flue gas passes through the PJFF by flowing from the outside of the bag to the inside, up the center of the bag through the hole in the tube sheet and out the PJFF. Fly ash particles are collected on the outside of the bags, and the cleaned gas stream passes through the fabric filter and on to the chimney. A long narrow wire cage is located within the bag to prevent collapse of the bag as the flue gas passes through it. Each filter bag alternates between relatively long periods of filtering and short periods of cleaning. During the cleaning period, fly ash that has accumulated on the bags is removed by pulses of air and then falls into a hopper for storage and subsequent disposal.

Cleaning is either initiated at a preset differential pressure across the tubesheet or based on a maximum time between cleanings. Bags in a PJFF are cleaned by directing a pulse of pressurized air down the filter bag countercurrent to the flue gas flow to induce a traveling ripple (pulse) in the filter bag. This pulse travels the length of the bag, deflecting the bag outward and separating the dust cake as it moves.

An advantage of a fabric filter over an ESP is that a fabric filter is not dependent on the resistivity of the fly ash. Since the fabric filter uses bags instead of an electric charge to remove the particles, the resistivity of the particles is not an issue. Fabric filters also have a lower dependence on particle size than ESPs. A disadvantage of fabric filters is that they have a tendency to corrode and clog with high sulfur coal applications. The high sulfur coals produce more SO_3, which tends to create problems with the fabric filters. Therefore, ESPs are typically used on high sulfur coal applications instead of fabric filters. Another disadvantage of fabric filters is the associated pressure drop. The bags, which collect a cake of particles, create an obstruction to the gas path. Fabric filters typically have approximately three times the pressure drop of an ESP. Fabric filters have been proven to control PM removal efficiency in excess of 99%.

C3.0ELECTROSTATIC PRECIPITATOR (ESP)

ESPs are commonly used as the primary filterable PM control device on coal fired units. The ESP discharge electrodes generate a high voltage electrical field that gives the particulate matter an electric charge (positive or negative). The charged particles will then be collected on a collection plate. A rapper or hammer system will be utilized to vibrate the collected particles off of the plates so they can fall into the hoppers for storage and subsequent disposal.

The advantages of an ESP include the fact that an ESP can be applied to high sulfur coals, and the pressure drop across an ESP is relatively low compared to other alternatives such as a fabric filter. Unlike the fabric filter, which uses bags as the filter media, an ESP does not contain elements that can plug in the presence of SO_3. The unobstructed design of the ESP results in a pressure drop that is approximately 1/3 of a corresponding fabric filter. The disadvantage of the ESP is that its effectiveness to remove particulate is dependant on the resistivity of the fly ash and particle size. ESPs have been proven to control PM removal efficiency in excess of 99%.

IMPACT ANALYSIS of Basic SOFA with SNCR ALTERNATIVE for LELAND OLDS UNIT 1

This document is being provided in response to the North Dakota Department of Health's request issued in a December 1, 2006 letter to Basin Electric Power Cooperative regarding the NDDH's comments from their review of the final draft report of the BEPC LOS BART DETERMINATION STUDY for LELAND OLDS STATION UNIT 1 and 2 (August 2006).

This is intended to be in addition to the following sections:

2.4.2 Energy Impacts of NO_X Control Alternatives – LOS Unit 1;

2.4.3 Non Air Quality and Other Environmental Impacts of NO_X Control Alternatives – LOS Unit 1;

2.4.4 Visibility Impairment Impacts of Leland Olds Station NO_X Controls – Unit 1;

2.4.5 Summary of Impacts of LOS NO_X Controls – Unit 1;

CORRECTIONS:

Included in this document are replacements to the following sections of the August 2006 BEPC BART Determination Study report:

2.4.1.2 Operating and Maintenance Cost Estimates for NO_X Controls – LOS Unit 1;

2.4.1.3 Cost Effectiveness for NO_X Controls – LOS Unit 1;

The following describes corrections to Section 2.4.1.2 O&M costs, and Section 2.4.1.3 Cost Effectiveness, for those LOS Unit 1 alternatives that involve a chemical reagent injected for NOx control. These corrections are included in front of the updated impacts evaluation added for the basic SOFA with SNCR NO_X Control alternative for LOS Unit 1.

Additional coal consumption for those alternatives that involve a chemical reagent injected for NOx control to compensate for the heat of vaporization of the reagent dilution water should be included in the O&M costs; this follows EPA OAQPS convention. For the purposes of this study, this additional coal consumption has been included in the annual O&M costs provided in the August 2006 final draft of the BEPC LOS BART Report. For example, the cost of this extra coal consumption was incorrectly calculated as $10 per year for LOS Unit 1's basic SOFA + SNCR alternative for both the historic and PTE cases in the August 2006 final draft of the BEPC LOS BART Report, assuming $0.91/mmBtu. It should have been 53,645 mmBtu/yr x $0.91/mmBtu = $48,600/yr annual O&M cost for LOS Unit 1's basic SOFA + SNCR alternative.

Similarly, included in this document are replacements to the following sections of the August 2006 BEPC BART Determination Study report:

2.5.1.2 Operating and Maintenance Cost Estimates for NO_X Controls – LOS Unit 2;

2.5.1.3 Cost Effectiveness for NO_X Controls – LOS Unit 2;

The following describes corrections to Section 2.5.1.2 O&M costs, and Section 2.5.1.3 Cost Effectiveness, for those LOS Unit 2 alternatives that involve a chemical reagent injected for NO_X control. These corrections are also included at the back of this updated impacts evaluation.

The cost of this extra coal consumption for those alternatives that involve a chemical reagent injected for NOx control to compensate for the heat of vaporization of the reagent dilution water was incorrectly calculated as $20 per year for LOS Unit 2's SNCR + ASOFA alternative and $40 per year for RRI+SNCR with ASOFA alternative for both the historic and PTE cases in the August 2006 final draft of the BEPC LOS BART Report, assuming $0.91/mmBtu. It should have been 204,807 mmBtu/yr x $0.91/mmBtu = $185,400/yr annual O&M cost for LOS Unit 2's SNCR + ASOFA alternative, and 389,490 mmBtu/yr x $0.91/mmBtu = $352,700/yr annual O&M cost for LOS Unit 2's RRI+SNCR with ASOFA alternative.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study report)

2.4.1.2 OPERATING AND MAINTENANCE COST ESTIMATES FOR NO_X CONTROLS – LOS UNIT 1

The operation and maintenance costs to implement the NO_X control technologies evaluated for LOS Unit 1 were largely estimated from cost factors established in the EPA's Air Pollution Control Cost Manual[1] (OAQPS), and from engineering judgment applied to that control technology. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

Fixed and variable operating and maintenance costs considered and included in each NO_X control technology's Levelized Total Annual Costs are estimates of:

- Auxiliary electrical power consumption for operating the additional control equipment;
- Reagent consumption, and reagent unit cost for SNCR alternatives; and
- Reagent dilution water consumption and unit cost for SNCR alternatives.
- Increases or savings in auxiliary electrical power consumption for changes in coal preparation equipment and loading, primarily for fuel reburn cases;
- General operating labor, plus maintenance labor and materials devoted to the additional emission control equipment and its impact on existing boiler equipment.
- Reductions in revenue expected to result from loss of unit availability, i.e. outages attributable to the control option, which reduce annual net electrical generation available for sale (revenue).

Table 2.4-3 and Table 2.4-4 show the estimated annual operating and maintenance costs and levelized annual O&M cost values for the NO_X control options evaluated for LOS Unit 1. The cost methodology summarized in Section 1.3.5 provides more details for the levelized annual O&M cost calculations and cost factors. The annual operating and maintenance costs of the control options in Table 2.4-3 is based on LOS Unit 1 operation with the control options at 2,622 mmBtu/hr heat input and 8,760 hrs/yr operation. These O&M costs are relative to unit pre-control baseline operation at 0.285 lb/mmBtu for the highest 24-month NOx emission summation at 2,443 mmBtu/hr heat input for 8,510 hrs/yr operation of LOS Unit 1 with existing close-coupled overfire air and low-NO_X burners.

---

[1] See Basin LOS BART Determination Study report NO_X Section Reference number 49.

TABLE 2.4-3 – Estimated O&M Costs for NO_X Control Options (Relative to Historic Pre-Control Annual Emission Baseline) – LOS Unit 1

NO_X Control Alternative	Annual O&M Cost(1) ($1,000)	Levelized Annual O&M Cost(2) ($1,000)
SNCR (using urea) w/ boosted SOFA (Rotamix)	2,518	3,004
SNCR (using urea) w/ basic SOFA	2,142	2,556
SNCR (using urea) w/ CCOFA	2,461	2,936
Coal Reburn (conventional, pulverized) w/ boosted SOFA	3,072(3)	3,665(3)
Coal Reburn (conventional, pulverized) w/ basic SOFA	2,420(3)	2,887(3)
Boosted Separated Overfire Air (ROFA)	626	747
Separated Overfire Air (SOFA, basic)	21	25
Baseline, based on annual operation at historic 24-mo average pre-control emission rate	0	0

(1) – Annual O&M cost figures in 2005 dollars.
(2) – Levelized annual O&M cost = Annual O&M cost x 1.19314 Annualized O&M cost factor.
(3) – Costs for increased PM collection capacity included in coal reburn option are $901,000 for annual O&M cost, and $1,074,000/yr levelized annual O&M cost.

The annual operating and maintenance costs of the control options in Table 2.4-4 are based on LOS Unit 1 operation with the control option at 2,622 mmBtu/hr heat input and 8,760 hrs/yr operation. These O&M costs are relative to unit baseline operation at 0.29 lb/mmBtu for the highest 24-month NO_X emission summation at 2,622 mmBtu/hr heat input for 8,760 hrs/yr operation of LOS Unit 1 with existing close-coupled overfire air and low-NO_X burners.

TABLE 2.4-4 – Estimated O&M Costs for NO_X Control Options (Relative to Presumptive BART Annual Emission Baseline – Future PTE Case)

LOS Unit 1

NO_X Control Alternative	Annual O&M Cost[1] ($1,000)	Levelized Annual O&M Cost[2] ($1,000)
SNCR (using urea) w/ boosted SOFA (Rotamix)	2,518	3,004
SNCR (using urea) w/ basic SOFA	2,142	2,556
SNCR (using urea) w/ CCOFA	2,461	2,936

Coal Reburn (conventional, pulverized) w/ basic SOFA	2,420[3]	2,887[3]
Boosted Separated Overfire Air (ROFA)	626	747
Separated Overfire Air (SOFA, basic)	21	25
Baseline, based on annual operation at future PTE case pre-control emission rate	0	0

(1) – Annual O&M cost figures in 2005 dollars.
(2) – Levelized annual O&M cost = Annual O&M cost x 1.19314 O&M cost factor.
(3) – Costs for increased PM collection capacity included in coal reburn option are $901,000 for annual O&M cost, and $1,074,000/yr levelized annual O&M cost.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.4.1.3 COST EFFECTIVENESS FOR NO_X CONTROLS – LOS UNIT 1

In order to compare a particular NO_X emission reduction alternative during the cost of compliance impact analysis portion of the BART determination process, the basic methodology defined in the BART Guidelines was followed [70 FR 39167-39168]. The sum of estimated annualized installed capital plus levelized annual operating and maintenance costs, which is referred to as “Levelized Total Annual Cost” (LTAC) of each alternative, was calculated. The LTAC for all NO_X control alternatives was calculated based on the same economic conditions and a 20 year project life (see Section 1.3.5 for cost methodology details).

The Average Cost Effectiveness (also called Unit Control Cost) was then determined as the LTAC divided by annual tons of pollutant emissions that would be avoided by implementation of the respective alternative. There are two different NO_X emission baselines; the first assumes the highest historic 24-month average NO_X emission rate expressed in tons per year. The second baseline derives tons per year from the maximum future PTE case average NO_X emission rate.

This approach results in two different average cost effectiveness values for the control options evaluated for LOS Unit 1. The annual NO_X emission reduction is the difference between the pre-control baseline and post-control emissions in tons per year. Average control cost for a particular technology is LTAC divided by annual tons of expected emission reduction. A summary of the annual emissions, reductions, control and levelized annual costs for the two LOS Unit 1 baselines are presented in Table 2.4-5 and 2.4-6.

TABLE 2.4-5 – Estimated Annual Emissions and LTAC for NO_X Control Alternatives (Historic Pre-Control Annual Emission Baseline) – LOS Unit 1

Alt. No.(1)	NO_X Control Alternative	Annual NO_X Emissions(2) (Tons/yr)	Annual NO_X Emissions Reduction(2) (Tons/yr)	Levelized Total Annual Cost(3),(4) ($1,000)	Average Control Cost(4) ($/ton)
G	Coal Reburn with boosted SOFA (future PTE case)	1,666	1,301	7,032(5)	5,404(5)
F	Coal Reburn with basic SOFA (future PTE case)	1,746	1,221	5,983(5)	4,898(5)
E	SNCR with boosted SOFA (Rotamix) (future PTE case)	1,782	1,185	3,819	3.223
D	SNCR with basic SOFA (future PTE case)	1,883	1,084	3,099	2,858
C	SNCR with Close-Coupled OFA (future PTE case)	2,450	517	3,361	6,504
B	Boosted Separated Overfire Air (ROFA), (future PTE case)	2,483	484	1,137	2,347
A	Separated Overfire Air (SOFA, basic)	2,642	325	144	441
--	Baseline, based on annual operation at highest historic 24-mo average pre-control emission rate	2,967	0	0	

(1) – Alternative designation has been assigned from highest to lowest annual NO_X emissions.

(2) – NO_X emissions and control level reductions relative to the highest historic 24-month average pre-control annual baseline for LOS Unit 1.

(3) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #2 for Tables 2.4-2 and 2.4-3 for annualized cost factors.

(4) – Annualized cost figures in 2005 dollars.

(5) – LTAC for increased PM collection capacity included in coal reburn option are $1,372,000 for annualized capital cost plus $1,074,000 for annualized O&M cost, for a total of $2,446,000/yr. This results in an average control cost of $1,762/ton with boosted SOFA and $1,870/ton with basic SOFA.

TABLE 2.4-6 – Estimated Annual Emissions and LTAC for NO_X Control Alternatives (Presumptive BART Annual Emission Baseline – Future PTE Case)

LOS Unit 1

Alt. No.(1)	NO_X Control Alternative	Annual NO_X Emissions(2) Tons/yr	Annual NO_X Emissions Reduction(2) Tons/yr	Levelized Total Annual Cost(3),(4) $1,000	Average Control Cost(4) $/ton
G	Coal Reburn with boosted SOFA (future PTE case)	1,693	1,638	7,032(5)	4,293(5)
F	Coal Reburn with basic SOFA (future PTE case)	1,774	1,557	5,983(5)	3,844(5)
E	SNCR with boosted SOFA (Rotamix) (future PTE case)	1,811	1,519	3,819	2,513
D	SNCR with basic SOFA (future PTE case)	1,913	1,417	3,099	2,187

B	SNCR with Close-Coupled OFA (future PTE case)	2,490	841	3,362	4,000
A	Separated Overfire Air (SOFA, basic)	2,641	689	144	208
	Baseline, based on annual operation at future PTE scenario pre-control emission rate	3,330	0	0	

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

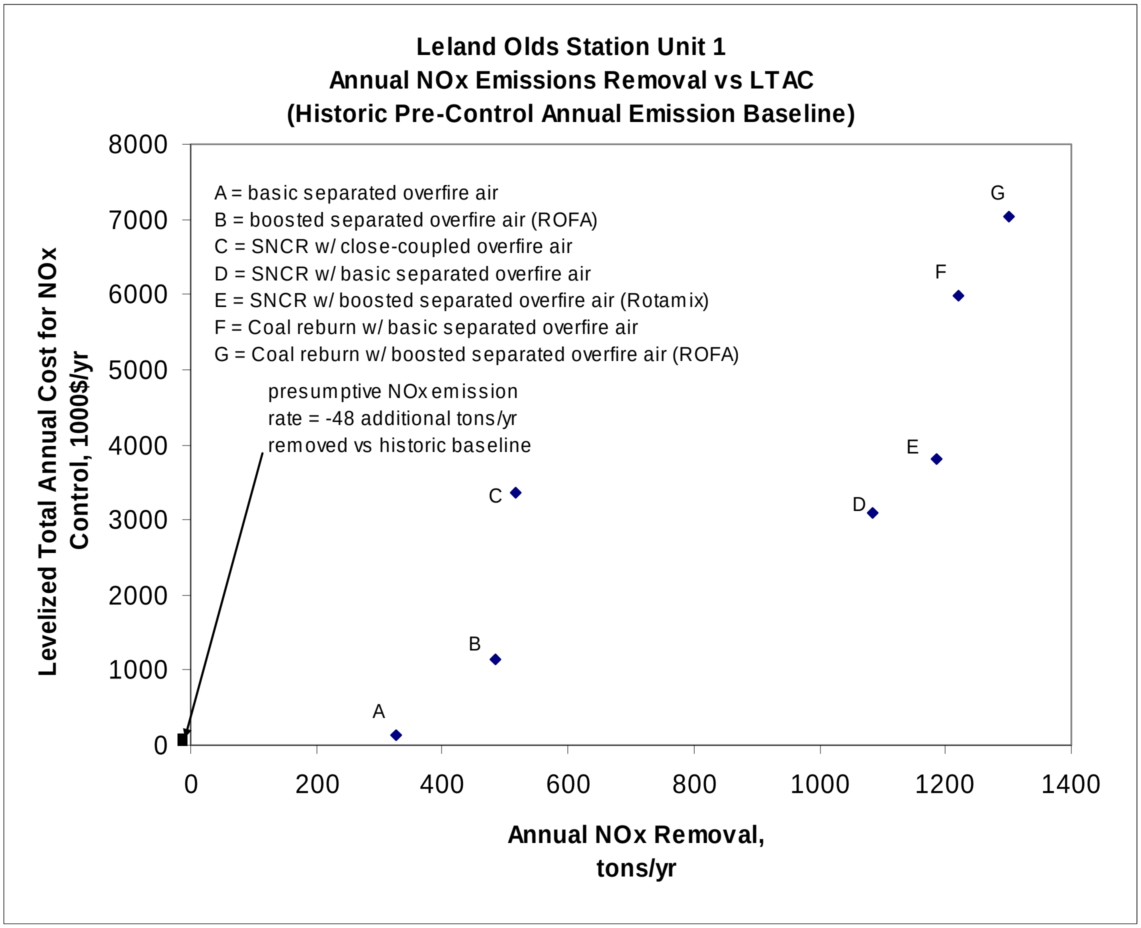
(2) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE scenario applied to LOS Unit 1.

(3) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #2 for Tables 2.4-2 and 2.4-4 for annualized cost factors.

(4) – Annualized cost figures in 2005 dollars.

(5) – LTAC for increased PM collection capacity included in coal reburn option are $1,372,000 for annualized capital cost plus $1,074,000 for annualized O&M cost, for a total of $2,446,000/yr. This results in an average control cost of $1,493/ton with boosted SOFA and $1,571/ton with basic SOFA.

Figure 2.4-1 – NO_X Control Cost Effectiveness – LOS Unit 1 (Historic Pre-Control Annual Emission Baseline)(1)



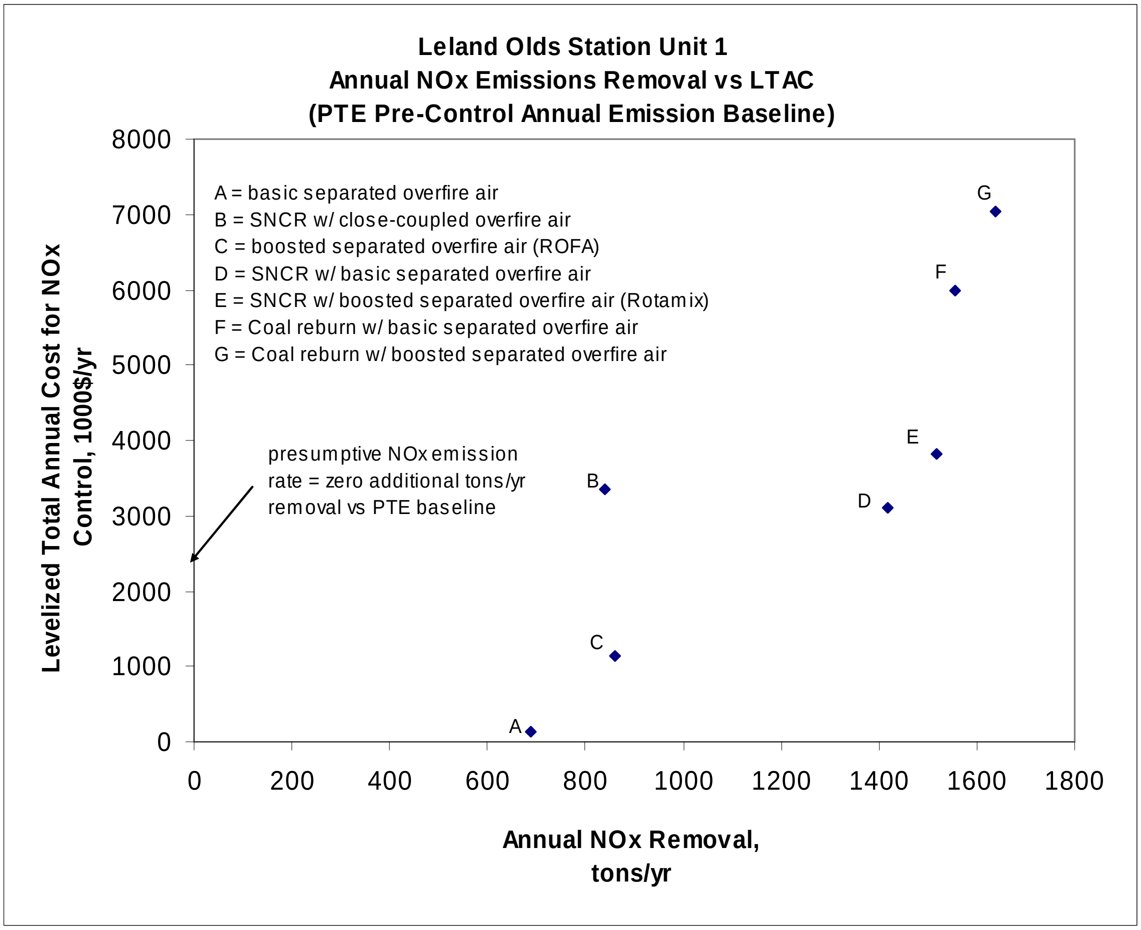
(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-5.

The comparison of the cost-effectiveness of the control options evaluated for LOS Unit 1 relative to two different NO_X emission baselines was made and is shown in Figures 2.4-1 and 2.4-2. The estimated annual amount of NO_X removal (emission reduction) in tons per year is plotted on the ordinate (horizontal axis) and the estimated levelized total annual cost in thousands of U.S. dollars per year on the abscissa (vertical axis).

Figure 2.4-1 is for the control options evaluated relative to the baseline historic pre-control annual baseline, compared to the post-control maximum annual NO_X emissions for operation of LOS Unit 1 under the future PTE case.

Figure 2.4-2 plots estimated levelized total annual costs versus estimated annual amount of NO_X removal (emission reduction) for the control options evaluated relative to the maximum pre-control annual baseline and future potential-to-emit post-control NO_X emissions for operation of LOS Unit ` under the future PTE case.

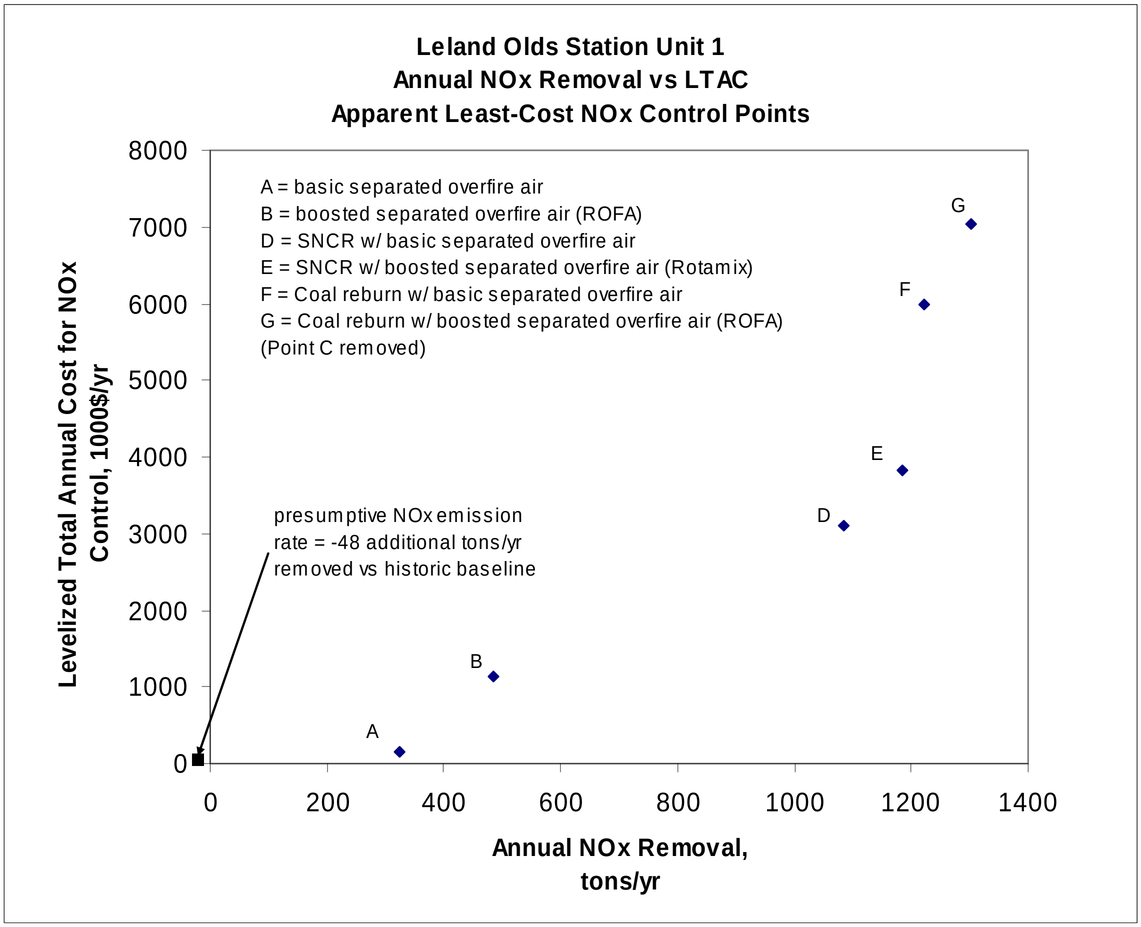
Figure 2.4-2 – NO_X Control Cost Effectiveness – LOS Unit 1 (PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-6.

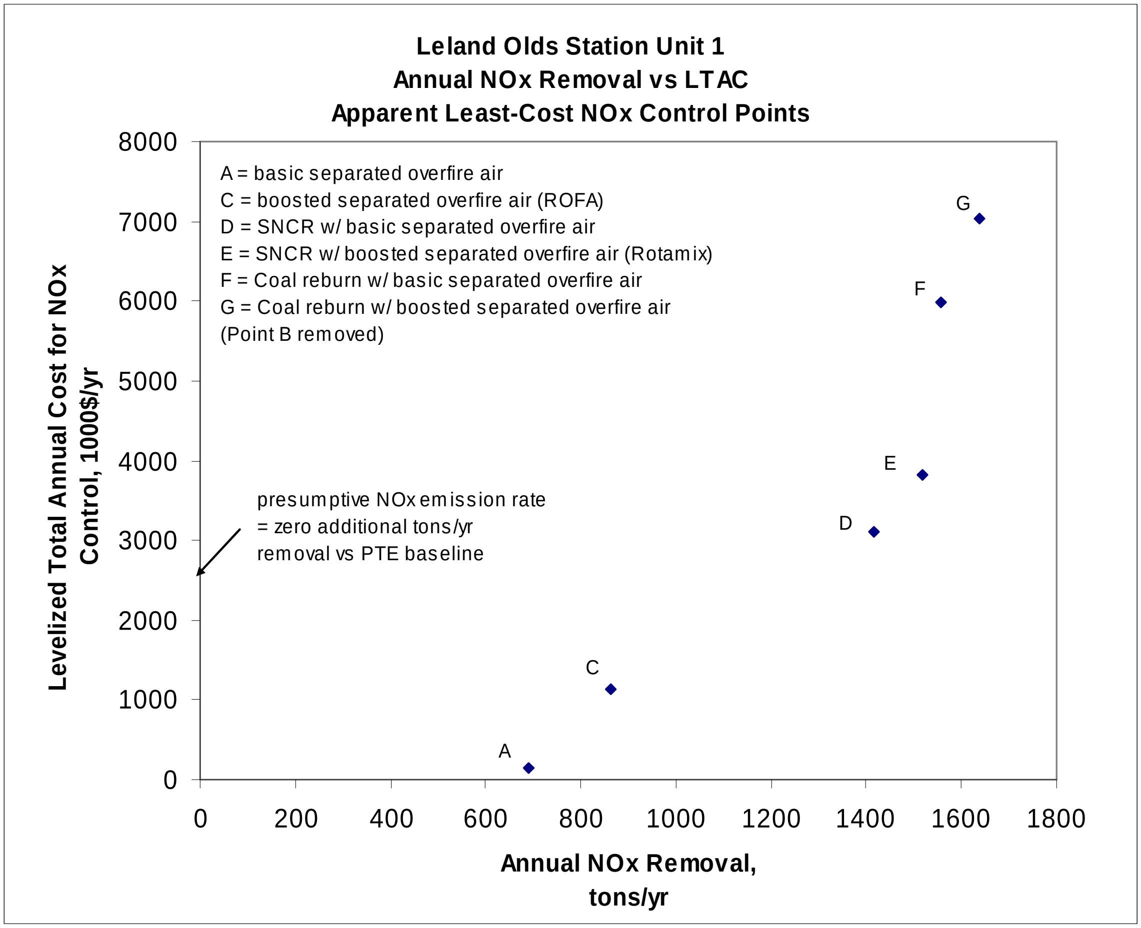
The purpose of Figures 2.4-1 and 2.4-2 is to show the range of control and cost for the evaluated NO_X reduction alternatives and identify the least-cost controls so that the Dominant Controls Curve can be created. The Dominant Controls Curve is the best fit line through the points forming the lower rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual NO_X removal tonnage for the various remaining BART alternatives. Points distinctly to the left of and above this curve are inferior control alternatives per the BART Guidelines and BART Guidelines on a cost effectiveness basis. Following a “bottom-up” graphical comparison approach, each of the NO_X control technologies represented by a data point to the left of and above the least cost envelope should be excluded from further analysis on a cost efficiency basis. Of the highest-performing versions of the technically feasible LOS Unit 1 NO_X control alternatives evaluated for cost-effectiveness, the data point for SNCR with close-coupled OFA is seen to be more costly for fewer tons of NO_X removed than for boosted separated overfire air (ROFA). SNCR with CCOFA appears to be an inferior control, and thus should not be included on the least cost and Dominant Controls Curve boundary. Note that cost-effectiveness points for conventional gas reburn and fuel-lean gas reburn alternatives would be distinctly left and significantly above the least cost-control envelope, so these options were not included in the cost-effectiveness analysis. Figures 2.4-3 and 2.4-4 show the revised least-cost control points without SNCR with CCOFA.

Figure 2.4-3 – NO_X Control Cost Effectiveness – LOS Unit 1
Apparent Least-Cost NOx Control Points
(Historic Pre-Control Annual Emission Baseline)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-5.

Figure 2.4-4 – NO_X Control Cost Effectiveness – LOS Unit 1 Apparent Least-Cost NOx Control Points (PTE Pre-Control Annual Emission Baseline – Future PTE Case)[(1)]



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-6.

The next step in the cost effectiveness analysis for the BART NO_X control alternatives is to review the incremental cost effectiveness between remaining least-cost alternatives. Figure 2.4-5 and Figure 2.4-6 contain a repetition of the levelized total annual cost and NO_X control information from Figure 2.4-3 and Figure 2.4-4 with SNCR with CCOFA removed (Point C in Figure 2.4-1, and Point B in Figure 2.4-2), and shows the incremental cost effectiveness between each successive set of least-cost NO_X control alternatives. The incremental NO_X control tons per year, divided by the incremental levelized annual cost, yields an incremental average unit cost ($/ton). This represents the slope of a line, if drawn, from one least-cost point as compared with another least-cost point.

--	Baseline, based on annual operation at future PTE case pre-control emission rate	0	0			

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost.
See footnote #3 for Tables 2.4-2 and 2.4-3 for annualized cost factors.
Costs for increased PM collection capacity are included in coal reburn options.

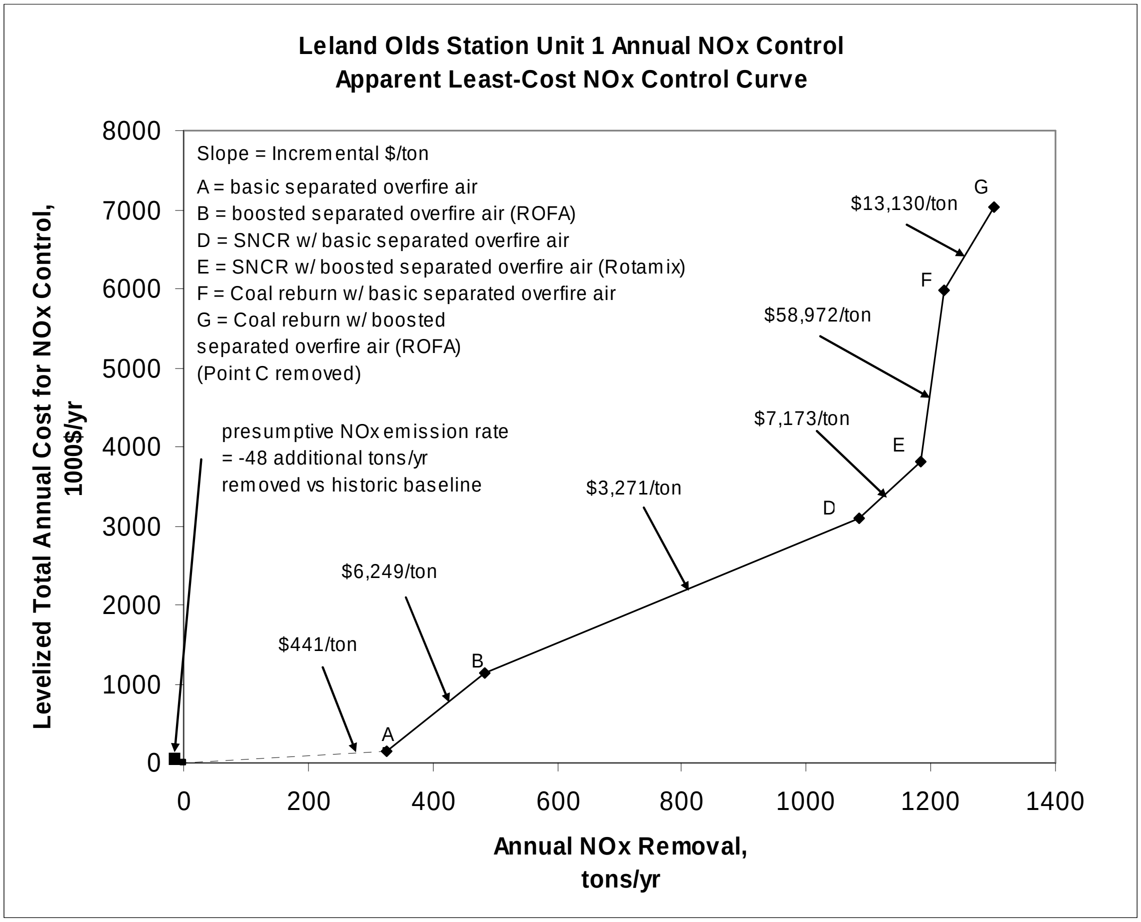
(3) – Annualized cost figures in 2005 dollars.

(4) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 1.

(5) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest.

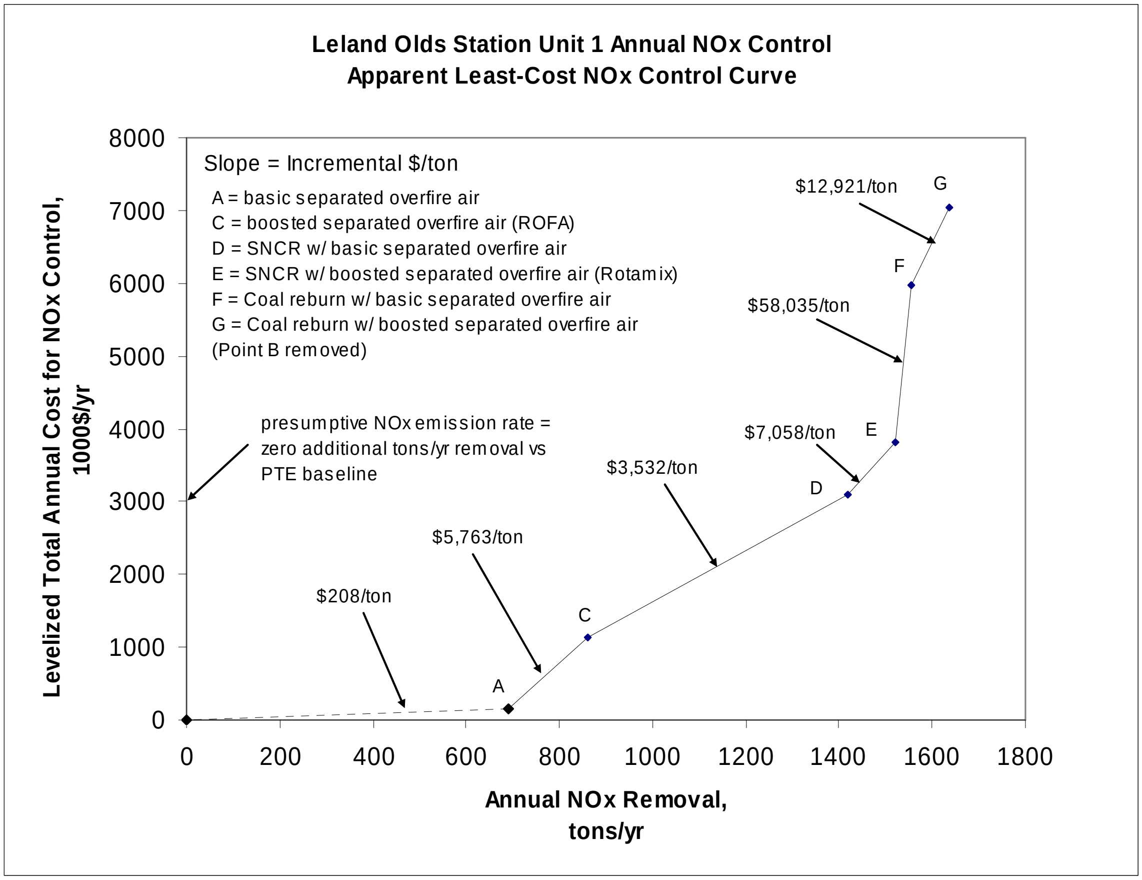
(6) – Incremental control cost effectiveness is incremental LTAC divided by incremental annual emission reduction (tons per year).

Figure 2.4-5 – NO_X Control Cost Effectiveness – LOS Unit 1 Apparent Least-Cost Controls Curve (Historic Pre-Control Annual Emission Baseline)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-7.

Figure 2.4-6 – NO_X Control Cost Effectiveness – LOS Unit 1 Apparent Least-Cost Controls Curve (PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.4-8.

In the comparison displayed in Figure 2.4-5 and Figure 2.4-6, for the data shown in Table 2.4-7 and Table 2.4-8, the boosted SOFA (ROFA) NO_X control alternative (Point B in Figure 2.4-5, Point C in Figure 2.4-6) had a significantly higher incremental unit NO_X control cost (slope, $6,249/ton and $5,763/ton, respectively) compared against basic SOFA alternative (Point A) versus SNCR with basic SOFA (Points D) compared against ROFA. Also, Coal Reburn with basic SOFA (Points F) was significantly more incrementally expensive ($58,972/ton and $58,035/ton) compared against SNCR with boosted SOFA (Points E) versus Coal Reburn with boosted SOFA (Points G) compared against Coal Reburn with basic SOFA alternatives (Point F) ($13,130/ton and $12,921/ton). This indicates that Points C and Points F are inferior controls and do not occupy the Dominant Cost Control Curves.

After removal of Points C and F, the modified least-cost controls curve is the Dominant Cost Control Curve for NO_X emissions alternatives for each of the LOS Unit 1 pre-control baselines evaluated.

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #3 for Tables 2.4-2 and 2.4-3 for annualized cost factors. Costs for increased PM collection capacity are included in coal reburn option.
(3) – Annualized cost figures in 2005 dollars.
(4) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 1.
(5) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest.
(6) – Incremental control cost effectiveness is incremental LTAC divided by incremental annual emission reduction (tons per year).

The cost impact analysis for historic and PTE baseline conditions identifies those control alternatives that are on the Dominant Controls Cost Curve. Those alternatives are scrutinized for cost-effectiveness on both relative and absolute bases. In the comparison displayed in Figure 2.4-7 and Figure 2.4-8, for the data shown in Table 2.5-9 and Table 2.5-10, the SNCR with basic SOFA NO_X control alternative (Points D) had a significantly higher incremental unit NO_X control cost (slope, $3,894/ton and $4,060/ton, respectively, for historic and PTE baseline conditions) compared against basic SOFA alternative (Point A) versus baseline ($441/ton and $208/ton, respectively). The incremental cost-effectiveness of the least-cost SNCR alternative on the Dominant Cost Control Curve is on the order of eight to nineteen times the magnitude of basic SOFA. SNCR with boosted SOFA (Point E) had a significantly higher incremental unit NO_X control cost compared against the SNCR with basic SOFA alternative (Point D) ($7,173/ton and

$7,058/ton, vs $3,894/ton and $4,060/ton respectively). Coal Reburn with boosted SOFA (Points G) was even more incrementally costly versus SNCR with boosted SOFA (Points E) ($27,560/ton and $27,122/ton, vs $($7,173/ton and $7,058/ton respectively).

In the final BART Guidelines, the EPA neither proposes hard definitions for reasonable or unreasonable Unit Control Costs nor for incremental cost effectiveness values. As can be seen from a review of Table 2.4-5, the average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the highest 24-hour historic baseline NO_X emission ranges from $441/ton to $6,504/ton. Table 2.4-6 shows average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the presumptive NO_X emission level ranges from $208/ton to $4,293/ton. The latter has lower costs per ton of NO_X emission removal due to the higher number of tons removed for the maximum emissions for pre-control baseline and additional controls under the future PTE case.

Various combinations of NO_X control technologies evaluated for control and cost-effectiveness are considered to be technically feasible for LOS Unit 1, but have much higher installation and operating costs compared with basic SOFA alone. This confirms the analysis performed by the EPA for establishing the presumptive limits for BART NO_X emissions from pulverized coal-fired EGUs: that the application of current combustion control technology, [primarily low-NOx burners and overfire air] is generally, but not always, more cost-effective than post-combustion controls. Based on the cost impact analysis and the premise that LOS Unit 1's historic and PTE annual average baseline emissions already meet the presumptive BART NO_X level of 0.29 lb/mmBtu, only the least-cost alternative of basic separated overfire air was considered for further impact and visibility impairment evaluations for LOS Unit 1 NO_X emissions control.

The other elements of the fourth step of a BART analysis after the cost impact analysis include evaluating the following impacts:

- Energy impacts.
- Non-air quality environmental impacts.
- Remaining useful life of the source.

For the purposes of this BART analysis, the remaining useful life of the source was assumed to exceed the 20-year project life utilized in the levelized annual cost impact estimates. The other impacts for the single LOS Unit 1 NO_X emissions control alternative chosen to be evaluated further are discussed in Section 2.4.2 and Section 2.4.3. Visibility impairment impacts evaluated for selected LOS Unit 1 NO_X emissions controls are summarized in Section 2.4.4.

(The following article is an addition to the August 2006 BEPC BART Determination Study report.)

[The same basic kinds of energy impacts for NO_X emissions controls described in the August 2006 BEPC LOS BART Report were evaluated for the SOFA with SNCR alternative for LOS Unit 1.]

2.4.2.1 ENERGY IMPACTS OF SOFA with SNCR NO_X CONTROL ALTERNATIVE – LOS UNIT 1

Another feasible NO_X control alternative was reviewed for significant or unusual energy penalties or benefits associated with its use on LOS Unit 1.

Basic SOFA with SNCR operation on LOS Unit 1 may require slightly higher forced draft fan power consumption resulting from higher fan discharge pressure, with combustion air damper actuators' electrical power demand expected to be an insignificant (+ 1 kW) change in net electrical power consumption from LOS Unit 1. Higher windbox pressure and ductwork pressure drop impacts of the SOFA system on the forced draft fans' and induced draft fans' auxiliary electrical power consumption are expected to be negligible (less than 1% of the annual auxiliary power consumed by these fans).

The SNCR portion of this layered alternative involves a chemical reagent injected for NO_X control, assumed to be aqueous urea. The injection of a diluted urea solution requires some additional auxiliary power for heating and pumping the liquid, and using compressed air for atomization and cooling the reagent injection nozzles/lances. Heat is required for urea reagent storage, assumed to be applied to outside concentrated aqueous urea storage tank(s). For the basic SOFA with SNCR alternative, the source of heat is assumed to be auxiliary electrical power. Together, the addition of SNCR to LOS Unit 1 is estimated to consume 35.8 kW, which was calculated following EPA OAQPS convention[2]. Based on operation for the entire year with the assumed 99% availability factor, this would consume approximately 310,000 kW-hr/yr of additional auxiliary electrical power.

Additional coal consumption for those alternatives that involve a chemical reagent injected for NOx control to compensate for the heat of vaporization of the reagent dilution water; this follows EPA OAQPS convention[1], but is not accepted practice by an experienced SNCR vendor (Fuel Tech) who claims that the heat produced from the exothermic reaction of urea and NO_X is approximately equal to the heat required to evaporate the dilution water. Reagent dilution water for those SNCR alternatives that involve a chemical reagent injected for NOx control were assumed to be four times the amount of delivered aqueous urea solution consumption (assumes urea is a 50% solution as delivered and is

---

[2]. See Basin LOS BART Determination Study report NO_X Section Reference number 49, page 1-34.

injected as a 10% solution); this also follows EPA OAQPS convention[3]. This was estimated to be approximately 6.2 million Btu per hour, or 53,645 mmBtu/yr.

Likewise, operation of a basic SOFA with SNCR alternative may cause a small increase in levels of unburned carbon in the flyash emitted from the LOS Unit 1 boiler compared with current operation. This represents a slight amount of lost potential electrical power generation from the incompletely burned fuel, so this inefficiency could have a small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kW-hr). This impact was not quantified, as the historical variation in coal heat content that influences plant unit heat rate is expected to have more significant impacts.

As discussed above, SNCR operation will cause a slight decrease (approximately 0.2%) on the LOS Unit 1 plant unit heat rate (higher Btu/kW-hr), primarily to higher flue gas moisture with corresponding sensible and latent heat losses which would require a slightly higher gross heat input to evaporate the extra dilution water input. This ignores the slight increase in induced draft fan horsepower and auxiliary electrical power consumption to handle the extra coal combustion products, urea and dilution water flows that will result in increased flue gas mass flow during SNCR operation.

LOS Unit 1 boiler furnace exit gas temperature and superheater steam / reheater steam outlet temperatures is not expected to change significantly, as a slight increase during air-staged burner operation with SOFA may be offset by a slight depression from the injection of the urea dilution water. This impact on the boiler’s operation is typically small, and within the design capabilities of the boiler from a heat transfer and mechanical stress standpoint. This impact on the LOS Unit 1 boiler’s thermal conversion efficiency and steam cycle impacts from small steam temperature changes was not quantified, but is not expected to be significant.

SOFA and SNCR are not expected to significantly reduce LOS Unit 1 reliability and availability to generate electrical power. There may be some changes in the degradation rate of the boiler’s furnace waterwall tubes resulting from exposure of more area of the furnace walls to slightly air-starved conditions during SOFA operation. Such conditions can promote corrosion of the steel waterwall tubes by sulfur compounds in the furnace gases being created above the burners and below the SOFA injection ports. Due to the moderate sulfur content in the lignite and modest amount of air-staging during firing of the existing low-NO_X burners expected during SOFA operation, this potential change in corrosion rate of the boiler tubes is expected to be minor. This degradation is expected to occur

---

[3] See Basin LOS BART Determination Study report NO_X Section Reference number 49, page 1-35.

over many years of operation, and normally requires periodic replacement of the deteriorated sections of boiler furnace waterwall tubes and superheater/reheater tube banks to avoid forced outages to repair tube leaks or failed sections. The potential change in the frequency of furnace wall tube and superheater/reheater tube failures and changeouts is difficult to estimate, and has not been quantified. SNCR with SOFA operation of LOS Unit 1 may also cause a slight increase in fireside deposit accumulation, especially in the primary and possibly secondary superheater and reheater tube banks. This is expected to be minor, and removed during periodic scheduled outages of LOS Unit 1.

Table 2.4-11 summarizes the gross demand and usage of auxiliary electrical power estimated for the two NO_X control alternatives evaluated for impacts on LOS Unit 1. This assumes annual operation for 8,760 hours at a heat input rate of 2,622 mmBtu/hr at the future PTE case conditions.

TABLE 2.4-11 – Expected Auxiliary Electrical Power Impacts for NO_X Controls – LOS Unit 1

		NO_X Control Equipment Estimated Annual Average Auxiliary Electrical Power Demand and Usage (future PTE case)		
Alt. No.	**NO_X Control Technique**	**Aux. Power Demand (1) (kW)**	**Generation Reduction from Aux. Power Demand(2) (kW-hrs/yr)**	**Generation Reduction from Reduced Unit Availability(3) (kW-hrs/yr)**
D	SNCR with basic SOFA	36.8	318,749	18,893
A	Separated OFA	1	8,760	0

(1) – The NO_X control equipment gross auxiliary electrical power demand is estimated.

(2) – The annual change in NO_X equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.

(3) – The estimated total hours per year of unit unavailability multiplied by average gross generation multiplied by annual running plant capacity factor for the particular control alternative. For this analysis, SOFA was not expected to reduce annual hours of possible operation.

(The following article is an addition to the August 2006 BEPC BART Determination Study report)

[The same basic kinds of non-air environmental impacts for NO_X emissions controls described in the August 2006 BEPC LOS BART Report were evaluated for the SOFA with SNCR alternative for LOS Unit 1.]

2.4.3.2 NON AIR QUALITY AND OTHER ENVIRONMENTAL IMPACTS OF SOFA with SNCR – LOS UNIT 1

Operation of an SNCR-related system will normally create a small amount of unreacted urea or ammonia to be emitted. The amount of ammonia slip produced by SNCR depends on the amount of reagent utilization and location of the injection points. Higher SNCR NO_X reduction performance involves greater amounts of reagent usage and ammonia slip. This potential air emission increase does not qualify as a non-air environmental impact evaluated for the BART impact analysis, and therefore has not been quantified.

Ammonia slip is typically controlled to less than 10 ppmvd, especially since the possible formation of sulfates such as ammonium sulfate [$(NH_4)_2SO_4$] and ammonium bisulfate [NH_4HSO_4] will be more problematic at higher slip levels. Sulfur trioxide (SO_3) formed during combustion in the boiler can combine with ammonia during passage through the flue gas ductwork to form the sulfates. Boiler combustion air heaters, whether tubular or rotary regenerative types, can become fouled with such sulfate compounds. An extension of scheduled unit outages or forced outages (unlikely) could occur as a result of these sulfate deposit accumulations and the time spent to remove them. This could reduce unit operating time (annual availability), but for LOS Unit 1 is expected to be very small, estimated to be 1% of the annual operating time possible.

Some of the unreacted ammonia from SNCR operation will be collected with the flyash in the electrostatic precipitator. This is not expected to pose any significant hazards in the subsequent disposal of the flyash in the nearby permitted landfill currently used by BEPC for this coal combustion byproduct material.

Storage of urea or ammonia reagent on-site creates the potential for accidents, leaks, and subsequent releases to air, ground, and surface water immediately surrounding the facility. Regulation of storage and containment of such reagents as hazardous substances will be under the requirements of various federal Acts, which are not part of this BART impact analysis.

The amount of unburned carbon in the flyash produced by the boiler, collected for disposal or potentially emitted to the atmosphere may increase by small increments due to operation of LOS Unit 1 using separated overfire air for NO_X emissions control. The potential changes in the annual amounts of flyash disposal rates are expected to be inconsequential, and have not been quantified. This potential air emission increase does not qualify as a non-air environmental impact evaluated for the BART impact analysis, and therefore has not been quantified.

The operation of a system using a basic form of separated overfire air for NO_X emissions control may increase carbon monoxide concentrations in the stack flue gas emitted from the LOS Unit 1 boiler. This potential air emission increase does not qualify as a non-air environmental impact evaluated for the BART impact analysis, and therefore has not been quantified.

The operation of a conventional SNCR system is not expected to significantly impact emissions of CO or volatile organic compounds (VOCs). The chemical form of the reagent will affect the amount of carbon dioxide emitted, since urea contains CO which is readily converted to CO_2 in the boiler-furnace and convection sections by combining with available free oxygen. One mole of carbon dioxide (CO_2) will be created and emitted for every mole of urea injected for reaction with NO_X. This is a relatively small increase in the total amount of CO_2 produced as part of the combustion of carbon-based fossil fuel in the form of lignite. This potential air emission increase does not qualify as a non-air environmental impact evaluated for the BART impact analysis, and therefore has not been quantified.

Any remaining ammonia slip that is not collected or condensed in the air pollution control system will be emitted from the stack as an aerosol or condensable particulate. This has the potential to increase atmospheric visibility impairment downwind of the facility compared with a pristine condition. Although the predicted amount of such potential impact from ammonia slip emissions has not been determined, it is expected to be small in comparison with the significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NO_X emission reductions from the use of SNCR-related alternatives. This potential air emission increase does not qualify as a non-air environmental impact evaluated for the BART impact analysis, and therefore has not been quantified.

There were no other adverse or significant changes in non-air quality environmental impacts identified for LOS Unit 1 as a result of using separated overfire air with SNCR for NO_X emissions control. Predicted visibility impairment improvement impacts from the reduction in nitrogen oxides emissions predicted to result from operation of LOS Unit 1 with SOFA and SNCR are discussed in the next section.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study report)

2.4.4 VISIBILITY IMPAIRMENT IMPACTS OF LELAND OLDS STATION NO_X CONTROLS –UNIT 1

The fifth step in a BART analysis is to conduct a visibility improvement determination for the source.

For this BART analysis, there were two baseline NO_X emission rates modeled for LOS Unit 1 – one for the historic pre-control NO_X emission rate listed in the NDDH BART protocol[3], and one applying the presumptive BART NO_X emission rate. The historic pre-control emission baseline was the 24-hour average actual NO_X emission rate from the highest emitting day of the years 2000-2002 (meteorological period modeled per the NDDH BART protocol[3]). The historic (protocol) NO_X baseline condition emission rate was modeled simultaneously with the highest 24-hour average SO_2 emission rate, and the highest 24-hour average PM emission rate of the 2000-2002 time period.

The historic (protocol) baseline hourly NO_X emission rate used for modeling visibility impacts due to LOS Unit 1 under the conditions stated above was 813 lb/hr. Visibility impact modeling was performed using the CALPUFF model with the difference between the impacts from historic pre-control baseline and post-control average hourly NO_X emission rates representing the visibility impairment impact reduction. One CALPUFF model run was performed with the LOS Unit 1's basic SOFA NO_X emission rate and another run was subsequently conducted with LOS Unit 1's SOFA with SNCR NO_X emission rate, constant PM emissions, and BART level of SO_2 control assuming the Potential-To-Emit (PTE) boiler design rating for heat input (2,622 mmBtu/hr). The unit NO_X emission rate of 0.168 lb/mmBtu multiplied by the boiler PTE heat input rating of 2,622 mmBtu/hr yields 441 lb/hr for LOS Unit 1 under the future PTE case. This compares to the visibility model using an average post-control hourly future PTE LOS Unit 1 NO_X emission rate of 0.23 lb/mmBtu with the PTE boiler heat input rating to yield 603 lb/hr for operation with basic SOFA.

In keeping with the NDDH BART visibility impairment impact modeling protocol, the BART NO_X post-control future PTE presumptive emission rate (760 lb/hr), basic SOFA, and SOFA with SNCR alternatives all have a different boiler heat input basis than the LOS Unit 1 historic highest 24-hour pre-control NO_X emission baseline (813 lb/hr). The post-control conditions for LOS Unit 1 all assume operation at the boiler PTE heat input capacity rating (future PTE case) of 2,622 mmBtu/hr.

The results of the historic LOS Unit 1 pre-control baseline, presumptive BART NO_X PTE baseline, and future post-control PTE NO_X emission rates for basic SOFA alternatives with and without SNCR-enhancement, modeled with the PTE 90% sulfur emission control rate for LOS Unit 1, are shown in Table 2.4-12. The results of the visibility impairment modeling at the pre-control (protocol) baseline emission rate for LOS Unit 1 showed that Lostwood National Wildlife Refuge exceeded 0.5 deciView for the highest predicted visibility impairment impact (90th percentile, averaged for 2000-2002). Average predicted visibility impairment impacts decreased significantly for the presumptive BART NO_X PTE baseline emission rate, and improved slightly with post-control SOFA with and without SNCR-enhanced PTE NO_X emission rates, modeled with the 90% PTE sulfur emission control rates for LOS Unit 1. The comparison of the incremental average visibility impairment impacts that are predicted for the three PTE sulfur emission control rates for LOS Unit 1 is shown elsewhere in Section 3.4.4.

TABLE 2.4-12 – Average Visibility Impairment Impacts from NO_X Controls – LOS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts(1)			
	Historic Pre-Control (Protocol) Baseline(2) (dV)	Presumptive BART NO_X PTE Baseline(3) (dV)	PTE Emissions with basic SOFA NO_X Control(4) (dV)	PTE Emissions with basic SOFA+SNCR NO_X Control(5) (dV)
TRNP-South Unit	0.423	0.107	0.099	0.091
TRNP-North Unit	0.450	0.118	0.111	0.102
TRNP-Elkhorn Ranch	0.287	0.080	0.073	0.066
Lostwood NWR	0.639	0.171	0.153	0.132

(1) - Average predicted visibility impairment impacts (90th percentile) relative to background for years 2000-2002. Pre-control baseline impacts are from highest historic 24-hour NO_X, SO_2, and PM emission rates (NDDH BART protocol). Presumptive BART NO_X emission limit, basic SOFA NO_X and basic SOFA + SNCR NO_X emission rate impacts are from PTE heat input conditions. A summary of the initial modeling scenarios was provided in the August 2006 BART Determination Study final draft report Table 1.4-1 and the modeling results were presented in Appendix D. SO_2 emissions reduced by 90% over pre-control baseline for the future PTE case.

(2) - Average of year 2000-2002 (annual) predicted visibility impairments modeled at historic pre-control NO_X emission baseline of 813 lb/hr.

(3) - Average of year 2000-2002 (annual) predicted visibility impairments modeled at presumptive BART post-control PTE NO_X mass emission hourly rate of 760.4 lb/hr (0.29 lb/mmBtu x 2,622 mmBtu/hr).

(4) - Average of year 2000-2002 (annual) predicted visibility impairments modeled at basic SOFA control alternative's post-control PTE NO_X mass emission hourly rate of 603.1 lb/hr (0.23 lb/mmBtu x 2,622 mmBtu/hr).

(5) - Average of year 2000-2002 (annual) predicted visibility impairments modeled at basic SOFA with SNCR control alternative's post-control PTE NO_X mass emission hourly rate 441 lb/hr (0.168 lb/mmBtu x 2,622 mmBtu/hr).

The results of the visibility impairment modeling at the presumptive BART NO_X PTE emission rate (760 lb/hr) with the PTE 90% sulfur emission control rate for LOS Unit 1 again showed that Lostwood National Wildlife Refuge had the highest predicted improvement in visibility impairment compared to the pre-control (protocol) baseline levels. Average predicted visibility impairment reduction also increased with basic SOFA with and without SNCR-enhanced post-control NO_X PTE emission rates from LOS Unit 1 for Lostwood NWR (approximately 0.5 deciView reduction). This is shown in Table 2.4-13.

TABLE 2.4-13 – Average Visibility Impairment Impact Reductions from NO_X Controls – LOS Unit 1 (Post-Control PTE Emissions vs Historic Baseline)

Federal Class 1 Area	Visibility Impairment Reductions(1)		
	Presumptive BART NO_X PTE Baseline(2) (dV)	**PTE Emissions, basic SOFA NO_X Control(3) (dV)**	**PTE Emissions with basic SOFA+SNCR NO_X Control(4) (dV)**
TRNP-South Unit	0.316	0.323	0.332
TRNP-North Unit	0.332	0.339	0.348
TRNP-Elkhorn Ranch	0.207	0.214	0.220
Lostwood NWR	0.467	0.486	0.507

(1) - Average predicted visibility impairment impact reductions (90th percentile) relative to historic pre-control emission rates (NDDH BART protocol) for years 2000-2002. Presumptive BART NO_X and SOFA NO_X impacts are from PTE heat input emission rates. SO_2 emissions reduced by 90% over pre-control baseline for the future PTE case scenario.

(2) - Difference of average of year 2000-2002 (annual) predicted visibility impairments modeled at historic pre-control NO_X emission baseline of 813 lb/hr minus average of year 2000-2002 (annual) predicted visibility impairments modeled at presumptive BART post-control PTE NO_X mass emission hourly rate of 760.4 lb/hr (0.29 lb/mmBtu x 2,622 mmBtu/hr).

(3) - Difference of average of year 2000-2002 (annual) predicted visibility impairments modeled at historic pre-control NO_X emission baseline of 813 lb/hr minus average of year 2000-2002 (annual)

predicted visibility impairments modeled at basic SOFA control alternative's post-control PTE NO_X mass emission hourly rate of 603.1 lb/hr (0.23 lb/mmBtu x 2,622 mmBtu/hr).

(4) - Difference of average of year 2000-2002 (annual) predicted visibility impairments modeled at historic pre-control NO_X emission baseline of 813 lb/hr minus average of year 2000-2002 (annual) predicted visibility impairments modeled at basic SOFA with SNCR control alternative's post-control PTE NO_X mass emission hourly rate 441 lb/hr (0.168 lb/mmBtu x 2,622 mmBtu/hr).

This analysis includes calculation of the average incremental reduction of the predicted visibility impairment impact for basic SOFA with and without SNCR-enhanced alternatives' PTE emission levels evaluated for the future PTE case operation of LOS Unit 1 compared to presumptive BART NO_X control effectiveness. The results are shown in Table 2.4-14.

TABLE 2.4-14 –Visibility Impairment Reduction from NO_X Controls (vs Presumptive BART NO_X Baseline Emissions) – LOS Unit 1

Federal Class 1 Area	Incremental Visibility Impairment Reduction PTE Emissions, basic SOFA NO_X Control[1] (dV)	Incremental Visibility Impairment Reduction PTE Emissions with basic SOFA+SNCR NO_X Control[2] (dV)	Additional Incremental Visibility Impairment Reduction PTE Emissions with basic SOFA+SNCR NO_X Control[3] (dV)
TRNP-South Unit	0.00733	0.0157	0.00833
TRNP-North Unit	0.00733	0.0160	0.00867
TRNP-Elkhorn Ranch	0.00733	0.0137	0.00633
Lostwood NWR	0.0183	0.0393	0.0210

(1) - Incremental average predicted visibility impairment impact reductions (90th percentile) relative to presumptive BART post-control PTE NO_X mass emission hourly rate for years 2000-2002. SOFA NO_X post-control impacts are from PTE heat input emission rates, with SO_2 emissions reduced by 90% over pre-control PTE heat input baseline for the future PTE case.

(2) - Incremental average predicted visibility impairment impact reductions (90th percentile) relative to presumptive BART post-control PTE NO_X mass emission hourly rate for years 2000-2002. SOFA + SNCR post-control NO_X impacts are from PTE heat input emission rates, with SO_2 emissions reduced by 90% over pre-control PTE heat input baseline for the future PTE case.

(3) - Additional incremental average predicted visibility impairment impact reductions (90th percentile) relative to basic SOFA post-control PTE NO_X mass emission hourly rate for years 2000-2002. SOFA + SNCR post-control NO_X impacts are from PTE heat input emission rates, with SO_2 emissions reduced by 90% over pre-control PTE heat input baseline for the future PTE case.

Table 2.4-14 shows that incremental visibility impairment improvements predicted to result from applying the basic SOFA with and without SNCR-enhanced alternatives to the presumptive BART NO_X PTE emission rate for LOS Unit 1 are very small. The amount of visibility impairment predicted for natural background conditions is much greater in magnitude than the amount predicted from LOS Unit 1's post-control NO_X PTE emissions contribution alone. The data also shows that reductions in predicted visibility impairment impacts that result from a combination of presumptive

BART NO_X PTE emissions and SO_2 PTE emissions at the 90 percent (or better) control levels compared to the pre-control (protocol) emission conditions are much greater in significance than the incremental improvements of predicted visibility impairment from additional reductions in NO_X emissions.

This analysis also includes a determination of the incremental cost-effectiveness of reducing predicted visibility impairment impact for the SOFA with and without SNCR-enhanced alternatives being evaluated for LOS Unit 1. The estimated LTAC for reducing NO_X emissions from LOS Unit 1 expected to result from separated overfire air (SOFA) for the future PTE case are shown in Table 2.4-6. The comparison in Table 2.4-15 shows that the ratio of the estimated additional annualized costs of installing and operating SOFA with and without SNCR-enhanced alternatives for the future PTE conditions to the average predicted visibility impairment improvement relative to the presumptive BART NO_X PTE baseline emission rate for the future PTE case applied to LOS Unit 1 would result in millions of dollars per deciView of visibility impairment improvement.

TABLE 2.4-15 – Cost Effectiveness of Visibility Impairment Reduction from NO_X Controls (vs Presumptive NO_X Baseline Emissions) – LOS Unit 1

Federal Class 1 Area	Incremental Visibility Impairment Reduction Unit Cost PTE Emissions, basic SOFA NO_X Control(1) ($/dV-yr)	Incremental Visibility Impairment Reduction Unit Cost PTE Emissions, basic SOFA + SNCR NO_X Control(2) ($/dV-yr)	Additional Incremental Visibility Impairment Reduction Unit Cost PTE Emissions, basic SOFA + SNCR vs SOFA NO_X Control(3) ($/dV-yr)
TRNP-South Unit	19,640,000	197,800,000	354,600,000
TRNP-North Unit	19,640,000	193,700,000	341,000,000
TRNP-Elkhorn Ranch	19,640,000	226,800,000	466,600,000
Lostwood NWR	7,860,000	78,800,000	140,700,000

(1) - Average predicted visibility impairment impact reductions (90th percentile) relative to presumptive BART NO_X PTE baseline emission rates for years 2000-2002 with SO_2 emissions reduced by 90% over pre-control baseline for the future PTE case. Basic SOFA NO_X impacts are from PTE heat input emission rates. Control costs are levelized annual values for installed capital + O&M for basic SOFA NO_X control. All cost figures in 2005 dollars. See Table 2.4-6 for details.

(2) - Average predicted visibility impairment impact reductions (90th percentile) relative to presumptive BART NO_X PTE baseline emission rates for years 2000-2002 with SO_2 emissions reduced by 90% over pre-control baseline for the future PTE case. Basic SOFA+SNCR NO_X impacts are from PTE heat input emission rates. Control costs are levelized annual values for

installed capital + O&M for basic SOFA+ SNCR NO_X control. All cost figures in 2005 dollars. See Table 2.4-6 for details.

(3) - Average predicted incremental visibility impairment impact reductions (90th percentile) relative to basic SOFA NO_X PTE emission rates for years 2000-2002 with SO_2 emissions reduced by 90% over pre-control baseline for the future PTE case. Basic SOFA and basic SOFA with SNCR NO_X impacts are from PTE heat input emission rates. Incremental control costs are levelized annual values for installed capital + O&M for basic SOFA with SNCR control vs basic SOFA NO_X control. All cost figures in 2005 dollars. See Table 2.4-6 for details.

The number of days predicted to have visibility impairment due to LOS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the historic pre-control (protocol) hourly NO_X, SO_2, and PM emission rates described previously in this Section. The results are summarized and presented in the Screening Analysis Table of Appendix D. Similarly, the same information for the post-control SO_2 and PM alternatives for LOS Unit 1 with presumptive BART NO_X PTE emission rates was summarized and is shown in Table 3.4-15. The differences in average visibility impairment impact and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between presumptive BART NO_X emission rates versus basic SOFA-controlled LOS Unit 1 NO_X emission rates with post-control SO_2 and PM alternatives are summarized and shown in Table 2.4-16. The reductions in the average visibility impairment impact and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between presumptive BART NO_X emission rates versus basic SOFA with SNCR-controlled NO_X emission rates with post-control SO_2 and PM alternatives for LOS Unit 1 are also summarized and shown in Table 2.4-16.

The magnitude of predicted visibility impairment impacts and number of days predicted to have visibility impairment impact greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 area. The highest number of days in which the predicted visibility impairment impact above background exceeded 0.5 deciViews was for the pre-control (protocol) emission case in year 2000 for Lostwood NWR. A series of bar charts showing the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for both the pre-control and post-control model results is included in Section 3.4. The post-control SO_2 and PM alternatives with SOFA for NO_X control were only slightly lower for the predicted visibility impairment impacts and number of days predicted to have visibility impairment impacts greater than 0.50 and 1.00 deciViews compared to the same post-control SO_2 and PM conditions with presumptive BART NO_X PTE emission rates. The number of days are presented in Appendix D. A series of bar charts showing the difference in the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the SOFA-controlled PTE emission rates compared to presumptive BART NO_X PTE emission rates with post-control SO_2 and PM alternatives is included in Figures 2.4-9, 2.4-10, and 2.4-11.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.4.5 SUMMARY OF IMPACTS OF LOS NO_X CONTROLS – UNIT 1

Table 2.4-17 summarizes the various quantifiable impacts discussed in Sections 2.4.1 through 2.4.4 for the single BART NO_X alternative evaluated for LOS Unit 1.

Table 2.4-16 – Visibility Impairment Reductions – Basic SOFA and Basic SOFA + SNCR vs Presumptive BART NO_X Control with SO_2 and PM Controls

LOS Unit 1

Class 1 Area	NO_X Control Technique(1)	Visibility Impairment Reduction (ΔdV)	ΔDays(2) Exceeding 0.5 dV in 2000	ΔDays(2) Exceeding 0.5 dV in 2001	ΔDays(2) Exceeding 0.5 dV in 2002	ΔDays(2) Exceeding 1.0 dV in 2000	ΔDays(2) Exceeding 1.0 dV in 2001	ΔDays(2) Exceeding 1.0 dV in 2002	ΔConsecutive Days(2) Exceeding 0.5 dV 2000	ΔConsecutive Days(2) Exceeding 0.5 dV 2001	ΔConsecutive Days(2) Exceeding 0.5 dV 2002

					TRNP-Elk	0.00633(5)	466,600,000(5)		
					LNWR	0.0210(5)	140,700,000(5)		

(1) - All cost figures in 2005 dollars. See Table 2.4-6 for details.

(2) - LTAC for post-control NO_X control alternative divided by Incremental ΔdV.

(3) - Average predicted visibility impairment impact improvements (incremental, 90th percentile) for years 2000-2002 (annual) modeled at presumptive BART post-control PTE NO_X mass emission hourly rate of 760.4 lb/hr (0.29 lb/mmBtu x 2,622 mmBtu/hr) minus average of year 2000-2002 (annual) predicted visibility impairments modeled at basic SOFA control alternative's post-control PTE NO_X mass emission hourly rate of 603.1 lb/hr (0.23 lb/mmBtu x 2,622 mmBtu/hr) with SO_2 and PM post-control alternatives at PTE heat input emission rates (future PTE case) for both cases. This case assumes 90% SO_2 control over pre-control baseline.

(4) - Average predicted visibility impairment impact improvements (incremental, 90th percentile) for years 2000-2002 (annual) modeled at presumptive BART post-control PTE NO_X mass emission hourly rate of 760.4 lb/hr (0.29 lb/mmBtu x 2,622 mmBtu/hr) minus average of year 2000-2002 (annual) predicted visibility impairments modeled at basic SOFA with SNCR control alternative's post-control PTE NO_X mass emission hourly rate 441 lb/hr (0.168 lb/mmBtu x 2,622 mmBtu/hr) with SO_2 and PM post-control alternatives at PTE heat input emission rates (future PTE case) for both cases. This case assumes 90% SO_2 control over pre-control baseline.

(5) - Average predicted incremental visibility impairment impact improvements (incremental, 90th percentile) for years 2000-2002 (annual) modeled at SOFA post-control PTE NO_X mass emission hourly rate of 603.1 lb/hr (0.23 lb/mmBtu x 2,622 mmBtu/hr) minus average of year 2000-2002 (annual) predicted visibility impairments modeled at basic SOFA with SNCR control alternative's post-control PTE NO_X mass emission hourly rate 441 lb/hr (0.168 lb/mmBtu x 2,622 mmBtu/hr) with SO_2 and PM post-control alternatives at PTE heat input emission rates (future PTE case) for both cases. This case assumes 90% SO_2 control over pre-control baseline.

(The following article is a copy of the same section in the August 2006 BEPC BART Determination Study final draft report. It is included here for continuity from the corrected and amended Unit 1 portion of the BEPC BART Determination Study report and the corrected Unit 2 portion that follows)

2.5 EVALUATION OF IMPACTS FOR FEASIBLE NO_X CONTROLS – LOS UNIT 2

The fourth step of a BART analysis is to evaluate the following impacts of feasible emission controls:

- The cost of compliance.
- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

The purpose of the impacts evaluation is to determine if there are any energy, economic, non-air quality environmental reasons, or aspects of the remaining useful life of the source, which would eliminate the control technologies from consideration for Leland Olds Station Unit 2.

2.5.1 COST IMPACTS OF NO_X CONTROLS – LOS UNIT 2

An evaluation was performed to determine the compliance costs of installing various feasible NO_X control alternatives on LOS Unit 2 boiler. This evaluation included estimates for:

- Capital costs;
- Fixed and variable operating and maintenance costs; and
- Levelized total annual costs

to engineer, procure, construct, install, startup, test, and place into commercial operation the particular control technology. The results of this evaluation are summarized in Tables 2.5-1 through 2.5-8. From Step 3 of the BART analysis, compared with other similarly-effective NO_X controls, conventional gas reburn alternatives would have high expected capital costs for a natural gas supply pipeline and on-going natural gas costs. Thus, otherwise technically feasible gas-consuming alternatives are considered economically unattractive for application at LOS on the Unit 2 boiler.

Although the BART Guidelines prescribes following a “top down” analysis approach for BART determination, the development of a least cost envelope with dominant controls[1] [70 FR 39168] clearly labels points with lower emissions reductions and total annual costs first, i.e. “A”, “B”, etc. then proceeding with labeling and connecting points plotted further away from the zero emission reduction point. This “bottom-up” approach is for plotting the least-cost (dominant) control curve. The labeling of each unit’s NO_X control technique alternative has followed this approach.

2.5.1.1 CAPITAL COST ESTIMATES FOR NO_X CONTROLS - LOS UNIT 2

The capital costs to implement the various NO_X control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. In the cases involving SNCR, preliminary vendor budgetary cost information was obtained and used in place of, or to adjust, the published unit output cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

A review of the unit capital cost factor range and single point unit capital cost factor for the feasible NO_X emission reduction technology evaluated for LOS Unit 2 are presented in Table 2.5-1.

TABLE 2.5-1 – Unit Capital Cost Factors of Feasible NO_X Control Options for LOS Unit 2

Alt. No. (1)	**NO_X Control Technique**	**Range(2) ($/kW)**	**Single Point Unit Capital Cost Factor(3), ($/kW) LOS Unit 2**
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	20 + ?(4)	46(4),(5),(6)
C	SNCR (using urea) w/ ASOFA	20-35(7)	38(5),(6)
B	Coal Reburn (conventional, pulverized) w/ ASOFA	30-60(7)	153(6),(8)
A	Advanced Separated Overfire Air (ASOFA)	5-10(7)	23(6)

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – Unit capital cost factors ($/kW) of these individual technologies combined by simple addition. Actual installed costs may differ due to positive or negative synergistic effects. Range based on published values or vendor proposals.

(3) – Single point cost factor is best estimate for determination of total capital cost for a particular technology or combination, assuming maximum unit capacity is based on existing nameplate rating. Single point cost figures in 2005 dollars.

(4) – No published RRI unit capital cost factor was found in available technical literature. The installed capital costs for RRI are expected to be similar to SNCR. If both RRI and SNCR are installed together, capital cost of the RRI+SNCR portion was assumed to be 1.5x the capital cost of SNCR alone, due to commonality between the two systems sharing certain equipment and systems.

(5) – Estimated capital cost for SNCR point estimate derived from December 2004 budgetary proposal by Fuel Tech. See Appendix A for details.

(6) – The single point unit capital cost factor shown for the “advanced” version of SOFA derived from Burns & McDonnell internal database and cost estimate for North Dakota lignite-fired cyclone boilers.

(7) – NESCAUM 2005 Technical Paper, posted at their website for basic SOFA. See Appendix A for details.

(8) – The single point unit capital cost factor shown for a coal reburn system is highly site-specific, and assumes that new pulverizers and building enclosures are required. The general cost range for pulverized coal-fired boilers is included in the NESCAUM 2005 Technical Paper; for cyclone boilers is included in the 2005 WRAP Draft Report, posted at their website. The single point unit capital cost factor for this alternative for increased PM collection capacity included in coal reburn options is 57.5 $/kW. See Appendix A for details.

Annualized capital cost, which includes the time value of capital monies and its recovery, is determined from the estimated capital cost and the methodology described in Section 1. Table 2.5-2 shows the estimated installed capital cost and annualized capital cost values for the highest-performing form of the various feasible NO_X emission reduction technologies applied to LOS Unit 2. These were developed by multiplying the unit capital cost single point factors for the control option by the nameplate output capacity rating of the respective unit. These are listed in order of control effectiveness, with the highest ranked options at the top.

TABLE 2.5-2 – Installed and Annualized Capital Costs Estimated for NO_X Control Alternatives - LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Installed Capital Cost(2) ($1,000)	Annualized Capital Cost(3) ($1,000)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	20,200	1,760
C	SNCR (using urea) w/ ASOFA	16,800	1,470
B	Coal Reburn (conventional, pulverized) w/ ASOFA	67,400(4)	5,880(4)
A	Advanced Separated Overfire Air (ASOFA)	10,100	883
	Baseline	0	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – Installed capital cost is estimated for determination of total capital cost for a control technology, assuming maximum unit output capacity is based on existing nameplate rating of 440,000 kW. Installed capital cost figures in 2005 dollars.

(3) – Annualized capital cost = Installed capital cost x 0.08718 Capital Recovery Factor.

(4) – Costs for increased PM collection capacity included in coal reburn option are $25,300,000 for installed capital cost, and $2,200,000/yr annualized capital cost.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.5.1.2 OPERATING AND MAINTENANCE COST ESTIMATES FOR NO_X CONTROLS – LOS UNIT 2

The operation and maintenance costs to implement the various NO_X control technologies were largely estimated from cost factors (percentages of installed capital costs) established in the EPA's Air Pollution Control Cost Manual (OAQPS), and from engineering judgment applied to that control technology. In the cases including various forms of SNCR, preliminary vendor quotes were obtained and used in place of, or to adjust the OAQPS cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

Fixed and variable operating and maintenance costs considered and included in each NO_X control technology's Levelized Total Annual Costs are estimates of:

- Auxiliary electrical power consumption for operating the additional control equipment;
- Reagent consumption, and reagent unit cost for SNCR and RRI alternatives; and
- Reagent dilution water consumption and unit cost for SNCR and RRI alternatives.
- Increases or savings in auxiliary electrical power consumption for changes in coal preparation equipment and loading, primarily for fuel reburn cases;
- General operating labor, plus maintenance labor and materials devoted to the additional emission control equipment and its impact on existing boiler equipment.
- Reductions in revenue expected to result from loss of unit availability, i.e. outages attributable to the control option, which reduce annual net electrical generation available for sale (revenue).

Table 2.5-3 and Table 2.5-4 show the estimated annual operating and maintenance costs and levelized annual O&M cost values for the highest-performing form of the various feasible NO_X emission reduction technologies. These are listed in order of control effectiveness, with the highest ranked options at the top. The cost methodology summarized in Section 1.3.5 provides more details for the levelized annual O&M cost calculations and cost factors.

TABLE 2.5-3 – Estimated O&M Costs for NO_X Control Options (Relative to Historic Pre-Control Annual Emission Baseline) – LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Annual O&M Cost(2) ($1,000)	Levelized Annual O&M Cost(3) ($1,000)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	11,340	13,530
C	SNCR (using urea) w/ ASOFA	6,750	8,060
B	Coal Reburn (conventional, pulverized) w/ ASOFA	5,900(4)	7,040(4)
A	Advanced Separated Overfire Air (ASOFA)	152	182
	Baseline, based on annual operation at historic 24-mo average pre-control emission rate	0	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Annual O&M cost figures in 2005 dollars.
(3) – Levelized annual O&M cost = Annual O&M cost x 1.19314 Annualized O&M cost factor.
(4) – Costs for increased PM collection capacity included in coal reburn option are $1,740,000 for annual O&M cost, and $2,080,000/yr levelized annual O&M cost.

Annual operating and maintenance costs of the NO_X control options in Table 2.5-3 and Table 2.5-4 are based on LOS Unit 2 operation with the control option at 5,130 mmBtu/hr heat input and 8,760 hrs/yr operation. The Table 2.5-3 O&M costs are relative to unit pre-control baseline operation at 0.667 lb/mmBtu for the highest 24-month NO_X emission summation at 4,478 mmBtu/hr heat input for 8,050 hrs/yr operation of LOS Unit 2. The Table 2.5-4 O&M costs are relative to unit pre-control baseline operation at 0.667 lb/mmBtu for the maximum NO_X emissions associated with the future PTE case at 5,130 mmBtu/hr heat input for 8,760 hrs/yr operation of LOS Unit 2.

TABLE 2.5-4 – Estimated O&M Costs for NO_X Control Options (Relative to PTE Pre-Control Annual Emission Baseline – Future PTE Case) – LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Annual O&M Cost(2) ($1,000)	Levelized Annual O&M Cost(3) ($1,000)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	11,340	13,530
C	SNCR (using urea) w/ ASOFA	6,750	8,060
B	Coal Reburn (conventional, pulverized) w/ ASOFA	5,900(4)	7,040(4)
A	Advanced Separated Overfire Air (ASOFA)	152	182
	Baseline, based on annual operation at future PTE case pre-control emission rate	0	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Annual O&M cost figures in 2005 dollars.
(3) – Levelized annual O&M cost = Annual O&M cost x 1.19314 Annualized O&M cost factor.
(4) – Costs for increased PM collection capacity included in coal reburn option are $1,740,000 for annual O&M cost, and $2,080,000/yr levelized annual O&M cost.

The majority of the annual operating and maintenance costs for the alternatives using chemical reagent injection (urea) for NO_X emissions control are for the delivered reagent and dilution water. Both RRI and SNCR are assumed to dilute the 50% aqueous urea solution as-received to a 10% aqueous urea concentration for direct injection into the targeted furnace areas. Higher than theoretical normalized (molar) stoichiometric ratios (NSRs) for the moles of equivalent reagent injected (urea) per mole of inlet NO_X emission were assumed for SNCR with ASOFA, and for RRI+SNCR with ASOFA due to inefficiencies inherent in their use. These annual costs reflect a significant increase in reagent consumption above the theoretical rates based on expected amounts of reagent utilization.

In order to compare a particular NO_X emission reduction alternative during the cost of compliance impact analysis portion of the BART selection process, the basic methodology defined in the BART Guidelines was followed [70 FR 39167-39168]. The sum of estimated annualized installed capital plus levelized annual operating and maintenance costs, which in this analysis is referred to as "Levelized Total Annual Cost" (LTAC) of expected pollutant removal incurred by implementing that alternative, was calculated. The LTAC for these NO_X control alternatives was calculated based on the same economic conditions and a 20 year project life (see Section 1.3.5 of this BART evaluation for methodology details).

The Average Cost Effectiveness (also called Unit Control Cost) was then determined as the LTAC divided by baseline annual tons of pollutant emissions that would be avoided by implementation of the respective alternative. The feasible control alternatives were also compared by calculating the change in LTAC per incremental ton of pollutant removed for the next most stringent alternative (incremental cost effectiveness). This identified which alternatives produced the highest increment of expected pollutant reduction for the estimated lowest average LTAC increment compared with the pre-control baseline emission rate. The expected annual number of tons of pollutant removed versus estimated LTAC for each remaining control alternative was then plotted. These incremental and average control costs relative to the historic pre-control annual NO_X emission baseline for LOS Unit 2 are shown in Table 2.5-5. The incremental and average control costs relative to the PTE pre-control annual NO_X emission baseline for LOS Unit 2 are shown in Table 2.5-6.

TABLE 2.5-5 – Estimated Annual Emissions and LTAC for NO_X Control Alternatives (Historic Pre-Control Annual Emission Baseline) – LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Annual NO_X Emissions(2) (Tons/yr)	Annual NO_X Emissions Reduction(2) (Tons/yr)	Levelized Total Annual Cost(3),(4) ($1,000)	Average Control Cost(4) ($/ton)
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	5,895	6,128	15,290	2,500
C	SNCR (using urea) w/ ASOFA	6,762	5,261	9,520	1,810

	Baseline, based on annual operation at future PTE case pre-control emission rate	14,989	0	0	

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 2.

(3) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See footnote #3 for Tables 2.5-2 and 2.5-4 for annualized cost factors.

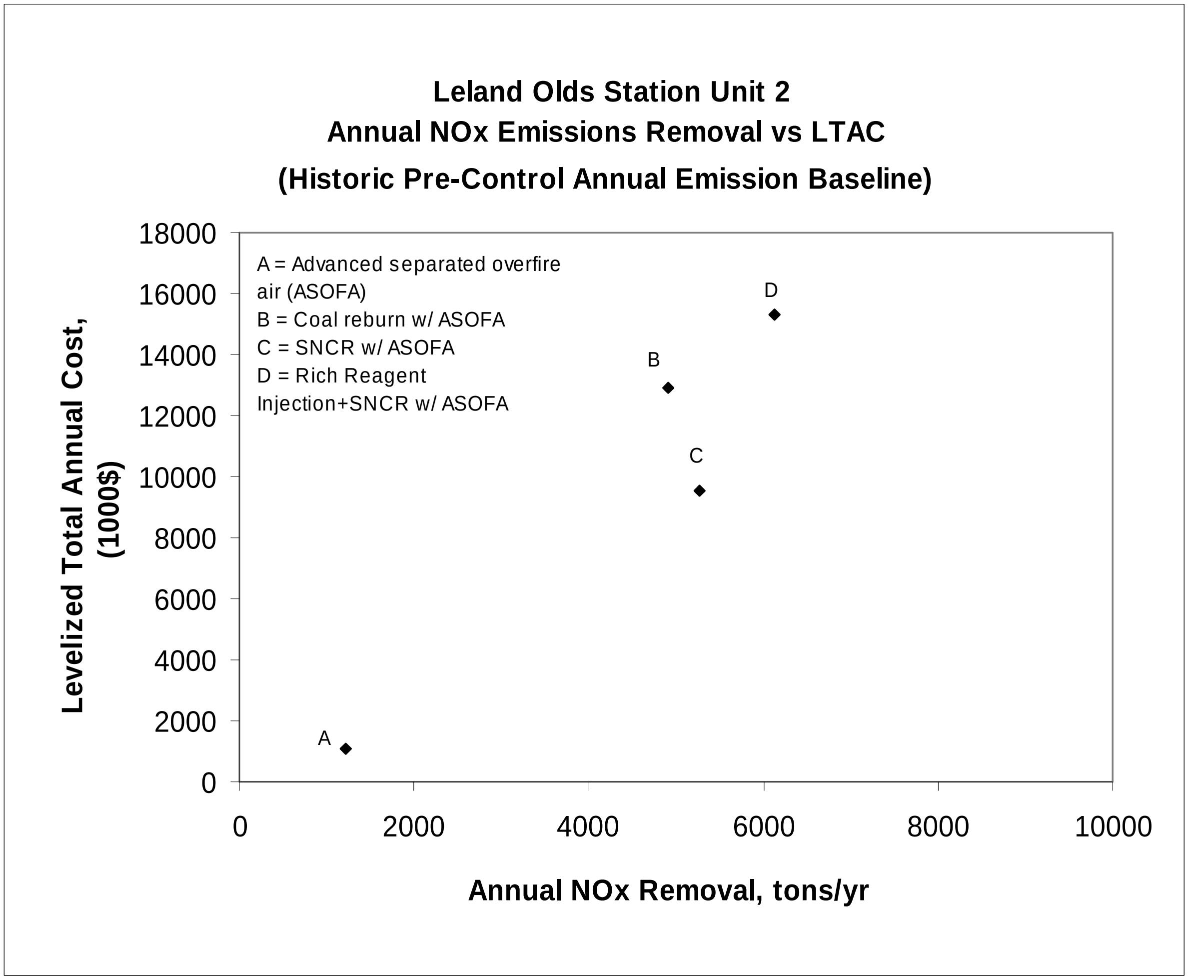
(4) – Annualized cost figures in 2005 dollars.

(5) – LTAC for increased PM collection capacity included in coal reburn option are $2,200,000 for annualized capital cost plus $2,080,000 for annualized O&M cost, for a total of $4,280,000/yr. This results in a average control cost of $544 per ton of NO_X removed.

The comparison of the cost-effectiveness of the control options evaluated for LOS Unit 2 relative to two different NO_X emission baselines was made and is shown in Figures 2.5-1 and 2.5-2. The estimated annual amount of NO_X removal (emission reduction) in tons per year is plotted on the ordinate (horizontal axis) and the estimated levelized total annual cost in thousands of U.S. dollars per year on the abscissa (vertical axis).

Figure 2.5-1 is for the control options evaluated relative to the baseline historic pre-control annual baseline, compared to the post-control maximum annual NO_X emissions for operation of LOS Unit 2 under the future PTE case.

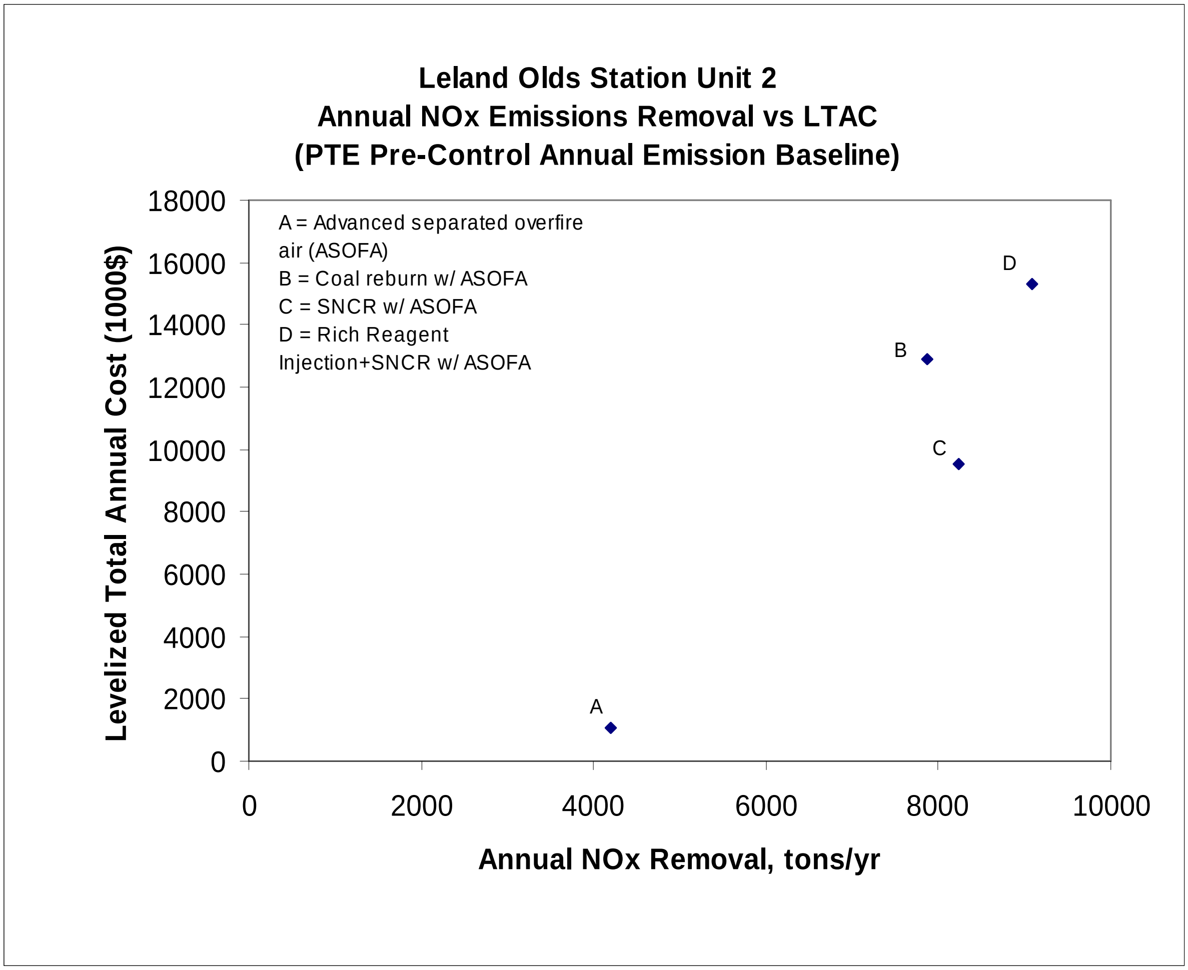
Figure 2.5-1 – NO_X Control Cost Effectiveness – LOS Unit 2 (Historic Pre-Control Annual Emission Baseline)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.5-5.

Figure 2.5-2 plots estimated levelized total annual costs versus estimated annual amount of NO_X removal (emission reduction) for the control options evaluated relative to the maximum pre-control annual baseline and future potential-to-emit post-control NO_X emissions for operation of LOS Unit 2 under the future PTE case.

Figure 2.5-2 – NO_X Control Cost Effectiveness – LOS Unit 2
(PTE Pre-Control Annual Emission Baseline – Future PTE Case)$^{(1)}$



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.5-6.

The purpose of Figures 2.5-1 and 2.5-2 is to show the range of control and cost for the evaluated NO_X reduction alternatives and identify the least-cost controls so that the Dominant Controls Curve can be created. The Dominant Controls Curve is the best fit line through the points forming the lower rightmost boundary of the data zone on a scatter plot of the LTAC versus the annual NO_X removal tonnage for the various remaining BART alternatives. Points distinctly to the left of and above this curve are inferior control alternatives per the BART Guidelines and BART Guidelines on a cost effectiveness basis. Following a “bottom-up” graphical comparison approach, each of the NO_X control technologies represented by a data point to the left of and above the least cost envelope should be excluded from further analysis on a cost efficiency basis. Of the highest-performing versions of the technically feasible LOS Unit 2 NO_X control alternatives evaluated for cost-effectiveness, the data point for coal reburn with ASOFA is seen to be more costly for fewer tons of NO_X removed than for SNCR with ASOFA. This appears to be an inferior control, and thus should not be included on the least cost and Dominant Controls Curve boundary. Note that cost-effectiveness points for conventional gas reburn and fuel-lean gas reburn alternatives would be distinctly left and significantly above the least cost-control envelope, so these options were not included in the cost-effectiveness analysis.

The next step in the cost effectiveness analysis for the BART NO_X control alternatives is to review the incremental cost effectiveness between remaining least-cost alternatives. Figure 2.5-3 and Figure 2.5-4 contains a repetition of the levelized total annual cost and NO_X control information from Figure 2.5-1 and Figure 2.5-2 with Point B removed, and shows the incremental cost effectiveness between each successive set of least-cost NO_X control alternatives. The incremental NO_X control tons per year, divided by the incremental levelized annual cost, yields an incremental average unit cost ($/ton). This represents the slope of a line, if drawn, from one least-cost point as compared with another least-cost point. This modified least-cost controls curve is the Dominant Controls Cost Curve for NO_X emissions alternatives for each of the LOS Unit 2 pre-control baselines evaluated.

TABLE 2.5-7 – Estimated Incremental Annual Emissions and LTAC for NO_X Control Alternatives (Historic Pre-Control Annual Emission Baseline) – LOS Unit 2

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost.
See footnote #3 for Tables 2.5-2 and 2.5-3 for annualized cost factors.
Costs for increased PM collection capacity are included in coal reburn option.
(3) – Annualized cost figures in 2005 dollars.
(4) – NO_X emissions and control level reductions relative to the future potential-to-emit pre-control annual baseline for the future PTE case applied to LOS Unit 2.
(5) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest.
(6) – Incremental control cost effectiveness is incremental LTAC divided by incremental annual emission reduction (tons per year).

In the comparison displayed in Figure 2.5-3 and Figure 2.5-4, for the data shown in Table 2.5-7 and Table 2.5-8, the RRI+SNCR with Advanced SOFA NO_X control alternative (Point D) had a significantly higher incremental unit NO_X control cost (slope, $6,650/ton) compared against SNCR with ASOFA alternative (Point C) versus SNCR with ASOFA (Point C) compared against the ASOFA alternative (Point A) ($2,100/ton).

Figure 2.5-3 – NO$_X$ Control Cost Effectiveness – LOS Unit 2 Dominant Cost Control Curve (Historic Pre-Control Annual Emission Baseline)(1)

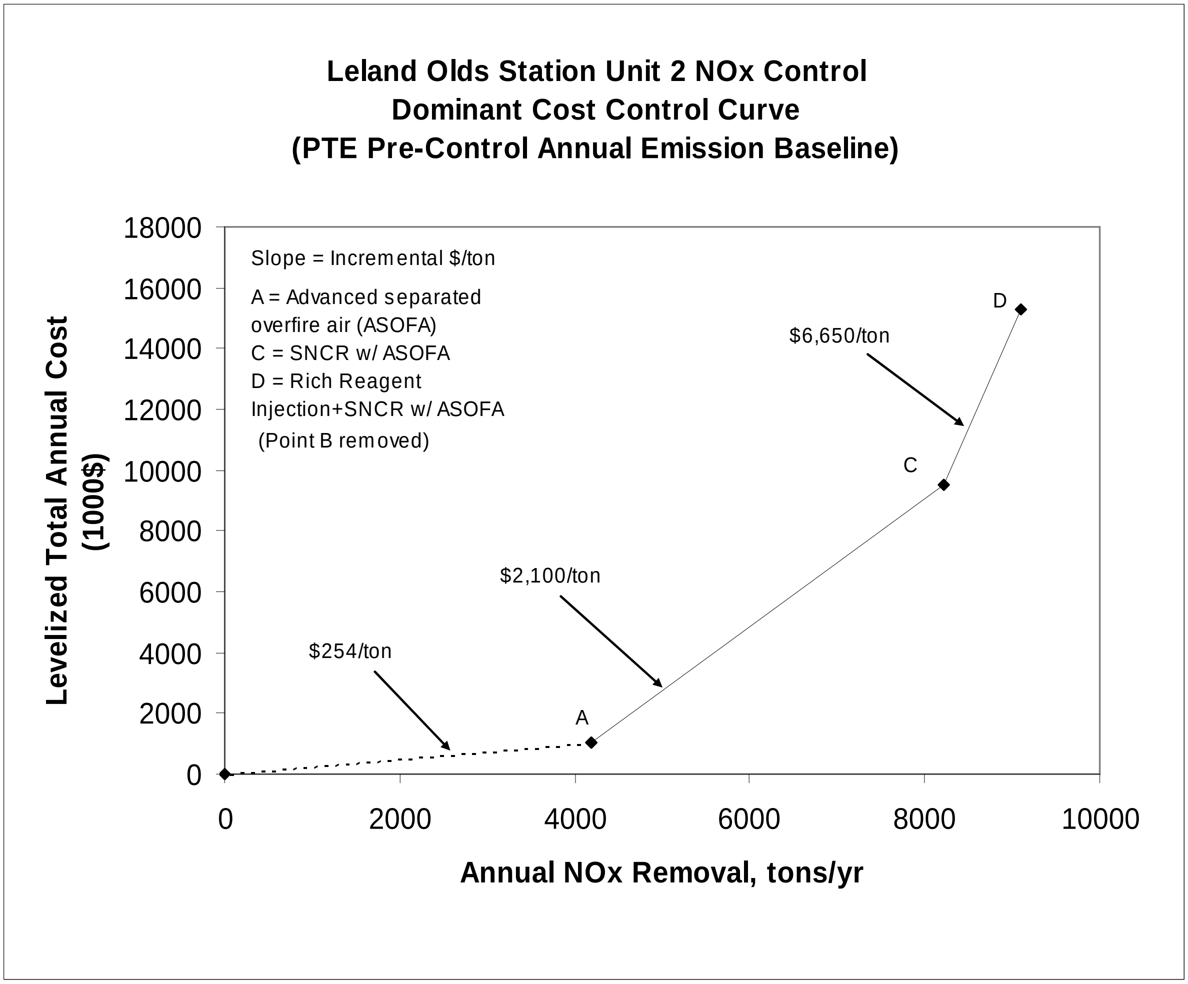
Figure 2.5-4 – NO_X Control Cost Effectiveness – LOS Unit 2 Dominant Cost Control Curve (PTE Pre-Control Annual Emission Baseline – Future PTE Case)(1)



(1) - All cost figures in 2005 dollars. Numbers are listed and qualifiers are noted in Table 2.5-8.

In the final BART Guidelines, the EPA neither proposes hard definitions for reasonable, or unreasonable Unit Control Costs nor for incremental cost effectiveness values. As can be seen from a review of Table 2.5-5, the average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the highest 24-hour historic baseline NO_X emission ranges from $867/ton to $2,630/ton. Table 2.5-6 shows average levelized control cost effectiveness of control alternatives calculated for the future PTE case relative to the presumptive NO_X emission level ranges from $254/ton to $1,680/ton. The latter has lower costs per ton of NO_X emission removal due to the higher number of tons removed for the maximum emissions for pre-control baseline and additional controls under the future PTE case.

The incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the Dominant Control Cost Curve) between successively more effective alternatives. The incremental cost analysis indicates that from a cost effectiveness viewpoint, the highest performing alternative is Rich Reagent Injection + SNCR with ASOFA (Point D). This control option is considered technically feasible for Leland Olds Station Unit 2 boiler, incurs a significant annual (levelized) incremental cost compared to the next highest feasible NO_X control technique, SNCR with ASOFA (Point C, slope from C to D =6,650 $/ton) compared against the next lowest alternative, ASOFA (Point A, slope from A to C = 2,100 $/ton).

The other elements of the fourth step of a BART analysis following cost of compliance are to evaluate the following impacts of feasible emission controls:

- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

For the purposes of this BART analysis, the remaining useful life of the source was assumed to exceed the 20-year project life utilized in the cost impact estimates. The other impacts for the LOS Unit 2 NO_X emissions control alternatives from the Dominant Control Cost Curve are discussed in Section 2.5.2 and Section 2.5.3. Visibility impairment impacts for these LOS Unit 2 NO_X emissions controls are summarized in Section 2.5.4.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.4.6 ENERGY IMPACTS OF NO_X CONTROL ALTERNATIVES – LOS UNIT 2

Operation of the top NO_X control technologies considered feasible for potential application at the Leland Olds Station impose direct impacts on the consumption of energy required for the production of electrical power at the facility. The details of estimated energy usage and costs for the various LOS Unit 2 NO_X control alternatives are summarized in Appendix A.

Control alternatives for reduction of NO_X emissions were reviewed to determine if the use of the technique or technology will result in any significant or unusual energy penalties or benefits. There are several basic kinds of energy impacts for NO_X emissions controls:

- Potential increase or decrease in power plant energy consumption resulting from a change in thermal (heat) energy to net electrical output conversion efficiency of the unit, usually expressed as an hourly unit heat rate (Btu/kW-hr) or the inverse of pounds of pollutant per unit electrical power output (MW-hr). This may or may not change the net electrical output (MW) capacity of the EGU, depending on if there are physical or imposed limits on the total heat input to the boiler or electrical power output.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in physical operational limitations imposed on the ability to sustain a fuel heat input rate (mmBtu/hr) which results in a potentially lower or higher unit net electrical output (MW) capacity. This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in auxiliary electrical power demand and usage (kW, kW-hrs). This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in reliability and availability to generate electrical power. This results in a change to the number of hours of annual operation, not necessarily a change in net electrical output (MW) capacity of the EGU.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.5.2.1 ENERGY IMPACTS OF SOFA ALTERNATIVES – LOS UNIT 1

There should not be a major impact on energy consumption by the operation of the advanced variation of a separated overfire air system. ASOFA was the only NO_X control technology common to all four alternatives evaluated for LOS Unit 2. SOFA does not significantly change the total amount of air introduced into the boiler, only the location where it is introduced. Combustion air damper actuators' electrical power demand would be insignificant (+ 1 kW) change in net electrical power consumption from LOS Unit 2. For cyclone boilers, providing effective volumes and velocities of separated overfire air at the injection ports should not require higher forced draft fan power consumption resulting from higher fan discharge pressure. Higher lignite drying system vent ductwork pressure drop impacts of the advanced SOFA system on the forced draft fans' auxiliary electrical power consumption are expected to be negligible (less than 1% of the annual auxiliary power consumed by these fans) so that unit net electrical output (MW) capacity is essentially the same as the current nameplate rating.

Operation of a SOFA system may cause a small increase in levels of unburned carbon in the flyash emitted from the boiler compared with current operation. This represents a slight amount of lost potential electrical power generation from the incompletely burned fuel, so this inefficiency could have a small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kw-hr). This impact was not quantified, as the historical variation in coal heat content that influences plant unit heat rate may be more significant.

Boiler furnace exit gas temperature and superheater steam / reheater steam outlet temperatures may be slightly elevated during air-staged cyclone operation with SOFA. This impact on the boiler's operation is typically small, and within the design capabilities of the boiler from a heat transfer and mechanical stress standpoint. This small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kW-hr) was not quantified, as the historical variation in coal heat content that influences plant unit heat rate is expected to have more significant impacts.

SOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, once the amount of secondary combustion air that can be withdrawn from the cyclones is established for consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for LOS Unit 2. There may be some changes in the degradation rate of the boiler's furnace waterwall tubes resulting from exposure of more area of the furnace walls to slightly air-starved conditions during SOFA operation. Such conditions can promote corrosion from sulfur compounds in the furnace gases being created above the cyclones and below the SOFA injection ports. Due to the relatively moderate amounts of sulfur content in the lignite, modest amount of air-staging of the existing cyclones during SOFA operation, and the potential use of recirculated flue gas along the lower furnace walls, the expected change in corrosion rate of the boiler tubes should be minor. This degradation is expected to occur over many years of operation, and normally requires periodic replacement of the deteriorated sections of boiler furnace waterwall tubes to avoid forced outages to repair tube leaks or failed sections. The potential change in the frequency of furnace wall tube failures and changeouts is difficult to estimate, and has not been quantified.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.5.2.2 ENERGY IMPACTS OF SNCR ALTERNATIVES – LOS UNIT 2

The SNCR portion of this layered alternative involves a chemical reagent injected for NO_X control, assumed to be aqueous urea. For SNCR-related NO_X control alternatives (with or without Rich

Reagent Injection), the injection of a diluted urea solution requires some additional auxiliary power for heating and pumping the liquid, and using compressed air for atomization and cooling the reagent injection nozzles/lances. Heat is required for urea reagent storage. For the Advanced SOFA + SNCR with and without RRI alternatives, the source of heat is assumed to be auxiliary electrical power, on the order of 150 to 300 kW, which was calculated following EPA OAQPS convention[4]. Based on operation for the entire year with the assumed 99% availability factor, this would consume approximately 310,000 kW-hr/yr of additional auxiliary electrical power.

Advanced SOFA + SNCR with and without RRI alternatives' operation is not expected to require higher forced draft fan power consumption. Combustion air damper actuators' electrical power demands are expected to be an insignificant (+ 1 kW) change in net electrical power consumption from LOS Unit 2.

Additional coal consumption for those alternatives that involve a chemical reagent injected for NOx control to compensate for the heat of vaporization of the reagent dilution water; this follows EPA OAQPS convention[1], but is not accepted practice by an experienced SNCR vendor (Fuel Tech) who claims that the heat produced from the exothermic reaction of urea and NO_X is approximately equal to the heat required to evaporate the dilution water. Reagent dilution water for those SNCR alternatives that involve a chemical reagent injected for NOx control were assumed to be four times the amount of delivered aqueous urea solution consumption (assumes urea is a 50% solution as delivered and is injected as a 10% solution); this also follows EPA OAQPS convention[5]. This was estimated to be approximately 23.7 million Btu per hour for Advanced SOFA + SNCR, or 204,800 mmBtu/yr and approximately 45.0 million Btu per hour for Advanced SOFA + SNCR with RRI, or 389,500 mmBtu/yr for LOS Unit 2.

Likewise, operation of a Advanced SOFA + SNCR with and without RRI alternatives may cause a small increase in levels of unburned carbon in the flyash emitted from the boiler compared with current operation. This represents a slight amount of lost potential electrical power generation from the incompletely burned fuel, so this inefficiency could have a small negative impact (much less than 1%) on the plant unit heat rate (higher Btu/kW-hr). This impact was not quantified, as the historical variation in coal heat content that influences plant unit heat rate is expected to have more significant impacts.

---

[4] See Basin LOS BART Determination Study report NO_X Section Reference number 49, page 1-34.
[5] See Basin LOS BART Determination Study report NO_X Section Reference number 49, page 1-35.

As discussed above, SNCR operation will cause a slight decrease (approximately 0.5-0.9%) on the plant unit heat rate (higher Btu/kW-hr), primarily to higher flue gas moisture with corresponding sensible and latent heat losses which would require a slightly higher gross heat input to evaporate the extra dilution water input. This ignores the slight increase in induced draft fan horsepower and auxiliary electrical power consumption to handle the extra coal combustion products, urea and dilution water flows that will result in increased flue gas mass flow during SNCR/RRI operation. The impact of additional flue gas created by operation of an SNCR-related system on induced draft fan power consumption should be insignificant.

Boiler furnace exit gas temperature and superheater steam / reheater steam outlet temperatures is not expected to change significantly, as a slight increase during air-staged burner operation with SOFA may be offset by a slight depression from the injection of the urea dilution water. This impact on the boiler's operation is typically small, and within the design capabilities of the boiler from a heat transfer and mechanical stress standpoint. This impact on the LOS Unit 2 boiler's thermal conversion efficiency and steam cycle impacts from small steam temperature changes was not quantified, but is not expected to be significant.

ASOFA and SNCR/RRI are not expected to significantly reduce unit reliability and availability to generate electrical power. There may be some changes in the degradation rate of the boiler's furnace waterwall tubes resulting from exposure of more area of the furnace walls to slightly air-starved conditions during SOFA operation. Such conditions can promote corrosion of the steel waterwall tubes by sulfur compounds in the furnace gases being created above the burners and below the SOFA injection ports. Due to the moderate sulfur content in the lignite and modest amount of air-staging during firing of the existing cyclone burners expected during ASOFA operation, this potential change in corrosion rate of the boiler tubes is expected to be minor. SNCR/RRI may cause a slight increase in fireside deposit accumulation, especially in the primary and possibly secondary superheater and reheater tube banks. This degradation is expected to occur over many years of operation, and normally requires periodic replacement of the deteriorated sections of boiler furnace waterwall tubes and superheater/reheater tube banks to avoid forced outages to repair tube leaks or failed sections. The potential change in the frequency of furnace wall tube and superheater/reheater tube failures and changeouts is difficult to estimate, and has not been quantified.

Table 2.5-9 summarizes the gross demand and usage from auxiliary electrical power estimated for the NO_X control alternatives evaluated for LOS Unit 2.

TABLE 2.5-9 – Expected Auxiliary Electrical Power Impacts for NO_X Controls – LOS Unit 2

		NO_X Control Equipment Estimated Annual Average Auxiliary Electrical Power Demand and Usage		
Alt. No.(1)	**NO_X Control Technique**	**Aux. Power Demand (2) (kW)**	**Generation Reduction from Aux. Power Demand(2),(3) (kW-hrs/yr)**	**Generation Reduction from Reduced Unit Availability(4) (kW-hrs/yr)**
D	RRI + SNCR (using urea) w/ ASOFA	285	2,464,300	38,500,000
C	SNCR (using urea) w/ ASOFA	156	1,349,600	38,500,000
A	Advanced Separated Overfire Air (ASOFA)	1	8,760	0

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.
(2) – The NO_X control equipment gross auxiliary electrical power demand is estimated.
(3) – The annual change in NO_X equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.
(4) – The estimated total hours per year of unit unavailability multiplied by average gross generation multiplied by annual running plant capacity factor for the particular control alternative. For this analysis, SOFA was not expected to reduce annual hours of possible operation.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.5.4 VISIBLITY IMPAIRMENT IMPACTS OF LELAND OLDS STATION NO_X CONTROLS – UNIT 2

The fifth step in a BART analysis is to conduct a visibility improvement determination for the source. For this BART analysis, there were two baseline NO_X emission rates assumed for LOS Unit 2 – one for the historic pre-control NO_X emission rate listed in the NDDH BART protocol[3], and one applying the Potential-To-Emit (PTE) pre-control annual NO_X emission rate associated with the future PTE case. The historic pre-control emission baseline was the 24-hour average NO_X emission rate from the highest emitting day of the years 2000-2002 (meteorological period modeled per the NDDH protocol[3]). The historic (protocol) NO_X baseline condition emission rate was modeled simultaneously with the highest 24-hour average SO_2 emission rate, and the highest 24-hour average PM emission rate of the 2000-2002 time period. The historic (protocol) baseline hourly NO_X emission rate used for modeling visibility impacts due to LOS Unit 2 under the conditions stated above was 3,959 lb/hr.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from historic (protocol) pre-control baseline and post-control average hourly emission rates representing the visibility impairment impact reduction for LOS Unit 2. Three post-control CALPUFF model runs for LOS Unit 2 were conducted with the same presumptive BART SO_2 emission baseline rate of 95%, constant PM emissions, and various levels of NO_X control assuming the same boiler design rating for heat input (5,130 mmBtu/hr). For the three post-control alternatives representing LOS Unit 2 PTE annual emissions associated with the future PTE case, the model used average unit NO_X emission rates of 0.48, 0.304, and 0.265 lb/mmBtu (corresponding to the design parameter in Table 1.2-1 and control rates in Table 1.4-1) multiplied by the boiler heat input rating of 5,130 mmBtu/hr to yield average hourly NO_X emission rates 2,462, 1,560, and 1,360 lb/hr. The boiler heat input basis for LOS Unit 2's historic highest 24-hour pre-control NO_X emission baseline, in keeping with the NDDH BART visibility impairment impact modeling protocol, is different than assumed for the PTE annual post-control conditions of the NO_X control alternatives evaluated for visibility impairment impacts.

The results of the visibility impairment modeling at the historic pre-control (protocol) baseline NO_X emission rate for LOS Unit 2 showed that all four of the designated Class 1 areas exceeded 0.5 deciView for highest predicted visibility impairment impact (90th percentile, averaged for 2000-2002). Lostwood National Wildlife Refuge (LNWR) showed the biggest predicted visibility impairment impact, which averaged 0.98 dV for the three years modeled (2000-2002). Average predicted visibility impairment impacts decreased significantly with presumptive BART SO_2 emission rate combined with constant PM emissions and various post-control ASOFA-enhanced NO_X emission rates for LOS Unit 2. This is shown in Table 2.5-10.

TABLE 2.5-10 – Average Visibility Impairment Impacts from Emission Controls – LOS Unit 2

Federal Class 1 Area	Visibility Impairment Impacts(1) (deciView)			
	Historic Pre-Control Baseline	PTE Emissions, ASOFA(2)	PTE Emissions, SNCR w/ ASOFA(2)	PTE Emissions, RRI+SNCR w/ ASOFA(2)
TRNP-South Unit	0.807	0.221	0.158	0.143
TRNP-North Unit	0.756	0.180	0.139	0.129
TRNP-Elkhorn Ranch	0.535	0.120	0.093	0.087
Lostwood NWR	0.979	0.285	0.206	0.191

(1) - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - SO_2 emissions reduction by 95% over pre-control PTE heat input baseline for the future PTE case. This case assumes existing ESP for PM collection.

Analysis of the reduction in visibility impairment impact included a comparison of the emission controls' effectiveness of reducing predicted visibility impairment impacts for the conditions of the future PTE case operation of LOS Unit 2 versus the historic pre-control (protocol) baseline that was modeled. LNWR again showed the highest average predicted visibility impairment impact reduction resulting from LOS Unit 2 emissions controls during PTE (future PTE case) heat inputs versus historic pre-control baseline emissions. These comparisons are shown in Table 2.5-11.

TABLE 2.5-11 –Average Visibility Impairment Impact Reductions From Emission Controls – LOS Unit 2 (vs Historic Maximum 24-Hour Average Hourly Emission Baseline)

Federal Class 1 Area	Visibility Impairment Reductions(1) (deciView)		
	PTE Emissions, ASOFA(2)	PTE Emissions, SNCR w/ ASOFA(2)	PTE Emissions, RRI+SNCR w/ ASOFA(2)
TRNP-South Unit	0.586	0.649	0.664
TRNP-North Unit	0.577	0.617	0.628
TRNP-Elkhorn Ranch	0.415	0.441	0.447
Lostwood NWR	0.694	0.773	0.788

(1) - Difference of average 90th percentile predicted post-control visibility impairment impact versus historic pre-control (protocol) baseline visibility impairment impact. A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

(2) - SO_2 emissions reduction by 95% over pre-control PTE heat input baseline for the future PTE case. This case assumes existing ESP for PM collection.

The comparison in Table 2.5-12 shows the reduction of average visibility impairment impact from LOS Unit 2 NO_X emissions expected to result from ASOFA combined with SNCR with and without RRI relative to the average visibility impairment impact from post-control ASOFA NO_X emission rates applied to LOS Unit 2.

TABLE 2.5-12 – Incremental Average Visibility Impairment Reductions from NO_X Controls – LOS Unit 2 (vs ASOFA Post-Control PTE Emission Visibility Impairment Impact)

	Incremental Visibility Impairment Impact Reductions, from NO_X Emission Controls(1)	
Federal Class 1 Area	**PTE Emissions, SNCR w/ ASOFA (dV)**	**PTE Emissions, RRI+SNCR w/ ASOFA (dV)**
TRNP-South Unit	0.063	0.078
TRNP-North Unit	0.040	0.051
TRNP-Elkhorn Ranch	0.027	0.033
Lostwood NWR	0.079	0.094

(1) - Incremental average 90th percentile predicted post-control visibility impairment impact, compared to ASOFA for NO_X control with 95% SO_2 emissions control and existing ESP for PM emissions control at PTE heat input rate (future PTE case). A summary of the modeling scenarios is provided in Table 1.4-1 and the modeling results are presented in Appendix D.

This analysis included a determination of the cost-effectiveness of reducing predicted visibility impairment impact for a particular NO_X emission rate associated with the control alternatives evaluated on LOS Unit 2. The basis of comparison was the average predicted visibility impairment impact and estimated levelized total annual cost (LTAC) for the advanced form of separated overfire air (ASOFA) alone under the future PTE case conditions. The estimated additional annualized costs of installing and operating each NO_X control alternative with PTE heat input (future PTE case) relative to the LTAC from post-control ASOFA NO_X emission rates applied to LOS Unit 2 are shown in Table 2.5-13.

TABLE 2.5-13 – LTAC for NO_X Controls – LOS Unit 2 (vs ASOFA Post-Control PTE Emission LTAC)

Incremental LTAC Change for NO_X Emission Reduction(1)	
PTE Emissions, SNCR w/ ASOFA ($/yr)	**PTE Emissions, RRI+SNCR w/ ASOFA ($/yr)**
8,460,000	13,230,000

(1) - Incremental Levelized Total Annual Cost for NO_X control alternatives compared to ASOFA for PTE heat input rate (future PTE case). All cost figures in 2005 dollars. See Table 2.5-8 for details.

The comparison in Table 2.5-14 shows that the additional annualized costs of installing and operating each NO_X control alternative with PTE heat input (future PTE case) divided by the additional average predicted visibility impairment impact reduction relative to the post-control ASOFA NO_X emission rates and LTAC applied to LOS Unit 2 would result in hundreds of millions of dollars per deciview of control cost visibility impairment impact effectiveness.

TABLE 2.5-14 – Cost Effectiveness for Incremental Average Visibility Impairment Reductions from NO_X Controls – LOS Unit 2 (vs ASOFA Post-Control PTE Emission LTAC and Visibility Impacts)

	Incremental Visibility Impairment Reduction Unit Cost, from NO_X Emission Controls(1)	
Federal Class 1 Area	**PTE Emissions, SNCR w/ ASOFA ($/deciView-yr)**	**PTE Emissions, RRI+SNCR w/ ASOFA ($/deciView-yr)**
TRNP-South Unit	135,000,000	183,000,000
TRNP-North Unit	210,000,000	279,000,000
TRNP-Elkhorn Ranch	317,000,000	436,000,000
Lostwood NWR	108,000,000	152,000,000

(1) - Incremental Levelized Total Annual Cost divided by incremental average 90th percentile predicted post-control visibility impairment impact, compared to ASOFA for NO_X control with 95% SO_2 emissions control and existing ESP for PM emissions control at PTE heat input rate (future PTE case). All cost figures in 2005 dollars.

The number of days predicted to have visibility impairment due to LOS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the historic pre-control (protocol) NO_X, SO_2, and PM emission rates described previously in this Section. The results were summarized and presented in Table 2.4-15. Similarly, the same information for the post-control SO_2 and PM alternatives with presumptive BART NO_X PTE emission rates was summarized and is shown in Table 2.5-16. The differences in average visibility impairment impact and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between post-control SO_2 and PM alternatives with SNCR with ASOFA-controlled and RRI+ SNCR with ASOFA-controlled NO_X emission rates versus ASOFA-controlled NO_X emission rates are summarized and shown in Table 2.5-15.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 area. The highest number of days in which the predicted visibility impairment impact above background exceeded 0.5 deciViews was for the pre-control (protocol) emission case in year 2002 for TRNP's South Unit. A series of bar charts showing the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the pre-control model results is included in Section 3.5. The pair of post-control SO_2 and PM alternatives combined with SNCR with ASOFA or RRI+SNCR with ASOFA for NO_X control were only slightly lower for the predicted visibility impairment impacts and number of days predicted to have visibility impairment impacts greater than 0.50 and 1.00 deciViews compared to the same pair of post-control SO_2 and PM conditions with ASOFA-controlled NO_X emission rates. A series of bar charts showing the difference in the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the RRI+SNCR with ASOFA-controlled PTE emission rates and SNCR with ASOFA-controlled PTE emission rates compared to ASOFA NO_X PTE emission rates with post-control SO_2 and PM alternatives is included in Figures 2.5-5, 2.5-6, and 2.5-7.

(The following article is a replacement of the same section in the August 2006 BEPC BART Determination Study final draft report)

2.5.5 SUMMARY OF IMPACTS OF LELAND OLDS STATION NO_X CONTROLS – UNIT 2

Table 2.5-16 summarizes the various quantifiable impacts discussed in Sections 2.5.1 through 2.5.4 for the NO_X control alternatives evaluated for LOS Unit 2.

BASIN ELECTRIC POWER COOPERATIVE
LELAND OLDS STATION
COMBINED UNIT 1 AND 2 MODELING ANALYSIS

The U.S. Environmental Protection Agency (EPA) finalized the Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations in July 2005. The final regulations require eligible sources to be analyzed to determine a BART emission limit for nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM). The North Dakota Department of Health (NDDH) determined that Basin Electric Power Cooperative, Inc.'s (BEPC's) Leland Olds Station (LOS) Units 1 and 2 are subject to a BART evaluation.

The NDDH prepared an air dispersion modeling protocol as a guideline to evaluate potential changes in visibility at nearby Class I Areas[1]. The NDDH modeling protocol requires that pre-control and post-control changes in visibility due to individual emission units be evaluated, and after the individual changes in visibility are determined, the entire facility's change in visibility is evaluated[2]. This document summarizes the facility change in visibility, and should be read in conjunction with the "BART DETERMINATION STUDY for Leland Olds Station Unit 1 and 2 Basin Electric Cooperative" Final Draft dated August 2006[3].

DEFINITION OF VISIBILITY IMPAIRMENT

Visibility impairment is caused by a combination of particles and gases in the atmosphere. Some particles and gases scatter light, others absorb light. The combined effect of scattering and absorption is called "light extinction" which is most commonly seen as haze. This haze is related to a haze index (HI) that is measured in deciview units; this haze index is related to light extinction coefficient by the following equation:

---

[1] A Class I Area has special national or regional value from a natural, scenic, recreational, or historic perspective. The EPA affords Class I Areas special protection against degradation of these values.

[2] NDDH "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota (Final), November 2005, page 53.

[3] The details of the BART modeling methodology, and changes in visibility from individual sources are summarized in the "BART DETERMINATION STUDY for Leland Olds Station Unit 1 and 2 Basin Electric Cooperative" Final Draft, August 2006.

$$HI = 10 \ln(b_{ext}/10)$$

Where HI is the haze index, and b_{ext} is light extinction coefficient in inverse megameters. An HI of 0.5 or more is considered a noticeable change in haziness, but not necessarily a visibility impairment.

Visibility impairment is a function of light extinction. Light extinction occurs when light energy is either scattered or absorbed by particles in the air. The amount of moisture in the air also plays a role in light extinction. Certain gases combine with moisture in the air to form small light scattering particles. These gases, most notably SO_2 and NO_X, are major components of coal-fired power plant emissions. Particulate matter (PM) also contributes to light extinction. In the final BART Determination Guidelines (70 FR 39160), EPA states that:

> "You may use PM_{10} as an indicator for particulate matter. [Note that we do not recommend the use of Total Suspended Particulates (TSP) as an indicator for particulate matter.]. As emissions of PM10 include the components of $PM_{2.5}$ as a subset, there is no need to have separate 250 ton thresholds for PM_{10} and $PM_{2.5}$. 250 tons of PM_{10} represents at most 250 tons of $PM_{2.5,}$ and at most 250 tons of any individual particulate species such as elemental carbon, crustal material, etc".

MODELING METHODOLOGY

The NDDH recommended using the current guideline version of the CALPUFF modeling system as modified by the NDDH to specifically address terrain, climate, and emission characteristics of the LOS[4]. One of the NDDH modifications is the CALBART post-processing program. CALBART uses the Federal Land Mangers' Air Quality Related Values Workgroup (FLAG) Method 6 for calculating light extinction. Along with the CALPUFF modeling system, the NDDH also provided the RUC2-MM5 gridded wind field data (2000-2002), the surface, upper air, and precipitation files, and the CALMET and CALPUFF input files. These input files contained the specific coordinate grid

---

[4] CALMET and CALPUFF were recompiled by the NDDH while the CALPOST executable used for this visibility analysis was the EPA guideline executable

points, wind field options, terrain, dispersion options, receptor coordinates, plume characteristics, and other model parameters that the NDDH has determined best represents the region.

The NDDH confirmed that the two Class I areas to be considered for visibility impairment analysis are the Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWWA).

BEPC performed an analysis to determine what emission levels would constitute BART. Those emission rates are listed in the attached Table 1[5]. In order to predict the change in light extinction at the TRNP and LWWA areas, SO_2, NO_x, and PM were modeled with CALPUFF using the emission controls determined to be BART. Even though other pollutants are emitted during coal combustion, the BART guidelines focus on SO_2, NO_x, and PM. The NDDH identified 104 receptors allocated over both the TRNP and the LWWA. These receptors are the points for which CALPUFF was used to perform a visibility calculation.

A BART visibility impact analysis measures visibility improvement over the worst 2 percent (98th percentile) and 20 percent (90th percentile) visibility days at each receptor. The 98th percentile is the 8th worst visibility day (2 percent times 365 days equals about eight days). Since visibility is a 24-hour averaged analysis, the 90th percentile is calculated where each receptor was tabulated for each day and the worst 73 days (365 days times 0.2 equals about 73 days) were averaged together to determine the worst 20 percent visibility days.

DEGREE OF VISIBILITY IMPROVEMENT

The NDDH does not have a target threshold for visibility improvement for BART analyses. The BART determination takes into account the following parameters:

1. The cost of compliance.

---

[5] Details of the controls and emission limits are found in the "BART DETERMINATION STUDY for Leland Olds Station Unit 1 and 2 Basin Electric Cooperative" Final Draft, August 2006.

2. The energy and non-air quality environmental impacts.
3. Any pollution control equipment in use at the source.
4. The remaining useful life of the source.
5. The visibility that may reasonably be anticipated to result from the use of such technology.

Parameter number five does not set a target threshold for visibility. As a result, Units 1 and 2 were combined to fulfill parameter number five, and to show the improvement in visibility from the LOS facility. The pre-control emissions were taken from the NDDH modeling protocol. The post-control emissions are the expected emissions after employing BART.

Table 2a presents the pre-control visibility impacts while Table 2b shows the post-control visibility impacts when employing BART. Both Tables 2a and 2b are the direct output from CALPUFF's CALBART post-processor. The tables show the change in deciview when compared to background values, the total deciview (background and LOS sources), and the year, day, and location of the occurrence (SEQ RECP, and ND RECP columns in Table 2a and 2b). The final four columns in both tables breakdown the contribution of the haziness into its components: sulfates, nitrates, fine particulate, and coarse particulate.[6]

Table 3a shows that the three-year average improvement in visibility ranged from 56 percent to over 77 percent when the largest, 98th percentile, and 90th percentile deciview changes are compared to pre-control levels. Table 3b shows that the average number of hazy days over 0.5 deciview decreased about 65 percent when compared to pre-control levels. The number of hazy days is the total number of hazy days over 0.5 and 1.0 change in deciview.

---

[6] Details of the CALPUFF modeling methodology are found in the "BART DETERMINATION STUDY for Leland Olds Station Unit 1 and 2 Basin Electric Cooperative" Final Draft, August 2006, pgs. 85, 116, 217, 227.

CONCLUSION

A BART analysis does not need to meet a target threshold for visibility improvement; in other words, the LOS does not need for a BART to achieve a certain HI value. The visibility values listed in Tables 2b, 3a and 3b should be considered the visibility that may reasonably be anticipated to result from the use of the BART controls.

Re: Revisions to BEPC BART Determination Study report,
LOS 1 with basic SOFA and SNCR NOx Control impacts, and
LOS Unit 1 and Unit 2 SNCR Cost Effectiveness Corrections

Dear Cris:

Burns & McDonnell has completed a supplemental report to the August 2006 final BART Determination Study report for Basin's Unit 1 and Unit 2 at Leland Olds Station.

This supplemental report includes expected impacts of LOS Unit 1 with basic SOFA and SNCR for NOx control. This document is being provided in response to the North Dakota Department of Health's request issued in a December 1, 2006 letter to Basin Electric Power Cooperative regarding the NDDH's comments from their review of the final draft report of the BEPC LOS BART DETERMINATION STUDY for LELAND OLDS STATION UNIT 1 and 2 (August 2006).

This is intended to be in addition to the following sections:

2.4.2 Energy Impacts of NO_X Control Alternatives – LOS Unit 1;
2.4.3 Non Air Quality and Other Environmental Impacts of NO_X Control Alternatives – LOS Unit 1;
2.4.4 Visibility Impairment Impacts of Leland Olds Station NO_X Controls – Unit 1;
2.4.5 Summary of Impacts of LOS NO_X Controls – Unit 1;

Included in this document are replacements to the following sections of the August 2006 BEPC BART Determination Study report:

2.4.1.2 Operating and Maintenance Cost Estimates for NO_X Controls – LOS Unit 1;
2.4.1.3 Cost Effectiveness for NO_X Controls – LOS Unit 1;

9400 Ward Parkway
Kansas City, Missouri 64114-3319
Tel: 816 333-9400
Fax: 816 333-3690
www.burnsmcd.com

Section 2.4.1.2 O&M Costs, and Section 2.4.1.3 Cost Effectiveness, were corrected for the costs of additional coal consumption for those LOS Unit 1 alternatives that involve a chemical reagent injected for NOx control alternatives to compensate for the heat of vaporization of the reagent dilution water.

Similarly, included in this document are replacements to the following sections of the August 2006 BEPC BART Determination Study report:

2.5.1.2 Operating and Maintenance Cost Estimates for NO_X Controls – LOS Unit 2;

2.5.1.3 Cost Effectiveness for NO_X Controls – LOS Unit 2;

Section 2.5.1.2 O&M costs, and Section 2.5.1.3 Cost Effectiveness, were corrected for the costs of additional coal consumption for those LOS Unit 2 alternatives that involve a chemical reagent injected for NOx control alternatives to compensate for the heat of vaporization of the reagent dilution water.

An electronic copy of the document has been sent to you via email.

As always, please contact Bob Blakley at (816) 822-3842 rblakley@burnsmcd.com, or Carl Weilert at (816) 822-3103 or cweilert@burnsmcd.com if questions arise.

NDDH Comments December 1, 2006
BART Determination Study

Dear Mr. Miller:

Burns & McDonnell has reviewed the letter issued by the North Dakota Department of Health (NDDH) to Basin Electric Power Cooperative (BEPC) dated December 1, 2006[1]. This letter report addresses the issues raised by the NDDH and refers to the results of additional visibility impairment improvement modeling for Unit 1 (submitted as separate documents under separate cover letters) as requested.

Burns & McDonnell was retained by BEPC to perform the previously issued BART Determination Study[2]. Basin Electric Power Cooperative's (BEPC's) Units 1 and 2 at the Leland Olds Station (LOS) were determined to be BART eligible by the NDDH. The referenced BART analysis was conducted in accordance with the eligibility conclusion made by NDDH and follows the steps outlined in the finalized Regional Haze Regulations [RHR] and Guidelines for Best Available Retrofit Technology (BART) Determinations[3] (July 6, 2005) to determine a BART emission limit for nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM). The NDDH protocol[4] (November 2005) provided a state specific modeling protocol for use in the analysis.

Burns & McDonnell responses are in the form of reiterating the NDDH's comments verbatim followed by a brief reply to address the issues raised.

NDDH Comment #1 *The National Park Service has indicated that 98% SO_2 control has been proposed on several other projects such as Thoroughbred, LGE-Trimble and Mustang. Although the Department recognizes that such sources have not been built, and that they will be firing coal not common to our region, we ask that Basin provide comments on this issue.*

B&McD Response #1 This issue has been addressed by the EPA in the New Source Performance Standards (NSPS) recently promulgated as final rule amendments to 40 CFR part 60, subparts Da, Db, and Dc emission standards effective February 27, 2006[5].

In establishing the final SO_2 emission standards for EUSGUs, in specific response to the issue of reflecting best demonstrated technology (BDT) for SO_2 removal greater than 98 percent, the "EPA has concluded that 98 percent control is possible with certain control and boiler configurations under ideal conditions. The amended SO_2 standard is based on a 30-day average that includes the variability that occurs from non-ideal operating conditions".[6]

Basin Electric has provided information regarding predicted future coal quality that indicates a higher level and variability of sulfur content that will be required to be controlled. Burns & McDonnell believes that it would not be possible to operate the units at Leland Olds Station continuously under ideal operating conditions such that an average 98% level of SO_2 emissions control could be sustained for every 30-day rolling period. The projects mentioned by the National Park Service have not been constructed and have not demonstrated the ability to achieve and sustain 98% SO_2 emissions control for every 30-day rolling period.

Burns & McDonnell believes that a 30-day rolling average requirement of 98 percent control suggested by the National Park Service as BART for SO_2 removal is inappropriate for the EUSGUs at Leland Olds Station. The referenced BART Determination Study report[7] analysis for Unit 1 and Unit 2 evaluated available technologies and recommended effective levels of SO_2 removal considered suitable for the determination of BART appropriate for this facility given the statutory factors required for the analysis.

NDDH Comment #2 *With respect to the 90% and 95% SO_2 control options, emission rates were provided that are based on coal-to-stack control efficiencies. We believe a wet scrubber is capable of achieving 95% control of the inlet concentration to the scrubber and dry scrubber is capable of achieving 90%. Emission rates that reflect 90% and 95% inlet to outlet control efficiencies should be provided.*

B&McD Response #2 The BART SO_2 emission rates provided in the BART Determination Study report were calculated based upon 100% of the sulfur input in the coal assumed to be converted to SO_2 in the boiler and emitted in the flue gas. The FGD scrubber SO_2 removal efficiencies for Leland Olds Station boilers were assumed to be relative to the inlet mass rate and type of scrubber for the respective boilers: 90% for Unit 1's dry scrubber, and 95% for Unit 2's wet scrubber. Likewise, the recommended 30-day rolling average SO_2 BART emission limits were calculated similarly, with sulfur and heat contents of the lignite coal being changed to be reflective of expected

---

[5] See Reference number 5.

[6] Ibid Reference 5, pg 9870.

[7] Ibid Reference 2.

higher short-term future variability in the sulfur concentration and lower fuel heat content[8]. The analysis did not assume any reduction of lignite sulfur input assumed due to fuel processing or boiler firing, and this is consistent with normally accepted practice for estimating emissions at the inlet of an SO_2 control device. This also agrees with the EPA's recommended method for calculating Potential To Emit emission rates as defined in the NSR Manual[9]. Burns & McDonnell believes that the appropriate method to calculate outlet emissions for the BART Determination Study analysis of the Leland Olds Station units is to assume that 100% of the calculated sulfur predicted to be contained in the future coal feed to the boiler is converted to sulfur oxides. The presumed level of SO_2 control was applied across the FGD scrubber to the inlet mass emissions, and subsequently resulted in the amount of SO_2 mass emissions released to the atmosphere that was included in the referenced study report.

NDDH Comment #3 *For Unit 1, basic separated overfire air (SOFA) with selective non-catalytic reduction (SNCR) was evaluated for costs. However, no modeling was conducted to show the effects on visibility for this alternative. The Department believes that close examination of all factors associated with this alternative will be necessary before such an alternative can be eliminated. As we have indicated in the past, BART selection is made using the top-down approach considering all the statutory factors including visibility improvement. Although the presumptive level factor will be weighed in our BART determination, we also believe it is necessary to conduct a complete evaluation of more efficient technologies that may be cost-effective. Therefore, the Department requests that modeling be conducted for the basic SOFA plus SNCR alternative and the results submitted for review. In addition, the remaining factors (i.e., energy impacts, non-air quality environmental impacts, etc.) should be addressed.*

B&McD Response #3 There is published and regulatory agency-provided information associated with the RHR that conflicts with the premise that all technically feasible control alternatives that are cost-effective and have minimal energy and non-air environmental impacts must be evaluated for visibility impairment impact as part of a BART Determination process. The BART Stakeholder Meeting with the NDDH on July 27, 2005 included an NDDH verbal response to the question (paraphrased) "If a source agrees to presumptive limits even though they are at a facility that is less than 750 MW, would a BART Determination be required along with Air Quality Modeling? The NDDH verbal response referenced the RHR BART Guideline (presumably pg 68 of the final July 6, 2005 FR version of the RHR) which, when paraphrased, essentially states that if a source applies the most stringent applicable technology, then it is not required to perform the Air Quality modeling. Also, the NDDH is believed to have asked EPA Region 8 this (or a similar) question and their quick answer was basically that if a utility accepted presumptive BART not only would they not perform the AQ modeling they would not have to perform a BART determination for that unit for that pollutant.

---

[8] Ibid Reference 2, pages 158 and 233 for Unit 1; pages 188 and 236 for Unit 2.

[9] See Reference number 6, Article II.B.6, page A.19.

In the EPA's corrected RHR Comment Response Document, the EPA provided a response to a commenter (0215) that said "if an EGU is achieving the default/presumption for NOx, it should not be required to do a BART determination for that pollutant" [10]. The EPA's response in this same document was "We agree that a streamlined BART process is warranted for such sources"[11].

Because the EPA established the presumptive BART NO_X emission limits based on combustion controls for boilers other than cyclone-fired ones, post-combustion controls for sources without existing post-combustion controls, including selective non-catalytic reduction (SNCR) technology "are generally not cost-effective except in very limited applications and therefore were not included in EPA's analysis"[12].

LOS Unit 1's highest 24-month rolling average NO_X emission rate during the years 2000-2004 was 0.285 lb/mmBtu. This was slightly below the presumptive BART level of 0.29 lb/mmBtu for a lignite-fired dry-bottom pulverized coal boiler greater than 200 MW located at a power plant with a generating capacity of more than 750 MW. The BART Determination Study report recommended a 30-day rolling average BART NO_X emission rate for LOS Unit 1 of 0.29 lb/mmBtu[13]. The RHR leaves it up to the individual states to determine whether to apply the EPA's presumptive BART NO_X emission rate limits for units greater than 200 MW operating at power plants with a total generating capacity of less than 750 MW.

Thus, due to the EPA's comment response coupled with direct feedback from NDDH regarding the specific relevant issue, there was reason to believe that if BEPC accepted the presumptive BART NO_X emission limit of 0.29 lb/mmBtu for a lignite-fired dry bottom pulverized coal boiler greater than 200 MW located at a power plant with a generating capacity of more than 750 MW for Unit 1, that a BART analysis and visibility modeling of all feasible NO_X reduction technologies including post-combustion alternatives would not be required for LOS Unit 1. Basin's BART Determination Study report analysis for Unit 1 did, however, include the technical feasibility analysis of appropriate, available NO_X reduction technologies, along with visibility modeling and impairment improvement evaluation for a single combustion control-based alternative with the next lowest emission rate (basic SOFA).

As shown in Table 2.4-14 of Basin's BART Determination Study report[14] analysis for Unit 1, the incremental visibility impairment reduction of SOFA vs. presumptive NO_X emissions based on future PTE heat input conditions was typically less than 0.01 at three TRNP Class 1 areas, and was below 0.02 at Lostwood NWR. The corrected incremental control cost increases significantly from basic SOFA to the SNCR with basic SOFA alternative ($4,060/ton) vs $208/ton for basic SOFA versus presumptive NO_X emissions for the future PTE pre-control case. The expected incremental

---

[10] See Reference 7, page 238.
[11] Ibid Reference 7, page 238.
[12] Ibid Reference 3, page 39134.
[13] Ibid Reference 2, page ES-4 and page 241.
[14] Ibid Reference 2, page 88.

visibility impairment reduction of SNCR with SOFA vs. basic SOFA was found to be of a similar very small magnitude (maximum 0.021 dV) because the NO_X emission rate change of 0.062 lb/mmBtu (0.230-0.168 lb/mmBtu) between these alternatives was comparable to the NO_X emission rate change of 0.060 lb/mmBtu (0.290-0.230 lb/mmBtu) from presumptive NO_X to basic SOFA.

While the RHR BART Guidelines[15] do not use the words "top-down", it is left up to the states to establish the appropriate approach for the BART analysis and determination. The referenced BART Determination Study report[16] analysis for Unit 1 evaluated available technologies and recommended effective levels of NO_X emissions considered suitable for the determination of BART appropriate for this facility given the statutory factors required for the analysis.

In a spirit of cooperation, the visibility improvement modeling and analysis of the impacts, including the other statutory factors required for a BART determination for the SNCR with basic SOFA alternative applied to LOS Unit 1's pre-control NO_X emissions are being provided to the NDDH as a separate document[17].

NDDH Comment #4 *We would like a better explanation of how the estimated emissions for the various alternatives for NO_X control were estimated. The discussion should include emissions achieved at other facilities based on these alternatives and how those numbers compare to proposed emission rates for Leland Olds Station.*

B&McD Response #4 The referenced BART Determination Study report[18] provided numerous references on pages 127-131 and an extensive list summarizing recent NO_X reduction projects in the United States in Appendix A3. Although there is a significant amount of experience with certain commonly applied techniques and technologies for NO_X control on coal-fired boilers, such as low-NO_X burners (LNBs) and separated overfire air, there is a noticeable lack of such experience on wall-fired pulverized coal and cyclone boilers designed and built for firing North Dakota lignite.

For LOS Unit 1, the long-term average pre-control NO_X levels with original burners but without close-coupled overfire air (CCOFA, prior to 1995) were estimated to be much higher than 0.29 lb/mmBtu. The EPA's Technical Support Document for BART NO_X Limits[19] published with the RHR Guidelines established a Pre-Control rate of 0.74 lb/mmBtu and an Effective Control Case 1a NO_X Emission Rate of 0.23 lb/mmBtu for LOS Unit 1. This would be a pre-to-post control reduction of approximately 69 percent, which is higher than the example low-NOx burner retrofits summarized in Appendix A3 (pages A3-13 though A3-15) of the referenced BART Determination Study report. The EPA's Case 1a assumed installation of current NO_X combustion

---

[15] Ibid Reference 3.

[18] Ibid Reference 2.
[19] See Reference 8, Excel Spreadsheet page 270.

controls (LNBs and SOFA) for units with no prior controls, or which have controls installed before 1997. This is the situation applicable to Leland Olds Station Unit 1.

Considering the information included above and in other available technical literature, the referenced BART Determination Study report established 0.23 lb/mmBtu as the estimated post-control 24-month rolling average NO$_X$ emission rate for LOS Unit 1 when retrofitted with SOFA in combination with low-NOx burners. This was a 20.7% reduction from the presumptive BART NO$_X$ rate of 0.290 lb/mmBtu[20]. The referenced BEPC LOS BART study's Unit 1 visibility improvement modeling and impact analysis also assumed a 20.7% reduction from the average NO$_X$ rate of 760.4 lbs/hr (presumptive BART) to 603.1 lbs/hr for the highest 24-hour (daily) post-control condition with low-NOx burners and SOFA[21]. SNCR with basic SOFA assumed an additional 26.8 percent reduction beyond the 0.23 lb/mmBtu basic SOFA control level, estimated to be 0.168 lb/mmBtu or 42 percent below the presumptive BART baseline of 0.29 lb/mmBtu[22]. This estimated additional reduction percentage for SNCR performance applied to LOS Unit 1 is similar to the levels achieved by other wall-fired boilers retrofitted with this technology as summarized in Appendix A3 (pages A3-21 though A3-26) of the referenced BART Determination Study report. It is also 77.3% lower than the EPA's Pre-Control NO$_X$ emission rate of 0.74 lb/mmBtu.

For LOS Unit 2, the long-term average pre-control NO$_X$ levels with previous firing practices was estimated to be much higher than the pre-control future PTE baseline of 0.67 lb/mmBtu established in the referenced BART Determination Study report[23]. The EPA's Technical Support Document for BART NO$_X$ Limits[24] published with the RHR Guidelines established a Pre-Control rate of 1.03 lb/mmBtu and an Effective Control Case 1a NO$_X$ Emission Rate of 0.52 lb/mmBtu for LOS Unit 2. This would be a pre-to-post control reduction of approximately 50 percent, which is similar or higher than some of the cyclone SOFA retrofits with modest amounts of substoichiometric combustion summarized in Appendix A3 (pages A3-1 though A3-2) of the referenced BART Determination Study report. The EPA's Case 1a assumed installation of current NO$_X$ combustion controls for units with no prior controls, or which have controls installed before 1997. The current combustion control technology analyzed by the EPA for cyclone units is coal reburning[25]. This is the situation applicable to Leland Olds Station Unit 2.

Considering the information included above and in other available technical literature, the referenced BART Determination Study report established 0.48 lb/mmBtu as the estimated post-control 24-month rolling average NO$_X$ emission rate for LOS Unit 2 with the advanced form of SOFA, which was a 28% reduction from the pre-control

---

[20] Ibid Reference 2, Table 2.3-2 on page 58.

[21] Ibid Reference 2, Table 1.4-1 on page 19, and pages 85-95.

[22] Ibid Reference 2, Table 2.3-2 on page 58.

[23] Ibid Reference 2, Table 2.3-4 on page 61.

[24] Ibid Reference 8, Excel Spreadsheet page 270.

[25] Ibid Reference 3, page 39134, footnote 63.

future PTE baseline rate of 0.67 lb/mmBtu[26]. The referenced BART study's LOS Unit 2 visibility improvement modeling and impact analysis also assumed a 0.48 lb/mmBtu NO_X emission rate with the advanced form of SOFA, which represents a reduction of nearly 38 percent from the average NO_X rate of 3,959 lbs/hr for the highest 24-hour (daily) post-control condition without ASOFA[27]. The referenced BART study also assumed an additional 36.7 percent reduction beyond the 0.48 ASOFA control level for the 24-month rolling average NO_X emission rate of LOS Unit 2's SNCR with ASOFA alternative, estimated to be 0.304 lb/mmBtu or 54.5 percent below the future PTE pre-control baseline of 0.67 lb/mmBtu[28].

The expected post-control SNCR NO_X emission rate depends on the NO_X inlet concentration, type of reagent (aqueous urea), the amount of time that the flue gas is within the optimum temperature window for the SNCR process, and the amount of ammonia slip that is considered acceptable. Generally, the higher the NO_X inlet concentration and/or allowable ammonia slip in the boiler outlet flue gas, the higher the NOx reduction percentage that can be achieved. This estimated additional reduction performance for SNCR applied to LOS Unit 2 is similar to or better than the percentage reductions achieved by other cyclone-fired boilers retrofitted with this technology as summarized in Appendix A3 (pages A3-7 though A3-9) of the referenced BART Determination Study report. The amount of ammonia slip emitted was not always disclosed in the technical literature or vendor experience summaries for SNCR projects, and this has a significant influence on the resulting NO_X reduction expected.

The Alliant Edgewater Unit 4 and AmerenUE Sioux Unit 1 cyclone SOFA retrofits were operated with substantially more substoichiometric combustion conditions (below 0.90) than expected to be sustainable at LOS for Unit 2. Therefore, those NO_X reduction projects summarized in the referenced BART Determination Study report have reported greater percentage NO_X emission rate reductions resulting from deeply-staged cyclones and SOFA than are anticipated for LOS Unit 2 for operation with modestly-staged cyclones and ASOFA. As described in the referenced BART study, there is significant concern about the ability to control and sustain adequate ash slag fluidity, coverage, and tapping during deeply-staged cyclone operation for LOS Unit 2 when firing lignite coal. This means that the subsequent estimates for NO_X emission rates when ASOFA is considered alone and when combined with other technically-feasible technologies at LOS for Unit 2 will not reach the low levels of NO_X emission rates that were demonstrated on subbituminous coals at these other cyclone-fired boilers[29].

NDDH Comment #5 *We ask that you address the use of combustion optimization systems (COS) for the reduction of* NO_X *emissions from both units.*

---

[26] Ibid Reference 2, Table 2.3-4 on page 61.

[27] Ibid Reference 2, Table 1.4-1 on page 19, and pages 116-126.

[28] Ibid Reference 2, Table 2.3-4 on page 61.

[29] Ibid Reference 2, Appendix A3, pages A1, and A3-7 through A3-9.

B&McD Response #5 When establishing presumptive NO_X emission limits for BART-eligible coal-fired units, the RHR Guidelines did not include combustion optimization systems as "types of current combustion [NO_X] control technology options assumed include low NO_X burners, over-fire air, and coal reburning"[30]. All boilers that fire fuel to generate steam include some form of combustion control, primarily to safeguard personnel and equipment from inappropriate operation that could result in explosions. "Combustion optimization systems (COS) refers to the active control of combustion. These active combustion control measures seek to find an optimum combustion efficiency and to control combustion (and hence emissions) at that efficiency. Another approach uses a neural network computer software program to find the optimum control point. Still another approach is to use software to optimize inputs for the defined output"[31].

COS have been developed over the past ten years to manipulate boiler fuel/air combustion hardware adjustments to reduce NO_X and minimize CO emissions, increase boiler thermal efficiency, decrease flyash combustibles loss (also called LOI or loss-on-ignition), and decrease flue gas temperature variations within the furnace. There are two major aspects to COS:

- the control system with its software and hardware controllers; and
- the field devices, which include actuators and sensors.

COS can be operated on a stand-alone basis or combined with other optimization systems for furnace sootblowers, boiler steam cycle efficiency and capacity, and post-combustion NO_X reduction and reagent injection control.

A reference technical paper summarizing combustion controls for the western region of the United States stated that the number of neural networks installed at any of the 110 coal-fired EGUs in the WRAP paper was "unknown but significant". It also stated that "at least 35 installations of GNOCIS have been identified, and Pegasus [NeuSIGHT, by NeuCo, Inc.] has many more, however, the total number of installations of neural networks with enhanced monitoring could not be identified. However, enhanced monitoring has been in use for a number of years and it is expected that many units do utilize some form of it to optimize performance"[32]. It should be noted that neural networks were listed as an addition to low NO_X burners, close-coupled and separated overfire air combustion controls for state-of-the-art NO_X reduction techniques, but not for cyclone-firing.

One COS vendor offers technology "to integrate existing controls, control systems, sensors and computer hardware with advanced optimization techniques in a proprietary software environment to reduce emissions, increase efficiency, and increase availability. [This technology] literally learns on-line the interrelationships between important process control settings and real-time performance, constantly searching for overall performance improvements and make adjustments automatically and in real-

time"[33]. One of the COA projects mentioned in the referenced technical literature is a 2003-2007 U.S. DOE Clean Coal Power Initiative (CCPI) project at Dynegy Midwest Generation's Baldwin Energy Complex[34]. The initial potential benefits expected from the implementation of this demonstration project identified "NO_X emissions reductions of 5%"[35].

According to data presented in a early 2006 technical journal, the average NO_X concentration at the inlets to the Baldwin Unit 1 cyclone boilers' SCR reactors can be reduced by approximately 7.7% from non-optimized baseline[36]. Total Project Funding is budgeted at $19 million, and this does not "entail the addition of process equipment" to the host facility[37]. It should be mentioned that a significant amount of field instrumentation and distributed control systems and local area networks already installed at Baldwin Station were likely the main reasons why this latter statement was made. Unfortunately, it is not possible to determine the actual installed cost of the NO_X emission reduction portion of this project that would normally be attributable to the scope of the neural network COS, and how this might relate to the cost of a commercially-available, dedicated COS for each cyclone or tangentially-fired boiler at Baldwin.

Another technical paper from April 2005 describes some improvements made to the neural control software model initially used for controlling NO_X by controlling cyclone combustion air/fuel stoichiometry at Baldwin Station. It is unclear that the claimed NO_X reductions achieved fairly early in the demonstration project (15-20%) were sustainable or that they represent only those gains strictly due to the COS. There were aspects of the COS methods that were incomplete or had detrimental effects to other operations that led to further changes in the tuning of the optimizer[38].

Several referenced technical papers have been written summarizing another COS called Generic NO_X Control Intelligence System (GNOCIS), applied at Southern Company's Georgia Power - Plant Hammond Unit 4. "GNOCIS is a software package designed to improve utility boiler efficiency and reduce NO_X emissions through careful control of operating parameters. GNOCIS can operate on units that burn gas, oil, or coal and is available for all combustion firing geometries". Also, "GNOCIS uses a neural network to model the combustion characteristics of a boiler. In one of the more common forms, a neural network (computer code that models a system's responses) consists of three layers: an input layer, a hidden layer, and an output layer. The input layer receives signals from monitored variables and transmits them to the hidden layer, which contains interconnected neurons for pattern recognition. After processing, signals are sent to the output layer, which outputs recommend settings for the control variables. Thus, a neural network is, in effect, a sophisticated curve-fitting tool. Neural networks

can recognize patterns in input data, but before the network can associate a particular pattern with a corresponding plant state, it must be "trained". The training phase can be time consuming and usually involves feeding historical data to the program. However, once a network has been trained, it can respond very rapidly to new inputs. An advantage of a neural network is that, if any inputs are faulty, prediction capability degrades only gradually compared to most other modeling techniques. In order for GNOCIS to function effectively, a properly designed and installed control system is essential"[39].

The vast majority of these COS are believed to have been applied to pulverized coal-fired boilers with low-NO_X burners and SOFA[40]. The reference technical literature stated that testing with the GNOCIS program set to control boiler operations, full-load NO_X emissions were reduced from between 14 percent and 10 percent over baseline, depending on the mode that the COS was operating in. The COS mode for minimizing NO_X emissions at full load produced the 14% reduction, maximizing efficiency operating mode showed a 12% decrease, while the minimize flyash LOI mode resulted in the 10% drop over full-load baseline emissions[41].

In regards to the cost of this COS, "If a distributed control system (DCS) is present, installing GNOCIS on the boiler is relatively inexpensive and can significantly improve plant operations".[42] Also, "Estimates by the participant for costs that could be used for planning a retrofit a 500-MWe power plant similar to Hammond Unit 4 are: GNOCIS \$0.25 million (\$0.50/kW). These estimates are based upon actual Hammond Unit 4 costs, as well as cost data available from EPRI and other sources. Of course, site-specific factors, such as boiler size, age, design, furnace configuration, windbox design, and condition, plant layout, etc., can significantly affect these estimates. Insufficient data are available to allow estimation of installing full unit optimization hardware and software"[43].

Due to the time span from the actual installation of the digital control system in June 1994 followed by GNOCIS testing starting in February 1996, until the date of the reference technical report (March 2004) and then to the present (January 2007), the expected cost of installing this COS at Hammond Unit 4 is difficult to estimate in today's dollars from a review of the available technical literature.
There have been few published technical papers or articles in utility trade journals/magazines that document COS applied to cyclone-fired boilers. One 2002 technical reference provided an implementation cost range between \$30 and \$60/kW, claiming fuel and operating flexibility for low NO_X emission rates from tangentially-fired, wall-fired, and cyclone-fired boilers[44]. The exact details of such modifications have not been published, although the general scope of this referenced firm's COS

involved changes that went well beyond what is typically included for these kinds of retrofit projects in terms of field instrumentation and controls hardware. Unfortunately, it is not possible to determine the actual installed cost of the portion and the amount of NO_X emission reductions for these projects that would normally be attributable to the scope of traditional COS "neural network" retrofit projects.

Basin has already implemented improvements to the Leland Olds Station Unit 2 boiler distributed controls system in spring 2006, and plans on installing similar DCS control upgrades on Unit 1 in fall 2007. It is difficult to estimate the amount of potential NO_X emission reductions and costs of adding available commercial COS to either LOS unit due to the site-specific nature of such installations. The need to identify the levels of field instrumentation and control devices for integration with the COS and the fact that the alternatives recommended as BART for NO_X control have not been installed would require further detailed investigation. The opportunity to make significant additional NO_X emission reductions strictly from adopting and adapting neural networks to the LOS boilers is uncertain but is believed to be limited due to the improvements already planned and/or incorporated by the installation of the DCS upgrades and other operational procedures in effect.

Dear Terry:

Per your request, Basin Electric Power Cooperative (Basin Electric) has developed a hypothetical cost effectiveness determination to supplement our previously submitted BART Determination Study for Leland Olds Unit's 1 and 2. This specific work product is a continuation of information surrounding the discussion of the applicability of selective catalytic reduction (SCR) and specifically the tail-end selective catalytic reduction (TE-SCR) to Leland Olds Unit 2.

As Sargent & Lundy has explained both in its March 11, 2009 presentation and in earlier communications with the Department, cyclone boilers burning North Dakota lignite coal have unique challenges that may make SCRs unfeasible because of the high alkalis (mainly sodium and potassium) levels combined with the high temperature and other properties that are uniquely found in cyclone boilers which vaporizes the alkalis into the flue gas stream. This high level of vaporized alkali products in the flue gas stream is known to cause deactivation and poisoning of the catalyst. The design issues for North Dakota lignite have not been addressed by Powder River Basin (PRB), Texas lignite, or other brown coals that do not have the same high alkali content and other chemical properties of North Dakota lignite. Extensive pilot testing is needed to resolve catalyst deactivation and other issues.

Sargent & Lundy developed the first application of SCRs on PRB coal. As they noted in their March 11 presentation to you, the following problems would have arisen for PRB if extensive pilot testing had not been done prior to the first commercial application of SCRs on facilities using PRB coal (slide 59):

- ✓ Catalyst would not have performed
- ✓ Reactors would have been too small
- ✓ Operation would have been problematic

TE-SCRs are a higher cost and much less applied technology than other SCRs. Based on the factors discussed in the March 11th presentation, Sargent & Lundy concluded (slide 68):

> There are attributes of this fuel [ND Lignite] in a tail-end SCR environment that are not well understood today and need more investigation to predict it's performance to make it commercially available technology.

Because of these uncertainties, and the huge potential consequences to our company and the North Dakota lignite resource if an SCR were installed and did not work, Basin Electric committed to completing pilot testing for the SCR technology on cyclone boilers using ND lignite before the next review period for Regional Haze. We ask that you allow us that opportunity, and emphasize that these highly hypothetical estimates are nothing more than an educated guess based on hypothetical performance levels (with a very high probability of being wrong) until pilot testing is completed. We emphasize that point, because there is a risk that these estimates will be cited as if they have the same degree of accuracy as estimates of costs for commercially available technologies. The law is clear that when pilot testing is needed, a technology is not considered "available." One of the reasons for doing this is to avoid putting on extremely expensive technologies such as SCRs, with no assurance that they will work.

Thus, we are supplying you with these cost estimates with the caveats and commitments just described, and ask that the estimates not be misused.

The hypothetical cost effectiveness determination for TE-SCR was performed by Sargent & Lundy, who as you know has significant technical expertise for all application of SCRs. This study indicates that the TE-SCR has numerous unknowns as to its applicability to a North Dakota lignite-fired cyclone boiler for NOx control. Specifically, unknown is the reactivity loss of the catalyst, design factors of the SCR (catalyst volume and surface area), reagent injection rates, reagent slip and economic volatility of the re-heat fuel. These areas need to be more defined prior to placing a pollution control technology on such an unlike flue gas stream that a North Dakota lignite-fired cyclone boiler represents.

Basin Electric's BART Determination submittal included the visibility impairment at the Class I areas in North Dakota using the Departments modeling Calpuff protocol. With the addition of a wet scrubber for SO_2 control and selective non-catalytic reduction (SNCR) technology for NOx control on both Leland Olds units there was significant visibility improvement on the Class I areas. It is expected that the ammonia slip from the TE-SCR may be greater than a SNCR control since it will be located beyond the wet scrubber. This increased ammonia slip in the presence of SO_3 may require additional controls such as a wet electrostatic precipitator (WESP) or other technologies such as sorbent injection in order to minimize potential plume blight issues and PSD requirements.

Based on this hypothetical economic analysis, the Department should consider both the high initial cost and large risk of failure of installing an unproven control technology.

Should you have questions or require additional information, please contact me at (701) 355-5635.

Sincerely,

Cris Miller

Project: Basin Electric Power Cooperative – Leland Olds Station
Subject: BART Evaluation Update – Tail End SCR

Dear Mr. Miller:

Per your request as a follow-up to our presentation to the North Dakota Department of Health (NDDH/Department) on March 11, 2009, this letter report has been prepared to provide supplemental information in support of Basin Electric Power Cooperative's (BEPC's) BART Determination Study for Leland Olds Station Units 1 and 2, which was submitted to the NDDH in August 2006 (the "BART Determination Study").

The BART Determination Study identified tail-end selective catalytic reduction (TE-SCR) as a potentially available post-combustion NOx retrofit control technology. However, the study determined that TE-SCR on Leland Olds Station (LOS) Unit 2 would be susceptible to unacceptable catalyst deactivation from soluble alkalis in the lignite (most notably sodium) not removed by the particulate matter and flue gas desulfurization control systems. The study concluded that TE-SCR was not a technically feasible NOx retrofit control technology due to the flue gas characteristics associated with the North Dakota lignite fired in LOS Unit 2.

Although there continue to be significant technical issues associated with the operation of a TE-SCR control system on a unit firing North Dakota lignite, NDDH has requested that BEPC provide a cost effectiveness evaluation for the TE-SCR control system on LOS Unit 2 recognizing the high level of uncertainty in doing so due to the lack of design and operational knowledge surrounding the application of a TE-SCR on a ND lignite–fired cyclone boiler. Cost estimates included in this letter report were prepared in response to the Department's request for a cost effectiveness evaluation. However, as we concluded in our presentation to the Department on March 11, 2009, significant pilot testing will be needed to understand the effect of lignite-derived flue gas on the SCR catalyst and evaluate the technical feasibility and effectiveness of TE-SCR on LOS Unit 2 with any degree of certainty. Without information developed from a testing program, cost estimates included herein should be considered hypothetical case studies based on technical judgment. More accurate estimates cannot be developed without first performing pilot tests, and, without that information, the actual cost effectiveness of the TE-SCR system (assuming it proves to be technically feasible) could be higher or lower than the costs identified below.

In addition, as described below, we still have significant concerns regarding the technically feasibility and effectiveness of a TE-SCR control system on a lignite-fired cyclone boiler. We concur with the conclusions included in the BART Determination Study that, at this point, TE-SCR is not a technically feasible or commercially available Best Available Retrofit Technology (BART) for LOS Unit 2. Again, pilot testing would be required to conclude, with any degree of certainty, that TE-SCR is a technically feasible and economically viable NOx retrofit control technology.

Nevertheless, to support BEPC's response to the Department's request, Sargent & Lundy (S&L) is providing the following supplemental information: (1) a brief technical description of the TE-SCR control system; (2) a hypothetical cost effectiveness evaluation of TE-SCR on LOS Unit 2 accounting for some of the uncertainty associated with the effectiveness and operation of the system; and (3) updated cost effectiveness tables and figures that were originally included in the BART Determination Study.

Tail-E SCR Application at Leland Olds Unit 2

LOS Unit 2 is a Babcock & Wilcox (B&W) cyclone-fired unit with a turbine-generator nameplate rating of 440 MW. LOS Unit 2 is equipped with two parallel electrostatic precipitators (ESPs) for particulate matter control. The unit is not currently equipped with a flue gas desulfurization (FGD) control system, but BEPC is in the process of installing a wet FGD control system for sulfur dioxide (SO_2) control. The wet FGD control system is anticipated to be operational in the fall of 2010. The primary fuel for LOS Unit 2 is North Dakota lignite from the Freedom Coal Mine in Beulah, ND.

Selective catalytic reduction (SCR) was evaluated in the BART Determination Study as a potentially available NOx retrofit control technology. SCR involves injecting ammonia (NH_3) into boiler flue gas in the presence of a catalyst to reduce NOx to nitrogen (N_2) and water. The overall SCR reactions can be shown as follows:

$$4NH_3 + 4NO + O_2 \rightarrow 4N_2 + 6H_2O$$
$$4NH_3 + 2NO_2 + O_2 \rightarrow 3N_2 + 6H_2O$$

The performance of an SCR system is influenced by several factors including flue gas temperature, SCR inlet NOx concentration, catalyst surface area, volume and age of the catalyst, and the amount of ammonia slip that is acceptable. SCR control systems on coal-fired power plants are typically located at the economizer outlet, where the flue gas temperature is most suitable for the NH_3/NOx reactions. However, flue gas characteristics at the economizer outlet can also have detrimental affects on the SCR catalyst. Studies suggest that these flue gas characteristics can be especially troublesome with North Dakota lignite, where the ash chemistry is highly alkaline and contact with the catalyst can lead to significant catalyst deactivation and a shorter catalyst life.

SCR catalyst deactivation occurs through two primary mechanisms: physical deactivation and chemical poisoning. Physical deactivation is caused by either exposure of the catalyst to excessive temperatures (thermal deactivation) or masking of the catalyst due to entrainment of particulate from the flue gas stream (fouling). Chemical deactivation is caused by either an irreversible reaction of the catalyst with a contaminant in the gas stream (poisoning) or a reversible absorption of a contaminant on the surface of the catalyst (inhibition). Loss of catalyst activity through thermal degradation or poisoning is permanent, and reactivity can only be restored by replacing the catalyst. Recovery of catalyst activity from the reversible phenomenon (i.e., inhibition) is controlled by the economics of new catalyst replacement and is highly dependent on the actual mechanism of deactivation.

In a North Dakota lignite application, SCR catalyst poisoning is expected to result from the presence of trace elements and strong alkaline substances (e.g., Li, Na, K, and Ca) in flue gas. Alkaline metals can chemically attach to active catalyst pore sites and cause deactivation. Sodium (Na) and potassium (K) are of prime concern especially in their water-soluble forms, which are more mobile and can penetrate into the catalyst pores. Earth metals, especially calcium (Ca), can react with SO_3 absorbed within the catalyst to form $CaSO_4$ and blind the catalyst. North Dakota lignite contains relatively high levels of organically associated alkali and alkaline-earth elements, including Na, Ca, K, and magnesium.

Sodium levels in North Dakota lignite are typically 5 to 20 times higher than sodium levels in bituminous and subbituminous coals, and sodium compounds can represent between 5% and 11% of the ash generated from firing North Dakota lignite. These sodium levels, occurring in both the vapor phase and particulate phase, along with relatively high levels of potassium and calcium, significantly increase the potential for catalyst deactivation, plugging, and erosion. Based on the ash chemistry, a conventional high dust SCR arrangement (i.e., SCR located at the economizer outlet) would experience unacceptable catalyst deactivation rates, and, as concluded in the BART Determination Study, high dust SCR is, therefore, not a technically feasible NOx retrofit control option on units firing North Dakota lignite.

One option that has been studied to address these technical issues is to locate the SCR after the particulate and FGD control systems (if present). SCR control systems located downstream of the particulate and SO_2 controls are generally referred to as tail-gas or tail-end SCRs (TE-SCR). The idea is to remove the alkaline elements that cause unacceptable catalyst deactivation upstream of the SCR. The TE-SCR would still have to be designed to handle vapor phase sodium and fine particulates that are not collected by the ESP and wet FGD.

The TE-SCR configuration requires the flue gas to be re-heated for effective NOx control. Flue gas exiting the wet FGD at approximately 140 °F is directed to a gas-gas heat exchanger (GGHE) to raise its temperature to approximately 550 °F. After the GGHE the flue gas is directed to either an in-duct gas burner or steam heat exchanger to raise its temperature an additional 50 °F. From the duct burner or steam heat exchanger the flue gas would enter the TE-SCR reactor at approximately 600 °F. Ammonia is injected and mixed into the flue gas stream as it enters the SCR reactor, where it reacts with NOx to form nitrogen and water as shown above. Flue gas exiting the TE-SCR is returned to the other side of the GGHE to recover the waste heat before it is exhausted through the stack.

Due to the limited effectiveness of the GGHE, the outlet temperature from the TE-SCR system will be approximately 50 °F to 60 °F higher than the flue gas inlet temperature, resulting in a stack temperature of approximately 190 °F. This stack temperature is about 50 °F higher that the stack gas expected from the wet FGD system currently being installed on LOS Unit 2. The existing stack liner is guaranteed to withstand only 150 °F temperature, thus, the liner may have to be replaced or coated to withstand the higher stack gas temperatures.

TE-SCR has not been demonstrated on a lignite-fired boiler, and there are still significant technical concerns associated with the viability of existing SCR catalysts on a lignite-fired unit. For example, it is not known whether the comparatively high level of soluble sodium and potassium in North Dakota lignite will be effectively removed by the upstream ESP and wet FGD. Furthermore, the potential exists for sodium and potassium compounds remaining in the flue gas as fine particulates to re-vaporize as the flue gas is re-heated in the aforementioned duct burners. The fine particulates remaining in the flue gas would also have tendency to get into the catalyst pores, forming water soluble salts and reducing catalyst activity, as the flue gas passes through the water dew point. SCR catalyst in a TE-SCR will still be vulnerable to alkali poisoning, pore pluggage, and premature catalyst deactivation. In order to understand the effect of lignite-derived flue gas on the SCR catalyst, identify potential design solutions, and evaluate the technical feasibility and effectiveness of TE-SCR on LOS Unit 2 with any degree of certainty, pilot testing will be needed as summarized in the PowerPoint presentation to the Department on March 11, 2009.

<u>TE-SCR Cost Estimate</u>

Notwithstanding the remaining technical issues and uncertainties, S&L prepared a cost estimate to install and operate a TE-SCR on LOS Unit 2. Given the technical uncertainties and limited amount of available cost information, the TE-SCR cost estimate should be considered a hypothetical case study based on technical judgment. This cost estimate is designed to supplement the NOx control cost effectiveness evaluation included in the BART Determination Study. To be consistent with cost estimates included in the BART Determination Study, S&L followed the cost estimating methodologies and assumptions outlined in Section 1.3.5 of the study. S&L did not reevaluate costs for the other potentially feasible NOx retrofit control technologies, but relied on costs included in the BART Determination Study. Capital costs for the other NOx retrofit control technologies were brought up to 2009 dollars using an average annual escalation rate of 4.0%.

Order of magnitude capital costs were developed for the TE-SCR control system. Capital costs include the equipment, material, labor, and all other direct costs needed to retrofit LOS Unit 2 with the control technology. An allowance was included into the capital cost estimate for the Unit 2 stack liner modifications. Fixed and variable O&M costs were also developed for the TE-SCR control system. Fixed O&M costs include operating labor, maintenance labor, maintenance material, and administrative labor. Variable O&M costs include the cost of consumables associated with operating the system, such as reagent usage (e.g., ammonia), auxiliary power requirements, secondary fuel and catalyst replacement.

<u>Accounting for Uncertainty</u>

As discussed above, significant technical issues remain unresolved regarding the effectiveness of a TE-SCR control system on LOS Unit 2. Without pilot scale testing it is not possible to know definitively how the flue gas chemistry will affect the SCR catalyst, and it is very difficult to estimate with any certainty the catalyst deactivation rate (required to estimate annual operating costs of the system). In addition to the catalyst deactivation issues, the cost effectiveness of a TE-SCR control system will be particularly sensitive to the cost of natural gas and ammonia. The TE-SCR control system will require significant quantities of both natural gas and ammonia, and the cost of these consumables will directly affect the cost effectiveness of the system. Finally, installation of the TE-SCR could trigger the necessity to install additional pollution controls to address resulting increases in sulfuric acid mist emissions (another PSD regulated pollutant). Methods used to account for these uncertainties are described below:

Catalyst Replacement Frequency

Based on our engineering judgment, an accelerated catalyst deactivation rate is anticipated with the lignite derived flue gas; therefore, we developed capital and O&M costs for the two most likely scenarios: (1) a catalyst deactivation rate that necessitates catalyst replacement every 12 months; and (2) a catalyst deactivation rate that necessitates catalyst replacement every 6 months. More frequent catalyst replacement requires more frequent shutdown of the unit. Typical catalyst replacement activities require the unit to be shutdown for a two week outage. Because planned major outages are only scheduled every three years, costs associated with the additional catalyst replacement outages were included in the annual O&M estimates.

Consumable Costs

The cost effectiveness of the TE-SCR will also be sensitive to the cost of consumables used in the system including natural gas and ammonia. As described above, effective NOx control with a TE-SCR requires re-heating the flue gas from approximately 140 °F to approximately 600 °F. Based on preliminary engineering calculations, re-heating the flue gas will consume approximately 115 mmBtu/hr natural gas. The cost of firing natural gas to re-heat the flue gas will have a significant impact on the cost effectiveness of the system.

Natural gas prices have been subject to significant volatility over the past several years. Volatility in natural gas prices are subject to short-term supply and demand shifts, coupled with the significant lead time required to bring additional natural gas supplies to market and expand pipeline capacity.[2] Natural gas prices are also sensitive to market factors such as weather swings and supply disruptions. Based on information published by the U.S. Energy Information Administration, the price of natural gas for electricity production is currently in the range of $6.60 to $8.00/mmBtu. As recently as 2007 natural gas prices for electricity production reached almost $14/mmBtu. Future swings in natural gas prices will directly affect the cost of operating the TE-SCR control system.

---

[2] See, e.g., "An Analysis of Price Volatility in Natural Gas Markets," U.S. Energy Information Administration, Office of Oil and Gas, August 2007.

Similarly, the TE-SCR will consume significant quantities of ammonia. Based on preliminary engineering calculations the TE-SCR will consume approximately 873 lb/hr of ammonia. Operating costs of the TE-SCR control system are directly related to the cost of ammonia. Ammonia prices are directly related to the price of natural gas. Approximately 33 mmBtu of natural gas are needed to produce one ton of ammonia, and natural gas accounts for approximately 80% of the ammonia production cost. Anhydrous ammonia costs are currently in the range of approximately $450/ton, but have historically been as high as $700/ton.

To account for potential swings in the cost of natural gas and ammonia, and to envelope potential O&M costs associated with the TE-SCR control system, annual O&M costs were calculated using natural gas prices of $8 and $12/mmBtu and ammonia costs of $450 and $700/ton.

Acid Mist Control

Finally, it is possible that the installation of the TE-SCR will trigger New Source Review (NSR) permitting and additional pollution control requirements for sulfuric acid mist (SAM). In addition to oxidizing NOx to N_2 and water, undesirable reactions can occur in an SCR system including the oxidation of SO_2 and formation of SAM. A fraction of the remaining SO_2 in the flue gas (approximately 1%) will oxidize to SO_3 in the presence of the SCR catalyst. SO_3 can react with water in the flue gas to form SAM. Assuming a controlled SO_2 emission rate of 35 ppmvd @ 15% O_2 and 1% SO_2 to SO_3 conversion across the SCR, SAM emissions from LOS Unit 2 would increase by approximately 24.1 tpy, a quantity in excess of the PSD significant level.

PSD would require increased SAM emissions to be controlled using BACT. Although it is possible that BACT could require the installation of a wet ESP control system after the TE-SCR (which would be very expensive), it is more likely that increased SAM emissions could be addressed using an upstream sorbent injection system. Sorbent injection involves the injection of a powdered absorbent directly into the flue gas exhaust stream upstream of the particulate control device. To address the potential need for SAM control, S&L prepared one cost estimate that includes the capital and O&M costs associated with a sorbent injection system.

The following TE-SCR with advanced separated overfire system (ASOFA) scenarios were developed for direct comparison with the scenarios A-D in the BART Determination Study. Five TE-ASOFA scenarios were developed to account for uncertainty regarding: (1) catalyst deactivation rate; (2) sorbent injection control requirements; and (3) the cost of natural gas and ammonia.

Scenario E: TE-SCR with ASOFA
12-month catalyst replacement frequency
$8/mmBtu natural gas
$450/ton ammonia
No sorbent injection system to address increased acid gas emissions

Scenario F: TE-SCR with ASOFA
6-month catalyst replacement frequency

$8/mmBtu natural gas
$450/ton ammonia
No sorbent injection system to address increased acid gas emissions

Scenario G: TE-SCR with ASOFA
6-month catalyst replacement frequency
$12/mmBtu natural gas
$450/ton ammonia
No sorbent injection system to address increased acid gas emissions

Scenario H: TE-SCR with ASOFA + Sorbent Injection System
6-month catalyst replacement frequency
$12/mmBtu natural gas
$450/ton ammonia
Sorbent injection system installed to address increased acid gas emissions

Scenario I: TE-SCR with ASOFA + Sorbent Injection System
6-month catalyst replacement frequency
$12/mmBtu natural gas
$700/ton ammonia
Sorbent injection system installed to address increased acid gas emissions

Unit costs used to develop annual O&M costs associated with each scenario are summarized below:

Parameter	**Units**	**Scenario E**	**Scenario F**	**Scenario G**	**Scenario H**	**Scenario I**
Inlet NOx Rate	lb/mmBtu	0.48	0.48	0.48	0.48	0.48
NOx Control System		TE-SCR	TE-SCR	TE-SCR	TE-SCR	TE-SCR
SAM Control		na	na	na	Sorbent Injection	Sorbent Injection
Total Initial Catalyst	m^3	530	530	530	530	530
Controlled NOx Rate	lb/mmBtu	0.07	0.07	0.07	0.07	0.07
Catalyst Replacement	frequency	12 months	6 months	6 months	6 months	6 months
Capacity Factor	%	96.2	92.3	92.3	92.3	92.3
Catalyst Cost	$\$/m^3$	7,500	7,500	7,500	7,500	7,500
Power Cost	$/MWh	50	50	50	50	50
Natural Gas Cost	$/mmBtu	8.0	8.0	12.0	12.0	12.0
Ammonia Cost	$/ton	450	450	450	450	700

Updated Cost Evaluation

Provided below are several tables updating the NOx retrofit cost effectiveness evaluation originally included in the Section 2.5.1 of the BART Determination Study. These tables include costs associated with potential NOx control technologies for LOS Unit 2. The control cost estimates included in the 2006 study have been updated to reflect 2009 dollars (costs were originally given as 2005 dollars). The tables also include estimates associated with the installation of TE-SCR and ASOFA on Unit 2. The table numbers included below are intended to match the table numbers used in the BART Determination Study.

Further, the TE-SCR/ASOFA cost effectiveness calculation is consistent with the methods and assumptions used in the BART Determination Study. Consistent with the approach used in the 2006 study, future potential-to-emit (PTE) annual emissions with the TE-SCR/ASOFA system were reduced to account for an annual outage requirement of 2 weeks for Scenario E (catalyst replacement every 12 months) and 4 weeks for Scenarios F thru I (catalyst replacement every 6 months). Levelized total annual costs for Scenarios F thru I vary depending the cost of natural gas and ammonia and the installation/operation of a sorbent injection control system. The following equation was used to calculate the cost effectiveness:

$$\text{Cost Effectiveness (\$/ton)} = \frac{\text{Levelized Total Annual Cost}}{\text{(Historic Pre-Control Annual Baseline Emissions – Future PTE Annual Emissions)}}$$

The following tables and figures were updated from the BART Determination Study to include the TE-SCR Scenarios:

F	Tail-End SCR + ASOFA (6 mo catalyst replacement) gas = $8/mmBtu / NH_3 = $450/ton No Sorbent Injection Control	> 300	376
E	Tail-End SCR + ASOFA (1 yr catalyst replacement) gas = $8/mmBtu / NH_3 = $450/ton No Sorbent Injection Control	> 300	376
D	Rich Reagent Injection (RRI) + SNCR (using urea) and ASOFA	20 + ?(4)	53(4),(5),(6)
C	SNCR (using urea) w/ ASOFA	20-35(7)	44(5),(6)
B	Coal Reburn (conventional, pulverized) w/ ASOFA	30-60(7)	178(6),(8)
A	Advanced Separated Overfire Air (ASOFA)	5-10(7)	26(6)

(1) – Alternative designation has been assigned from highest to lowest unit NO_X emission rate.

(2) – Unit capital cost factors ($/kW) of these individual technologies combined by simple addition. Actual installed costs may differ due to positive or negative synergistic effects. Range based on published values or vendor proposals.

(3) – Single point cost factor is best estimate for determination of total capital cost for a particular technology or combination, assuming maximum unit capacity is based on existing nameplate rating. Single point cost figures in 2009 dollars.

(4) – No published RRI unit capital cost factor was found in available technical literature. The installed capital costs for RRI are expected to be similar to SNCR. If both RRI and SNCR are installed together, capital cost of the RRI+SNCR portion was assumed to be 1.5x the capital cost of SNCR alone, due to commonality between the two systems sharing certain equipment and systems.

(5) – Estimated capital cost for SNCR point estimate derived from December 2004 budgetary proposal by Fuel Tech. See Appendix A for details.

(6) – The single point unit capital cost factor shown for the "advanced" version of SOFA derived from Burns & McDonnell internal database and cost estimate for North Dakota lignite-fired cyclone boilers.

(7) – NESCAUM 2005 Technical Paper, posted at their website for basic SOFA. See Appendix A for details.

(8) – The single point unit capital cost factor shown for a coal reburn system is highly site-specific, and assumes that new pulverizers and building enclosures are required. The general cost range for pulverized coal-fired boilers is included in the NESCAUM 2005 Technical Paper; for cyclone boilers is included in the 2005 WRAP Draft Report, posted at their website. The single point unit capital cost factor for this alternative for increased PM collection capacity included in coal reburn options is 57.5 $/kW. See Appendix A for details.

TABLE 2.5-2 – Installed and Annualized Capital Costs Estimated for NO_X Control Alternatives - LOS Unit 2

Alt. No. (1)	NO_X Control Alternative	Installed Capital Cost(2) ($1,000)	Annualized Capital Cost(3) ($1,000)
I	Tail-End SCR + ASOFA (6 mo catalyst replacement) gas = $12/mmBtu / NH_3 = $700/ton Sorbent Injection Control System	170,800	14,890

Conclusions

Significant technical issues remain unresolved regarding the installation of a TE-SCR on a unit firing North Dakota lignite. The flue gas characteristics from firing North Dakota lignite could rapidly accelerate catalyst deactivation due to potentially elevated sodium levels that are not captured in the ESP and wet FGD. Without pilot scale testing it is not possible to know how the flue gas chemistry will affect the SCR catalyst, and it is very difficult to estimate with any certainty the catalyst deactivation rate (required to design the SCR reactor and estimate annual operating costs of the system).

Despite the significant uncertainties surrounding the potential for accelerated catalyst deactivation on Unit 2 TE-SCR, a cost evaluation was performed for a TE-SCR on LOS Unit 2 (a North Dakota lignite fired cyclone furnace). Given the technical uncertainties and limited amount of available cost information, the TE-SCR cost estimate prepared for this evaluation should be considered hypothetical case studies based on technical judgment, and may not be representative of the actual costs associated with the control system. To account for uncertainties in the catalyst deactivation rate, natural gas and ammonia costs, and the need to provide additional acid mist control, S&L prepared costs for several operating scenarios.

The total levelized annual cost for the TE-SCR/ASOFA control systems is estimated to range from approximately $43.8 million per year (based on a 12-month catalyst replacement frequency and lower natural gas and ammonia costs) to approximately $61.2 million per year (based on a 6-month catalyst replacement frequency and assuming higher natural gas and ammonia costs). Levelized annual costs for the control system increases to approximately $63.2 million per year assuming sorbent injection control is needed to address increases in acid gas emissions. Assuming an average controlled NOx emission rate of 0.07 lb/mmBtu, the average annual cost effectiveness of the TE-SCR/ASOFA control system, based on the historic pre-control annual emission baseline, is estimated to range from approximately $4,200 to $6,000/ton, depending on the catalyst replacement frequency and cost of consumables.

The incremental cost effectiveness of the TE-SCR/ASOFA technology over the next lower-cost retrofit control option (RRI/SNCR/ASOFA) ranges from approximately $6,000/ton (assuming a 12-month catalyst replacement frequency and lower consumable costs) to more than $10,000/ton (assuming a 6-month catalyst replacement frequency, higher consumable costs, and the need to address increased SAM emissions).

Again, this economic analysis was based on a hypothetical engineering analysis of what we know today. A more accurate estimate cannot be developed without first performing significant pilot testing as suggested in our March 11, 2009 presentation to the Department. The actual cost effectiveness of the control system could therefore be higher or lower than those identified from this effort.

Should you need additional information, please do not hesitate to contact me.

Sincerely,

Executive Summary

This report describes the background and methods for the selection of the Best Available Retrofit Technology (BART) as proposed by Great River Energy (GRE) for the Coal Creek Station (CCS) located in Underwood, ND. CCS is a two unit, 1100 megawatt mine-mouth plant. Commercial operation commenced on CCS Unit 1 in 1979 and Unit 2 in 1980. The CCS steam generators are Combustion Engineering Controlled Circulation tangentially fired lignite boilers. Preliminary visibility modeling conducted by the North Dakota Department of Health (NDDH) found that the Coal Creek units cause or contribute to visibility impairment in a federally protected Class 1 area, therefore making the facility subject to BART.

Guidelines included in 40 CFR §51 Appendix Y were used to determine BART for the Coal Creek units. The existing pollution control equipment for each unit includes: ESP for particulate matter, low NOx burners (LNB) with a level of separated overfire air (SOFA) for NOx, and partially bypassed wet scrubbing for SO_2. The CALMET/CALPUFF/CALBART dispersion modeling sequence was used to assess the post-BART visibility impacts associated with the proposed BART emission limits. Based on the results of visibility modeling, economic impacts analysis and consideration for other non-air quality energy and environmental factors, GRE proposes the following as BART:

- Particulate matter (PM) emissions will continue to be controlled by the existing ESP for each unit. Additional PM controls, including condensable PM (CPM) controls, would provide little visibility improvement and require significant capital expenditures. Existing and proposed SO_2 controls may provide additional CPM reductions, primarily in the form of sulfuric acid mist (SAM). Therefore, the current PM performance standard of 0.1 lb/MMBtu will be maintained.

- NOx emissions will be reduced to the presumptive BART level of 0.17 lb/MMBtu on a 30-day rolling average. This will be achieved through the installation of an additional level of SOFA.

- SO_2 emissions will be reduced to the presumptive BART level of 0.15 lb/MMBtu on a station wide 30-day rolling average. This will be achieved through the use of coal drying, and the installation of trays or new liquid distribution rings (LDRs) and high flow mist eliminators (MEs)

The proposed BART emission rates will result in an overall visibility improvement of over 50% for Coal Creek Station.

It is GRE's goal to install controls that will meet or perform below the presumptive BART levels for both NOx and SO_2. In an effort to utilize the best available technology at the time of purchase, GRE will continue to evaluate which technology will provide the requisite removal efficiencies to meet presumptive BART emission limits and provide GRE with greatest operational flexibility. GRE was awarded a collaborative agreement for a Lignite Fuel Enhancement project under the Clean Coal Power Initiative DOE Solicitation DE-PS26-02NT41428. Phase I of the DOE project included a 75 ton/hour lignite drying system with a segregator for beneficiation of the fuel was designed and constructed in 2005. The drying system has been performance tested, and an evaluation of the benefits of the drying system was completed. A public version of this evaluation is included in Appendix J. Coal drying results in two major benefits to the station; first is a decrease in lignite moisture content resulting in higher boiler efficiency and a lower flue gas volume, subsequently resulting in increased scrubbing efficiency; and second is a decrease in fuel combustion quantities resulting in lower emissions.

1.0 Introduction

On July 15, 2005, the U.S. Environmental Protection Agency (EPA) published the final rules for regional haze and best available retrofit technology (BART). The BART rules[1], originally promulgated in September 1999, were in effect as of September 6, 2005.

The rules require that each state subject to BART, develop a Regional-Haze State Implementation Plan (RH SIP) to improve visibility impairment in federally-protected national parks and wilderness areas (Class I areas). The SIP must require BART on all BART-eligible sources and mandate a plan to achieve natural background visibility by 2064. Figure 1-1 illustrates the 6 BART eligible units and 4 Class 1 areas in North Dakota. Each state must submit an RH SIP by December 17, 2007 that includes milestones for establishing reasonable progress towards the visibility improvement goals, and plans for the first five-year period. Upon submission of the SIP, states must make the requirements for BART sources enforceable through rules, administrative orders or Title V permit amendments.

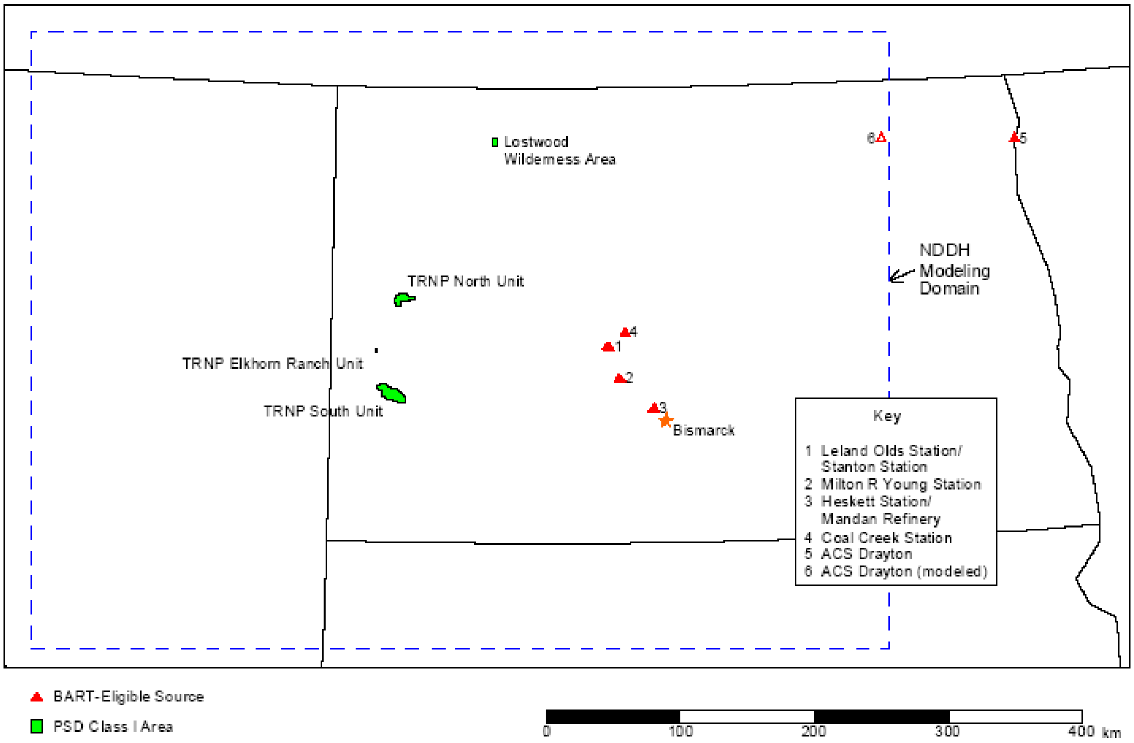

Figure 1-1 North Dakota's BART Geography: The North Dakota SIP will address the 4 PSD Class I Areas and 6 BART Eligible Units illustrated above. (Source *Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota, Final version)*

Expressly, reasonable progress means that the 20 best-visibility days must get no worse, and the 20 worst-visibility days must become as good as the 20 worst days under natural

---

[1] 40 CFR §51 and Clean Air Act §169A and 169B

conditions. Assuming a uniform rate of progress the default glide path, illustrated in Figure 1-2, would require 1 to 2 percent improvement per year in visibility on the 20 worst days. The state must submit progress reports every five years to establish their advancement toward the Class 1 area natural visibility backgrounds. If a state feels it may be unable to adopt the default glide path, a slower rate of improvement may be proposed on the basis of cost or time required for compliance and non-air quality impacts.

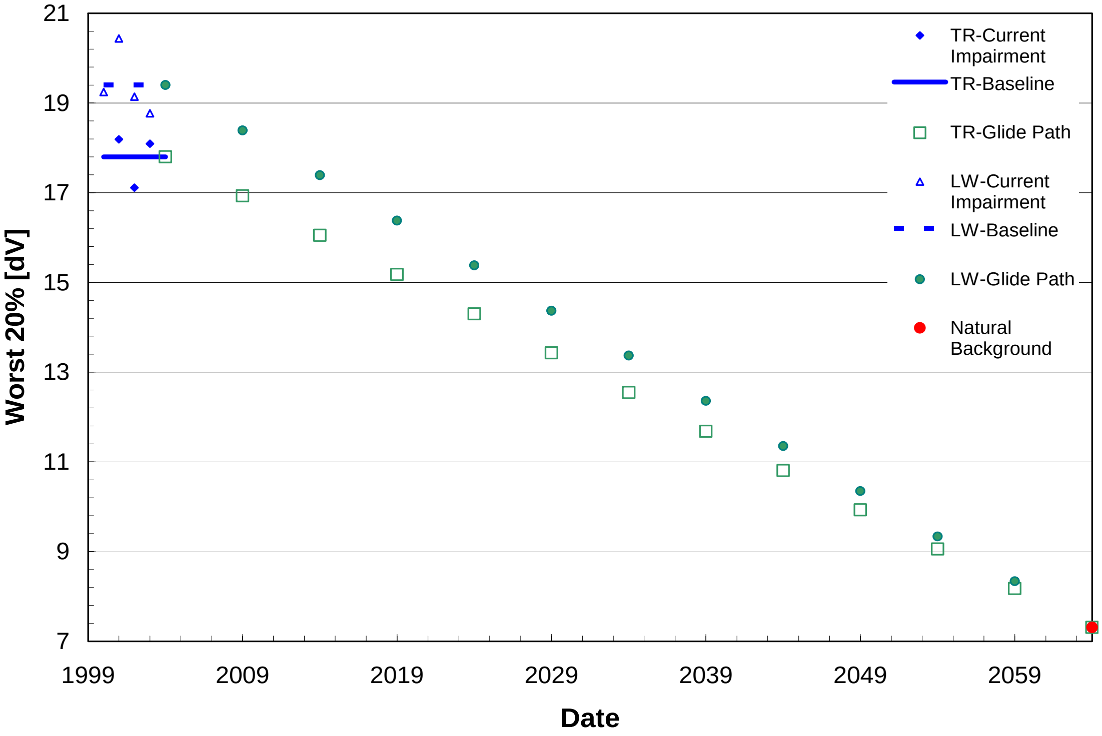

Figure 1-2 Theodore Roosevelt NP and Lostwood WA, ND. Current impairment includes both natural and anthropogenic contributions. (Data from VIEWS database trend analyzer, http://vista.cira.colostate.edu/views/web/AnnualSummaryDev/Trends.aspx DOA 06 Dec 2005)

1.1 BART Eligibility

Under the BART rules, large sources that have previously installed pollution-control equipment required under another standard (e.g., MACT, NSPS and BACT) will be required to conduct visibility analyses. Installation of additional controls may be required to further reduce emissions of visibility impairing pollutants such as PM, PM_{10}, $PM_{2.5}$, SO_2, NOx, and possibly VOCs and ammonia. Sources built before the implementation of the Clean Air Act (CAA) which had previously been grandfathered may also have to conduct such analyses and possibly install controls, even though they have been exempt to date from any other CAA requirements.

BART eligibility is established on the basis of 3 criteria. Sources that are BART-eligible must meet all three conditions described below:

1. Contain emission units in one or more of the 26 listed source categories under the PSD rules (e.g., fossil-fuel-fired steam electric plants larger than 250 MMBtu/hr,

fossil-fuel boilers larger than 250 MMBtu/hr, petroleum refineries, coal cleaning plants, sulfur recovery plants)

2. Were in existence on August 7, 1977, but were not in operation before August 7, 1962
3. Have total potential emissions from the emission units meeting the two criteria above greater than 250 tons per year for at least one visibility-impairing pollutant

If emissions from a BART-eligible source cause or contribute to visibility impairment at any Class I area, then that source is subject to BART. Visibility modeling conducted with CALPUFF or another EPA-approved visibility model is necessary to make a definitive visibility impairment determination. Sources that do not cause or contribute to visibility impairment are exempt from BART requirements, even if they are BART-eligible.

1.2 BART Determinations

Each BART-eligible source that is not exempt must determine BART on a case-by-case basis. Even if a source was previously part of a group BART determination, individual BART determinations must be made for each source. The analysis takes into account six criteria and is analyzed using five steps. The six criteria that comprise the engineering analysis include: the availability of the control technology, existing controls at a facility, the cost of compliance, the remaining useful life of a source, the energy and non-air quality environmental impacts of the technology and finally, the visibility impacts.[2] The five steps of a BART analysis are:

Step 1 - Identify all Control Technologies
The first step in the analysis is to identify all available retrofit control technologies for each applicable emission unit.

Step 2 - Eliminate Technically Infeasible Options
In the second step, the technical feasibility of each control option identified in step one is evaluated with respect to source-specific factors. Technologies which are determined to be technically infeasible are eliminated from further consideration.

Step 3 - Evaluate Control Effectiveness
In step three, rank the remaining controls based on the control efficiency at the expected emission rate as compared to the emission rate before addition of controls for the pollutant of concern.

Step 4 - Evaluate Impacts and Document Results
The fourth step utilizes an engineering analysis to document the impacts of each remaining control technology option. The economic analysis included in this step includes a dollar per ton of pollutant removed cost for each

---

[2] 40 CFR 51 Appendix Y

technology in addition to an incremental cost analysis to illustrate the economic effectiveness of one technology in relation to the others evaluated. Step four also includes an assessment of energy impacts and other non-air quality environmental impacts.

Economic impacts were analyzed using the procedures found in the EPA Air Pollution Control Cost Manual-Sixth Edition (EPA 452/B-02-001). Vendor cost estimates for this project were used when applicable. Equipment cost estimates from the EPA Control Cost Manual or EPA's Air Compliance Advisor (ACA) Air Pollution Control Technology Evaluation Model version 7.5 were used if no vendor data were available. The source of the control equipment cost data are noted in each of the control cost analysis worksheets as found in Appendix A.

Step 5 - *Evaluate Visibility Impacts*

The fifth step requires a modeling analysis conducted with EPA-approved models such as CALPUFF. The modeling protocol[3], including receptor grid, meteorological data, and other factors used for this part of the analysis were provided by the North Dakota Department of Health. The model outputs, including 98th and 90th percentile visibility impairment days are used to establish the degree of improvement that can be reasonably attributed to each technology.

The proposed BART was selected based on the results of information obtained in Steps 4 and 5.

---

[3] *Protocol for BART-Related Visibility Modeling Analyses in North Dakota*, Final Version, November, 2005.

2.0 Coal Creek Station BART Determination

As defined by federal guidance and ND 33-25-25-01, a source "causes or contributes to visibility impairment" if the 98th percentile of any year's modeling results meets or exceeds the threshold of five-tenths of a deciview (dV) at a Class I area receptor. The pre-BART modeled emission rates for eligible sources represent the highest 24-hour average emissions from the years 2000 through 2002. Pre-BART evaluations conducted by the North Dakota Department of Health using the CALPUFF[3] visibility model identified 6 BART eligible sources, including Coal Creek Station, that cause or contribute to visibility impairment in North Dakota.

Using a streamline method for BART determination, BART eligible sources at Coal Creek Station can be divided into groups based on function, utilization and actual emissions.

2.1 BART Eligible Units

Great River Energy's (GRE) Coal Creek Station, located in Underwood, ND, contains two main units. Both are tangentially fired lignite boilers with ratings of 6015 and 6022 MMBtu/hr respectively for a combined facility output of 1,100 megawatts. The two units have identical permit emission limits, and for the purpose of this analysis, identical characteristics. The BART analysis for each pollutant has been performed on the basis of a single unit with a rating of 6019 MMBtu/hr, meaning that the total impact with respect to economics or other environmental concerns should be doubled to encompass the entire facility. PM is currently controlled with an electrostatic precipitator (ESP). Low NOx burners (LNB) are used in combination with a level of separated over-fire air (SOFA) for NOx control. Each unit currently controls SO_2 emissions with a wet scrubber, with approximately 25% of the flow bypassing the scrubber. Continued operation of the station is predicted for the long term foreseeable future, therefore the remaining useful life of the source as defined by EPA guidance [4] was not used as an element of impact assessment.

At least three sets of emission parameters must be considered to successfully determine BART. The current Title V permitted emission limits represent the maximum allowable emission rates. The baseline actual emissions represent historical emissions inventories and are used in comparison with design basis emission rates for potential retrofit technologies. This emission rate is the long term (30-day or annual average) average expectation, and is used in the economic analysis. Finally, the pre-BART screening emission rate, which represents the maximum 24-hour average emission rate as mentioned above, is used as a baseline for visibility impacts analysis. Table 2-1 describes these three data parameters for Coal Creek Station.

Table 2-1 Single Unit Emission Bases

Pollutant	Permit Limit	Baseline Actual	BART Screen
PM	0.10 lb/MMBtu 528 lb/hr	0.03 lb/MMBtu 181 lb/hr	0.04 lb/MMBtu 250 lb/hr
NOx	0.4 lb/MMBtu 5,104 lb/hr	0.22 lb/MMBtu 1,294 lb/hr	0.29 lb/MMBtu 1,772 lb/hr
SO_2	1.2 lb/MMBtu 6,336 lb/hr	0.56 lb/MMBtu 3,356 lb/hr	0.95 lb/MMBtu 5,734 lb/hr

The BART analysis, as described in Section 1.2 of this document, will be presented on a pollutant by pollutant basis for the above units with the exception of the assessment of visibility impacts for SO_2 and NOx (Step 5). The visibility analysis for SO_2 and NOx was performed using a multi pollutant approach, and can be found in Section 7.0 of this document.

2.2 Other BART Eligible Units

The remaining BART eligible emission units at Coal Creek are exempt from BART analysis because they do not cause or contribute to visibility impairment, and are included under one of the two following categories.

i. *Low Utilization Units*

Based on the hours of operation, some emission units can be classified as low emitters. Table 2-2 lists the emergency and auxiliary units at Coal Creek and their four year average actual emissions. The limited expected operations of these units makes additional controls economically infeasible, and no further BART analysis is required.

Table 2-2 Coal Creek Station Low Utilization Units

Emission Unit Identification and Description	Fuel	Maximum Heat Input	2001-2004 Average, Actual				
			Hours of Operation	NOx (tpy)	SO_2 (tpy)	PM (tpy)	PM_{10} (tpy)
EUI 3 Auxiliary Boiler No. 91	Fuel oils	172 lb/MMBtu	25	0.06	0.02	4.23E-03	2.96E-03
EUI 4 Auxiliary Boiler No. 92	Fuel oils	173 lb/MMBtu	6	0.10	0.33	1.62E-01	3.23E-02
EUI 5 Emergency Generator	Nos. 1 and 2 fuel oils	3,500 hp	95	2.89	0.27	6.91E-02	4.78E-02
EUI 6 Fire Pump Engine	Nos. 1 and 2 fuel oils	200 hp	14	0.11	0.01	6.06E-03	5.98E-03

ii. Material Handling and Fugitive Sources

All material handling units (EUI 7 through EUI 26), including coal and lime handling operations and fly ash silos, are controlled through the use of fabric filter baghouses. Baghouses are currently recognized as the best available control technology (BACT) for PM emitting sources. No further BART analysis is required for emission units employing BACT or equivalent controls.

In step three of the BART guidance, the Federal Register[4] states, "Fugitive emissions, to the extent quantifiable, must be counted." The emissions from the sources listed in Table 2-3 consist of PM only, and because sulfates and nitrates are the primary contributors to visibility impairment, PM sources will not significantly contribute to visibility impairment in Class I areas. For this reason, these sources will not be considered further.

Table 2-3 Coal Creek Station Fugitive Sources

Fugitive Source Name
FS 1 Cooling towers No. 91, No. 92, and No. 93
FS 2 Boombelt conveyor (stackout)
FS 3 Conveyor 909 (stackout)
FS 4 Scrubber building flyash silo (stackout)
FS 5 Coal pile maintenance

---

3.0 Particulate Matter (PM) BART Analysis

Historical emissions inventories show that under normal operation, Coal Creek Station units emit PM at less than one third of their permitted limit. The existing ESP provides a great deal of filterable particulate control, and pre-BART modeling showed that the PM contribution to visibility impairment for Units 1 and 2 was almost negligible in comparison to the impairment attributed to sulfates and nitrates. EPA has interpreted 'total particulate' to include condensable particulate matter (CPM) and NDDH has requested that CPM be addressed as part of the BART analysis. As such, Section 6 below provides an estimation of CPM and concludes that CPM emissions from Units 1 and 2 do not significantly impact visibility impairment and will be reduced by the proposed SO_2 BART control. As illustrated in Section 7.0, post-BART modeling of Unit 1 alone shows a 1.6 Δ-dV improvement in visibility impairment while particulate controls can provide an improvement of only 0.06 Δ-dV as described in Section 3.5.

3.1 Identify PM Control Options

Table 3-1 lists the available retrofit PM options for Coal Creek Units 1 and 2.

Table 3-1 Available PM Control Technologies

PM Control Options
ESP – Current Control
WESP
Mechanical Collector (Multiclone)
Fabric Filter/Baghouse

3.2 Eliminate Infeasible PM Control Options

3.2.1 Electrostatic Precipitator (ESP)

An electrostatic precipitator applies electric forces to separate suspended particles from the flue gas stream. In an ESP, an intense electrostatic field is maintained between high-voltage discharge electrodes, typically wires or rigid frames, and grounded collecting electrodes, typically plates. A corona discharge from the discharge electrodes ionizes the gas passing through the precipitator, and gas ions subsequently ionize the particles. The electric field drives the negatively charged particles to the collecting electrodes. Periodically, the collecting electrodes are rapped mechanically to dislodge collected particulate matter, which falls into hoppers for removal. Collector dust is removed from the precipitator for disposal or recycling.

ESP control efficiency under normal loading conditions is typically in the range of 98% to 99%+. Reduced efficiencies will occur when the inlet particle concentration is low. Outlet particle concentrations can be reduced to as much as 0.005 gr/dscf. The actual outlet concentration will depend on the size range and nature of the particles. An ESP is currently used to control particulate emissions from the Coal

Creek units, making ESP replacement or modification a technically feasible control option.

3.2.2 Wet Electrostatic Precipitator (WESP)

A wet electrostatic precipitator operates in the same manner as a dry ESP; it applies electric forces to separate suspended particles from the flue gas stream. In a WESP, an intense electrostatic field is maintained between high-voltage discharge electrodes, typically wires or rigid frames, and grounded collecting electrodes, typically plates. A corona discharge from the discharge electrodes ionizes the gas passing through the precipitator, and gas ions subsequently ionize the particles. The electric field drives the negatively charged particles to the collecting electrodes. Particle removal in a WESP is accomplished with water sprays instead of mechanical cleaning methods. As a result of using water sprays, WESP's generate wastewater which must be treated to remove suspended particles and dissolved solids.

Since WESP's use electrical forces for particle collection, the electrical properties of the particles can adversely impact WESP operation. Particles with high resistivity may not readily accept an electric charge and will be difficult to collect. Particles with high conductivity or magnetic properties will strongly adhere to the collection plates and be difficult to remove; WESP water sprays may reduce this problem. However, WESP water spray systems will require more maintenance than dry ESP's in order to keep the waster spray system working properly.

WESP control efficiency under normal loading conditions is typically in the range of 98% to 99%+. Reduced efficiencies will occur when the inlet particle concentration is low. Outlet particle concentrations can be reduced to as much as 0.005 gr/dscf. The actual outlet concentration will depend on the size range and nature of the particles. WESP technology has been demonstrated on similar coal-fired boilers, making it a technically feasible option for the Coal Creek units.

3.2.3 Mechanical Collector

Cyclone separators are designed to remove particles by inducing a vortex as the gas stream enters the chamber, causing the exhaust gas stream to flow in a spiral pattern. Centrifugal forces cause the larger particles to concentrate on the outside of the vortex and consequently slide down the outer wall and fall to the bottom of the cyclone, where they are removed. The cleaned gas flows out of the top the cyclone. There are two principal types of cyclones: tangential entry and axial entry. In tangential entry cyclones, the exhaust gas enters an opening located on the tangent at the top of the unit. In axial flow cyclones, the exhaust gases enter at the middle of one end of a cylinder and flows through vanes that cause the gas to spin. A peripheral stream removes collected particles while the cleaned gas exits at the center of the opposite end of the cylinder.

Overall cyclone control efficiencies range from 50% to 99% with higher efficiencies being achieved with large particles and low efficiencies for smaller particles (< PM_{10}). Mechanical separators are often used upstream of other PM control devices to reduce the loading on the primary control device. This improves overall control efficiency and may reduce the overall cost of the control system when the waste gas is heavily laden with particulate matter.

According to a report prepared by EPRI[5] on the current controls used for coal-fired only power plants, this technology has only been permitted for use on one similar unit which is not yet operational. Due to the fact that a multiclone has not been successfully demonstrated on a comparable unit, it is infeasible for a retrofit at Coal Creek and will not be considered further in this analysis.

3.2.4 Fabric Filter/Baghouse

A fabric filter or baghouse consists of a number of fabric bags placed in parallel inside of an enclosure. Particulate matter is collected on the surface of the bags as the gas stream passes through them. The dust cake which forms on the filter from the collected particulate can contribute significantly to increasing the collection efficiency.

Two major fabric filter types are the reverse-air fabric filter and the pulse-jet fabric filter. In a reverse-air fabric filter, the flue gas flows upward through the insides of vertical bags which open downward. The particulate matter thus collects on the insides of the bags, and the gas flow keeps the bags inflated. To clean the bags, a compartment of the fabric filter is taken off-line, and the gas flow in this compartment is reversed. This causes the bags to collapse, and collected dust to fall from the bags into hoppers. Shaking or other methods are sometimes employed to dislodge the dust from the bags. The cleaning cycle in a reverse-air fabric filter typically lasts about three minutes per compartment. Because reverse-air cleaning is gentle, reverse-air fabric filters typically require a low air-to-cloth ratio of 2 ft/min. In a pulse-jet fabric filter, dirty air flows from the outside of the bags inward, and the bags are mounted on cages to keep them from collapsing. Dust that collects on the outsides of the bags is removed by a reverse pulse of high-pressure air. This cleaning does not require isolation of the bags from the flue gas flow, and thus may be done on-line.

The main operating limitation of a baghouse is that its operating temperature is limited by the bag material. Most filter materials are limited to 200ºF – 300º F. Some materials like glass fiber or nomex may be operated at 400ºF, but are more expensive.

Baghouse control efficiency under normal loading conditions is typically in the range of 98% to 99%+. Reduced efficiencies will occur when the inlet particle concentration is low. Outlet particle concentrations can be as low as 0.005 gr/dscf; however, outlet concentrations achieved will depend on the size range and nature of the particles being filtered. Baghouses are commonly used to control particulate

---

[5] *Status and Performance of Best Available Control Technologies*, EPRI, Palo Alto, CA: 2005. 1008114 (Appendix H)

emissions from coal-fired boilers, making it a viable control option for Coal Creek's BART.

3.3 Evaluate the Effectiveness of Feasible PM Options

Based on the current degree of control being achieved on Units 1 and 2, ESP, WESP and baghouse technologies can only reasonably provide a 50% reduction in actual emissions each from existing emissions. Table 3-2 describes the expected emissions from each of the three remaining control options.

Table 3-2 Control Effectiveness of Technically Feasible PM Control Options

Control Technology	Expected Control Efficiency[6]	Controlled Emissions lb/MMBtu
Dry ESP	50%	0.015
Polishing WESP	50%	0.015
Baghouse	50%	0.015

3.4 Evaluate the Impacts of Feasible PM Options

As illustrated above in Table 3-2, the three technically feasible options provide identical degrees of control. To differentiate the options, the economic and environmental impacts of each are presented below.

3.4.1 Economic Impacts

Each technology is expected to provide controlled emissions of roughly 388 tons per year, a 50% improvement from the pre-BART historical baseline. Table 3-3 details the expected costs associated with each technology based on the EPA cost model and site specific information. Due to space considerations, the retrofit of PM controls at Coal Creek Station would require significant additional expenses that were not included in the control cost evaluation below.

Table 3-3 PM Control Cost Summary, per Unit Basis

Control Technology	Installed Capital Cost (MM$)	Annualized Operating Cost (MM$/yr)	Pollution Control Cost ($/ton)
Polishing WESP	$7.23	$1.92	$4,969
Baghouse	$37.37	$7.67	$19,864
Dry ESP	$38.51	$10.06	$26,056

Because the technologies provide identical levels of control, an incremental analysis of the costs is not beneficial. All three options require significant capital investments and large increases in expected operation and maintenance costs. The

---

[6] Control efficiency reflects improvement beyond the performance of the existing ESP.

pollution control costs indicate that additional particulate control would involve an excessive investment for only a 50% reduction in already low particulate emissions.

3.4.2 Energy and Environmental Impacts

There are no energy or non-air quality environmental impacts that would discourage the use of an ESP, WESP or baghouse as BART. All three options would require energy usage comparable to the existing ESP. The flyash systems needed to handle the solid waste generated by particulate controls are already in place at Coal Creek.

3.5 PM Visibility Impacts

Figure 3-1 illustrates the visibility improvement of particulate controls. Reducing PM emissions from the existing permit limit of 0.1 lb/MMBtu to 0.015 lb/MMBtu results in visibility improvement of only 0.06 Δ-dV; negligible in comparison to the improvement attributed to SO_2 and NOx control as illustrated in Section 7.0.

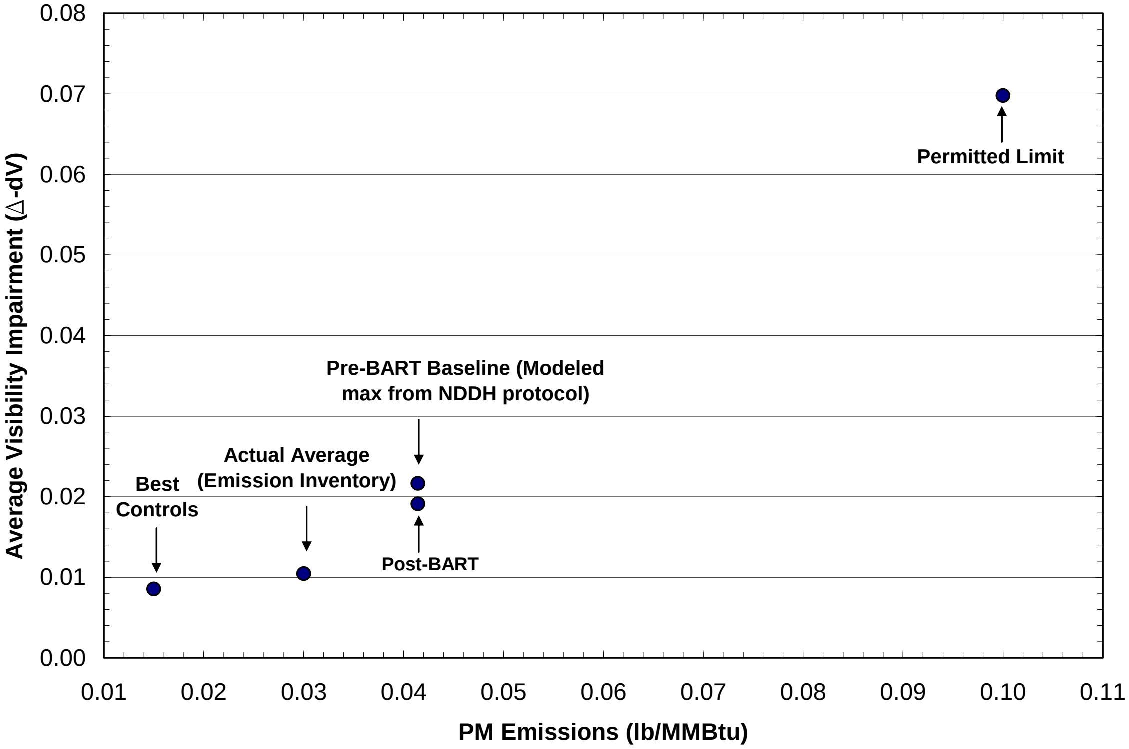

Figure 3-1 PM Visibility Contribution. Four modeled scenarios for Coal Creek Unit 1, modeled year 2002, 98th percentile, illustrate the negligible visibility impacts attributed to particulate matter. All scenarios except for "Pre-BART" were modeled with NOx and SO_2 at the presumptive levels of 0.17 lb/MMBtu and 0.15 lb/MMBtu respectively.

[2] Presumptive levels of 0.15 lb SO_2/MMBtu and 0.17 lb NOx/MMBtu were assumed for modeling purposes.
[3] Percentage attributed to PM emissions calculated from model output data (Appendix D).

3.6 Proposed BART for PM

Based on the above analysis and the visibility impacts found in Section 7.0, GRE is proposing the existing ESP and its current PM limit as BART for particulate emissions at Coal Creek's Unit 1 and Unit 2. Current actual emissions reflect a large degree of control and are below the current performance standard of 0.1 lb/MMBtu. A modification to the existing ESP or the retrofit of a baghouse is not cost effective on a dollar per ton basis[7], and additional controls will provide negligible improvement from a visibility standpoint.

---

[7] Comparisons of the cost guidelines from CAIR, NSPS, WRAP, EPA and court decisions indicates that a cost threshold of under $1500 per ton of pollutant removed is a reasonable estimate for BART (Appendix B).

4.0 Nitrogen Oxides (NOx) BART Analysis

There are three mechanisms by which NOx production occurs: thermal, fuel and prompt NOx. Fuel bound NOx is a primary concern with solid and liquid fuel combustion sources; it is formed as nitrogen compounds in the fuel are oxidized in the combustion process. The secondary mechanism of NOx production is through thermal NOx formation. This mechanism arises from the thermal dissociation of nitrogen and oxygen molecules in combustion air. The thermal oxidation reaction is as follows:

$$N_2 + O_2 \rightarrow 2NO \qquad (1)$$

Downstream of the flame, significant amounts of NO_2 can be formed when NO is mixed with air. The reaction is as follows:

$$2NO + O_2 \rightarrow 2NO_2 \qquad (2)$$

Thermal oxidation is a function of the residence time, free oxygen, and peak reaction temperature. Prompt NOx is a form of thermal NOx which is generated at the flame boundary. It is the result of reactions between nitrogen and carbon radicals generated during combustion. Only minor amounts of NOx are emitted as prompt NOx.

Coal Creek Station's NOx emissions are currently controlled to an average of 0.22 lb/MMBtu through the use of low NOx burners (LNB) with a level of separated overfire air (SOFA).

4.1 NOx Control Options

Table 4-1 lists the available retrofit NOx options for Coal Creek Units 1 and 2.

Table 4-1 Available NOx Control Technologies

NOx Control Options
Combustion Controls
• External Flue Gas Recirculation
• Overfire Air
• Low NOx Burners
Post Combustion Controls
• Selective Catalytic Reduction - High Dust - Low Dust
• Selective Non- Catalytic Reduction - NOxOUT®
• Low Temperature Oxidation - Tri-NOx® - LoTOx
• Non Selective Catalytic Reduction
• Novel Multi-pollutant Controls - Electro-Catalytic Oxidation - Pahlman Process

4.2 Eliminate Infeasible NOx Control Options

4.2.1 Combustion Controls

Various combustion controls exist for NOx reduction from combustion units. A few feasible examples of these controls include overfire air (OFA) and low NOx burners (LNB).

External Flue Gas Recirculation (FGR)

Flue gas recirculation is a flame-quenching technique that involves recirculating a portion of the flue gas from the economizer or air heater outlet and returning it to the furnace through the burner or windbox. The primary effect of FGR is to reduce the peak flame temperature through adsorption of the combustion heat by the relatively inert flue gas, and to reduce the oxygen concentration in the combustion zone. FGR reduces thermal NOx generation in high-temperature emission sources.

Additional ductwork and a blower would be required to recirculate flue gas. These elements must fit in the limited space around the burner's coal mill. The space constraints and the lowered flame temperature created by FGR make it incompatible with the existing combustion controls on Units 1 and 2. The addition of FGR could further result in reduced boiler capacity. Flue gas recirculation is therefore a technically infeasible control option and will not be considered further.

Overfire Air (OFA)

Overfire air diverts a portion of the total combustion air from the burners and injects it through separate air ports above the top level of burners. OFA is the typical NOx control technology used in lignite-fired boilers and is primarily geared to thermal NOx reductions. Staging of the combustion air creates an initial fuel-rich combustion zone for a cooler fuel-rich combustion zone. This reduces the production of thermal NOx by lowering combustion temperature and limiting the availability of oxygen in the combustion zone where NOx is most likely to be formed.

OFA technology is currently used to control NOx emissions on both Coal Creek units. Based on engineering analyses[8] performed on Unit 1, additional levels of separated overfire air (SOFA) are a technically feasible option for further NOx reduction.

Low NOx Burners (LNB)

LNB technology utilizes advanced burner design to reduce NOx formation through the restriction of oxygen, flame temperature, and/or residence time. LNB is a staged combustion process that is designed to split fuel combustion into two zones. In the

---

[8] *TLN3 System Assessment and Recommendations for Lower NOx Operation*. Foster Wheeler North America Corporation. September 9, 2005 (Appendix F).

primary zone, NOx formation is limited by either one of two methods. Under staged air rich (high fuel) condition, low oxygen levels limit flame temperatures resulting in less NOx formation. The primary zone is then followed by a secondary zone in which the incomplete combustion products formed in the primary zone act as reducing agents. Alternatively, under staged fuel lean (low fuel) conditions, excess air will reduce flame temperature to reduce NOx formation. In the secondary zone, combustion products formed in the primary zone act to lower the local oxygen concentration, resulting in a decrease in NOx formation. Low NOx burners typically achieve NOx emission reductions of 25% - 50%.

LNB is currently used to control NOx emissions from both Coal Creek units. In combination with SOFA, LNB is a technically feasible option to further reduce emissions. Based on the currently achieved emission rates, reduction in the range of 25%-30% would be expected.

4.2.2 Post Combustion Controls

NOx can be reduced to molecular nitrogen (N_2) in add-on systems located downstream of the furnace area of the combustion process. The two main techniques in commercial service include the selective non-catalytic reduction (SNCR) process and the selective catalytic reduction (SCR) process. There are a number of different process systems in each of these categories of control techniques.

In addition to these treatment systems, there are a large number of other processes being developed and tested on the market. These approaches involve innovative techniques of chemically reducing, absorbing, or adsorbing NOx downstream of the combustion chamber. One example of these alternatives is nonselective catalytic reduction (NSCR).

Selective Catalytic Reduction (SCR)

Selective catalytic reduction is a post combustion NOx control technology in which ammonia (NH_3) is injected into the flue gas stream in the presence of a catalyst. SCR control efficiency is typically 70% - 90%. NOx is removed through the following chemical reaction:

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_20 \qquad (1)$$

$$2NO_2 + 4NH_3 + O_2 \rightarrow 3N_2 + 6H_20 \qquad (2)$$

The catalyst bed lowers the activation energy required for NOx decomposition. The catalyst contains an active phase of such as vanadium pentoxide on a carrier such as titanium dioxide, and these are used for their ability to lower the activation energy required for NOx decomposition. SCR requires an optimum temperature range of 650-800°F.

High-dust SCR (upstream of particulate control) applications typically required soot blowers for catalyst cleaning. Firing lignite coal results in a stream heavily laden with particulate matter containing catalyst poisons such as sodium. The catalyst plugging observed at the lignite-fired boiler at Coyote Station [9] was caused by materials which could not be cleaned by a soot blower system. Due to the likelihood of catalyst surface plugging caused by high sodium concentrations, a high-dust SCR is technically infeasible on both Units 1 and 2. A low-dust SCR (downstream of particulate control), would require reheat to bring the stream temperature back to the effective range after it is cooled for particulate removal, but is a technically feasible option for NOx reduction. Based on current NOx emissions, an SCR could provide additional reduction in the range of 70%-80%.

Selective Non-Catalytic Reduction (SNCR)

In the SNCR process, urea or ammonia-based chemicals are injected into the flue gas stream to convert NO to molecular nitrogen, N_2, and water. SNCR control efficiency is typically 25% - 50%. Without the participation of a catalyst, the reaction requires a high temperature range to obtain activation energy. The relevant reactions are as follows:

$$NO + NH_3 + \frac{1}{4}O_2 \rightarrow N_2 + 3/2 H_2O \qquad (1)$$

$$NH_3 + \frac{1}{4}O_2 \rightarrow NO + 3/2 H_2O \qquad (2)$$

At temperature ranges of 1470 to 1830°F reaction (1) dominates. At temperatures above 2000°F, reaction (2) will dominate.

NOxOUT®

NOxOUT® is a commercially available urea based SNCR process for the reduction of NOx from stationary sources. The process requires injection of stabilized urea liquid into the combustion flue gas in a location where the temperature range is 1,600 - 2,000 °F.

SNCR is a technically feasible NOx control option for Units 1 and 2. Based on the current level of NOx control, an emissions reduction of approximately 50% would be expected.

---

[9] *SCR catalyst Performance in Flue Gases Derived from Subbituminous and Lignite Coals.* Steven A. Benson; Jason D. Laumb; Charlene R. Crocker; John H. Pavlish. 7/1/2004 (Appendix G)

Low Temperature Oxidation (LTO)

The LTO system utilizes an oxidizing agent such as ozone to oxidize various pollutants including NOx. In the system, the NOx in the flue gas is oxidized to form nitrogen pentoxide (equations 1, 2, and 3). The nitrogen pentoxide forms nitric acid vapor as it contacts the water vapor in the flue gas (4). Then the nitric acid vapor is absorbed as dilute nitric acid and is neutralized by the sodium hydroxide or lime in the scrubbing solution forming sodium nitrate (5) or calcium nitrate. The nitrates are removed from the scrubbing system and discharged to an appropriate water treatment system. Commercially available LTO systems include Tri-NOx® and LoTOx.

$$NO + O_3 \rightarrow NO_2 + O_2 \qquad (1)$$

$$NO_2 + O_3 \rightarrow NO_3 + O_2 \qquad (2)$$

$$NO_3 + NO2 \rightarrow N_2O_5 \qquad (3)$$

$$N_2O_5 + H_2O \rightarrow 2HNO_3 \qquad (4)$$

$$HNO_3 + NaOH \rightarrow NaNO_3 + H_2O \qquad (5)$$

LTO systems represent a technically feasible control option for Units 1 and 2, with an expected control efficiency of 80%-90%.

Tri-NOx®

This technology uses an oxidizing agent such as ozone or sodium chlorite to oxidize NO to NO_2 in a primary scrubbing stage. Then NO_2 is removed through caustic scrubbing in a secondary stage. The reactions are as follows:

$$O_3 + NO \rightarrow O_2 + NO_2 \qquad (1)$$

$$2NaOH + 2NO_2 + \tfrac{1}{2} O_2 \rightarrow 2NaNO_3 + H_2O \qquad (2)$$

Tri-NOx® is a commercially available multi-staged wet scrubbing process in industrial use. Several process columns, each assigned a separate processing stage, are involved. In the first stage, the incoming material is quenched to reduce its temperature. The second, oxidizing stage, converts NO to NO_2. Subsequent stages reduce NO_2 to nitrogen gas, while the oxygen becomes part of a soluble salt. A major advantage of the Tri-NOx® process is that concurrent scrubbing of SO_2 can be achieved. Tri-NOx is typically applied at small to medium sized sources with high NOx concentration in the exhaust gas (1,000 ppm NOx). Under these conditions control efficiencies of 99% can be achieved.

LoTOx

BOC Gases' Lo-TOx is an example of a commercially available version of an LTO system. LoTOx technology uses ozone to oxidize NO to NO_2 and NO_2 to N_2O_5 in a wet scrubber (absorber). This can be done in the same scrubber used for particulate or sulfur dioxide removal. The N_2O_5 is converted to HNO_3 in a scrubber, and is removed with lime or caustic. Ozone for LoTOx is generated on site with an electrically powered ozone generator. The ozone generation rate is controlled to match the amount needed for NOx control. Ozone is generated from pure oxygen. In order for LoTOx to be economically feasible, a source of low cost oxygen must be available from a pipeline or on site generation. The normal NOx control efficiency range for Lo-TOx is 80% to 95%.

Non-Selective Catalytic Reduction (NSCR)

A non-selective catalytic reduction (NSCR) system is a post combustion add-on exhaust gas treatment system. NSCR is often referred to as a three-way conversion catalyst because it simultaneously reduces NOx, unburdened hydrocarbons (UBH), and CO. Typically, NSCR can achieve NOx emission reductions of 90 percent. In order to operate properly, the combustion process must be near stoichiometric conditions. Under this condition, in the presence of a catalyst, NOx is reduced by CO, resulting in nitrogen (N_2) and carbon dioxide (CO_2). The most important reactions for NOx removal are:

$$2CO + 2NO \rightarrow 2CO_2 + N_2 \qquad (1)$$

$$[UBH] + NO \rightarrow N2 + CO_2 + H_2O \quad (2)$$

NSCR catalyst has been applied primarily in natural gas combustion applications. This is due in large part to the catalyst being very sensitive to poisoning, making it infeasible to apply this technology to the lignite-fired boilers at Coal Creek.

Novel Multi-Pollutant Controls

Electro-Catalytic Oxidation (ECO)

ECO technology utilizes a reactor in which SO_2 and NOx and mercury are oxidized to nitrogen dioxide (NO_2), sulfuric acid and mercuric oxide respectively using non-thermal plasma. The NO_2 and remaining SO_2 are then removed and concentrated in a scrubber with ammonia injection. This technology is intended for use on low-dust streams and must be located downstream of existing particulate controls.

Pahlman Process

The Pahlman process involves the treatment of flue gas with a sorbent containing magnesium oxide. Using the solubility properties of magnesium at different ionization states, SO_2 and NOx are captured and dissolved in a spray dry system. The sorbent is then captured at a downstream baghouse and can be regenerated.

Both ECO and the Pahlman process technologies are still in the testing and development phase. They are therefore not currently considered commercially available and are not considered further.

4.3 Evaluate the Effectiveness of Feasible NOx Options

Based on the current degree of control being achieved on Units 1 and 2, Table 4-2 describes the expected emissions from each of the remaining feasible control options.

Table 4-2 Control Effectiveness of Technically Feasible NOx Control Options

Control Technology	Expected Control Efficiency	Controlled Emissions lb/MMBtu	Controlled Emissions ton/year
LTO	90%	0.022	556
SCR with Reheat	80%	0.043	1,111
SNCR	50%	0.108	2,779
Foster Wheeler SOFA/LNB Option 1	30%	0.15	3,877
Foster Wheeler SOFA/LNB Option 2	21%	0.17	4,394

4.4 Evaluate the Impacts of Feasible NOx Options

As illustrated above in Table 4-2, the five technically feasible options each provide a different level of control. The economic and environmental impacts are presented below.

4.4.1 Economic Impacts

Table 4-3 details the expected costs associated with each technology based on pre-BART historical baseline emissions, the EPA cost model and site specific information. As required by ASTM International designation C618-05, the presence of ammonia in the ash caused by the use of SNCR or SCR would make it ineligible for beneficial use. The cost for SNCR and SCR technologies includes the predicted ash sales revenue losses. The results of the engineering analysis performed by Foster Wheel presented two options with different levels of control for SOFA/LNB control. The detailed cost analysis for each technology is provided in Appendix A.

Table 4-3 NOx Control Cost Summary, per Unit Basis

Control Technology	Installed Capital Cost (MM$)	Annualized Operating Cost (MM$/yr)	Pollution Control Cost ($/ton)	Incremental Control Cost ($/ton)
LTO	$44.33	$58.07	$11,610	$31,799
SCR with Reheat	$70.36	$40.40	$9,087	$19,862
SNCR	$6.16	$7.28	$2,621	$6,027
Foster Wheeler SOFA/LNB Option 1[*]	$5.26	$0.66	$395	$868
Foster Wheeler SOFA/LNB Option 2	$2.63	$0.34	$291	NA-Base

The incremental control cost listed in Table 4-3 represents the incremental value of each technology as compared to the technology with the next highest level of control. In this analysis, dominant controls are located on the least cost envelope, as illustrated graphically in Figure 4-1.

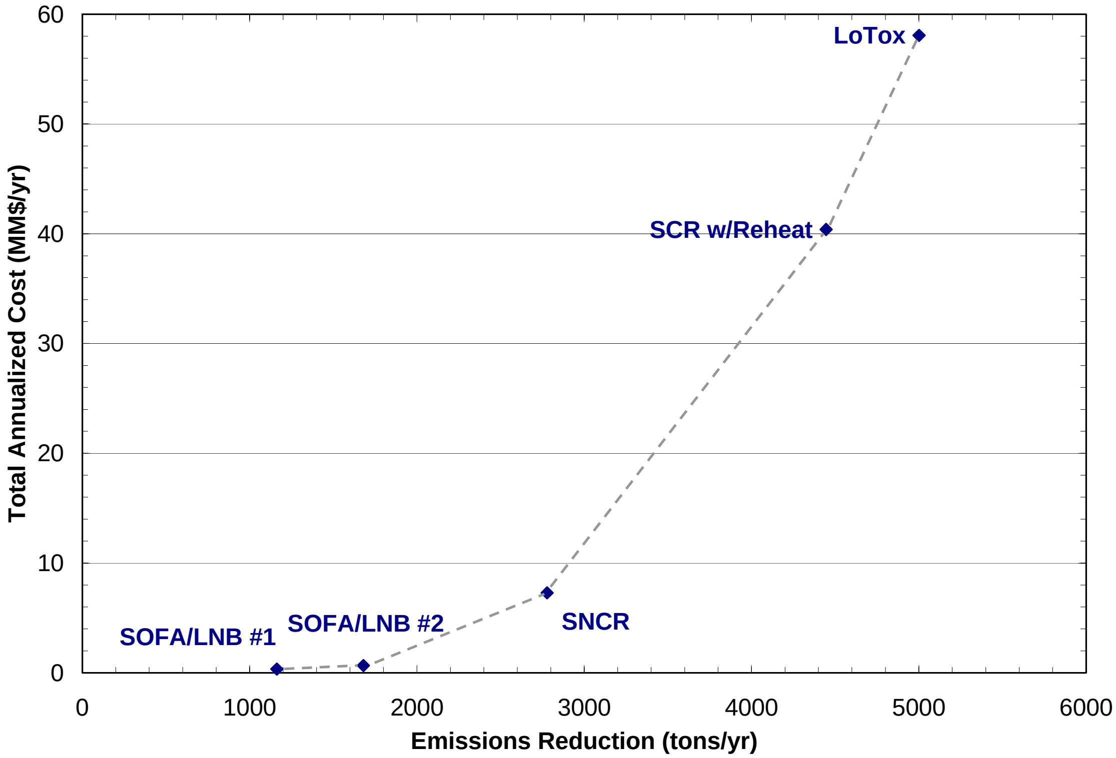

Figure 4-1 Incremental NOx Analysis The remaining feasible technologies are illustrated on the basis of annualized emission reduction in tons per year and total annualized cost in millions of dollars per year.

Based on the BART final rule and other similar regulatory programs like CAIR, cost-effective NOx controls are in the range of $1,300 to $1,800 per ton removed as

---

[*] Installation costs revised based on an updated Foster Wheeler proposal. The updated proposal is included in Appendix K.

illustrated in Appendix B. Accordingly, SNCR, SCR with reheat, and LTO should all be precluded from BART consideration on the basis of cost effectiveness. All three technologies represent significant capital investments that are not justified on a cost per ton or incremental cost basis.

4.4.2 Energy and Environmental Impacts

The energy and non-air quality environmental impacts for SOFA/LNB options, SNCR, SCR, and LTO are described in Table 4-4.

Table 4-4 NOx Control Technology Impacts Assessment

Control Option	Energy Impacts	Other Impacts
LTO	- The blower, circulation pump and wastewater discharge require additional electrical usage.	- Additional waste water generated by LTO technologies requires biotreatment.
SCR with Reheat	- The reheat required to make SCR technically feasible will result in high energy use and associated costs.	- Reheat would require additional natural gas use which is not currently available and would require installation of a larger natural gas line. - Ammonia slip concerns.
SNCR	- Minimal additional energy impacts.	- Ash would no longer be eligible for beneficial use options. Over $27 million has already been invested in the infrastructure for ash sales. Ash must be landfilled if beneficial use options are not available. - Ammonia slip concerns.
SOFA/LNB	- Minimal energy impacts.	- Potential for tube wastage.

4.5 Proposed BART for NOx

Based on the above analysis and the visibility impacts found in Section 7.0, GRE is proposing an additional level of separated overfire air (SOFA) as BART for NOx emissions at Coal Creek's Unit 1 and Unit 2. A comparison of the visibility modeling results for the two SOFA/LNB control options shows little difference in visibility improvement between the two. Regardless of this fact, the proposed BART will be the more stringent of the two options with a design emission rate of 0.15 lb/MMBtu. While this design emission rate may be achieved on a long term of annual average basis, a shorter term limit of 0.17 lb/MMBtu is required to account for potential variability due to operational conditions.

With tangential firing, the lateral impingement of the horizontally adjacent fuel and air streams produces a furnace vortex with a single flame envelope. The entire furnace acts as the burner; therefore, precise proportioning of fuel and air at each of the individual fuel and air admission points is not required. Locally fuel-rich or air-rich streams are mixed in passing through the furnace, resulting in complete combustion of the fuel. The furnace vortex produces a large amount of internal recirculation of bulk gas, which, couples with the longer residence time for burning, provides a combustion system inherently low in NOx production and virtually eliminates hydrocarbon and CO emissions.

Further reductions of NOx emissions are achieved through the use of close coupled and separated overfire air. Close coupled overfire air compartments are provided as extensions of the windboxes and the separated overfire air compartments are above the windboxes. Overfire reduces NOx formation by reducing the peak and bulk flame temperatures by extending the combustion zone and time necessary for fuel burnout. The close coupled overfire air is directed into the furnace through two elevations of separately tiled windbox registers and the separated overfire air is directed into the furnace through two additional elevations of registers that are separated above the main windbox. Optimum damper and tilt positions are established by field testing.

Current actual emissions reflect a large degree of control and are below the current permit limit of 5,104 lb/hr (0.85 lb/MMBtu) per unit on a 12-month rolling average. The additional level of SOFA/OFA presented in Foster Wheeler's Option 2 represents a cost effective method of further controlling NOx emissions. As stated above, the installed SOFA will be designed to meet an emission rate of 0.15 lb/MMBtu, but a design basis cannot be directly translated into an operational limit. With consideration for operational variability and potential emission spikes, the proposed BART emissions limit for both Unit 1 and Unit 2 is 0.17 lb/MMBtu on a 30-day rolling average, which corresponds to the presumptive limit established by EPA. The revised Foster Wheeler proposal included in Appendix J states an emission guarantee of 0.17 lb/MMBtu. An optimization study will be performed after the implementation of the full scale coal dryers and the installation of the upgraded NOx control system to determine actual performance levels, but at this time, an emission limit lower than the vendor guarantee will not be proposed.

5.0 Sulfur Dioxide (SO_2) BART Analysis

5.1 SO_2 Control Options

Coal Creek Units 1 and 2 are currently controlled using wet flue gas desulfurization scrubbers that operate at a dry stack condition with approximately 27% of the flue gas bypassing the scrubber. The remaining 73% of the gas from each unit is routed through an existing four-module scrubber with a removal efficiency of approximately 94%. The overall control efficiency for each unit is approximately 68%. Based on the current removal efficiency, only systems that can achieve greater than 68% overall control efficiency are evaluated. Table 5-1 lists the available SO_2 control options for Coal Creek Units 1 and 2.

Table 5-1 Available SO_2 Control Technologies

SO_2 Control Options
Pre-Combustion Controls
Flue Gas Desulfurization
Dry Sorbent Injection
Spray Dry Absorber
Wet Lime/Limestone Absorber
Novel Control: TurboSorp®

5.2 Eliminate Infeasible SO_2 Control Options

The pollutant SO_2 is formed when sulfur present in fuels is oxidized by either process conditions or by combustion. Pre-combustion controls utilize methods for improving the physical or chemical properties of the fuel before it is combusted. Existing methods for post-combustion SO_2 control can be categorized as either dry or wet flue gas desulfurization.

5.2.1 Pre-Combustion Controls

Coal impurities can be reduced through pretreatment options such as coal washing and coal drying. No information could be located in support of the effectiveness of washing lignite coal, but coal drying was explored and is a viable option. In this process, raw coal is crushed and screened to remove rocks and other impurities. Subsequently, the crushed coal is thermally processed to remove excess moisture. Coal drying is a technically feasible control option, and a full scale DOE project is beginning construction in the spring of 2007 at Coal Creek Station.

The lignite coal supplied to Coal Creek Station by the Falkirk Mining Company typically has a higher heating value of 6200 Btu/lb and a moisture content of 38%. A 75 ton/hour lignite drying system with a segregator for beneficiation of the lignite was designed and constructed in 2005. The drying system utilizes plant waste heat to process the coal at under 200ºF resulting in water evaporation with no additional volatiles production. The prototype dryer was built and tested to determine the final design for the full scale lignite coal drying demonstration project, beginning construction the spring of 2007. The major benefit of drying lignite is a decrease in the lignite moisture content which results in a higher boiler efficiency and a reduction in flue gas volume of up to 30%. Other benefits include reduced SO_2, NOx, CO_2 and Hg emissions (roughly 5%), reduced station power consumption by about 18%, and reduced water used by about 2.5%.

5.2.2 Flue Gas Desulfurization (FGD)

The FGD systems commonly used to control SO_2 emissions can be classified as either wet or dry systems. Both systems rely on creating turbulence in the gas stream to increase contact with the absorbing medium. Wet systems are commonly capable of achieving higher removal efficiencies than dry systems because it is easier to mix a gas with a liquid than a solid. FGD requires the use of an alkali powder of slurry, and lime (or limestone) is the most widely used compound for acid gas absorption. Sodium based reagents are also available, and while they provide better SO_2 solubility, they are significantly more expensive.

Wet FGD systems may discard all of the waste by-product streams or regenerate and reuse them. Wet systems generally require more extensive networks of pumps and piping than dry systems to recirculate, collect and treat the scrubbing liquid. As implied by the name, dry scrubbers require less water than wet systems but also require higher temperatures to ensure that all moisture has been evaporated before leaving the scrubber. There are many available FGD systems including wet scrubbing, spray dryer absorption, and dry sorbent injection.

Dry Sorbent Injection (DSI)

Dry sorbent injection involves the injection of a lime or limestone powder into the exhaust gas stream. The stream is then passed through a baghouse to remove the sorbent and entrained SO_2. The process was developed as a lower cost FGD option because the mixing occurs directly in the exhaust gas stream instead of in a separate tower. Depending on the residence time and gas stream temperature, sorbent injection control efficiency is typically between 50% and 70%. It should be noted that the maximum expected removal efficiency of this technology (70%) is very close to the existing scrubber removal of 68% for both units. While dry sorbent injection is a technically feasible retrofit option, it will provide only minimal improvement over the existing removal efficiency.

Spray Dry Absorption

Spray dry absorption is a dry scrubbing system that sprays a fine mist of lime slurry into an absorption tower where the SO_2 is absorbed by the droplets. The absorption of the SO_2 leads to the formation of calcium sulfite ($CaSO_3 \bullet 2H_2O$) and calcium sulfate ($CaSO_4$) within the droplets as illustrated by equations 1 and 2 below.

$$SO_2 + CaO + 1/2\ H_2O \rightarrow CaSO_3 \bullet 1/2\ H_2O \qquad (1)$$

$$CaSO_3 + ½O_2 + 2H_2O \rightarrow CaSO_4 \bullet 2H_2O \qquad (2)$$

The liquid-to-gas ratio is such that the heat from the exhaust gas causes the water to evaporate before the droplets reach the bottom of the tower. This leads to the formation of a dry powder which is carried out with the gas and collected with a fabric filter. Spray dryer absorption control efficiency is typically in the 70% to 90% range. A spray dry scrubber is a technically feasible retrofit control option.

Wet Lime/Limestone Scrubbing

Wet lime/limestone scrubbing involves scrubbing the exhaust gas stream with a slurry comprised of lime (CaO) or limestone ($CaCO_3$) in suspension. The process takes place in a wet scrubbing tower located downstream of a PM control device to prevent the plugging of spray nozzles and other problems caused by the presence of particulates in the scrubber. Similarly to the chemistry illustrated above for spray dry absorption, the SO_2 in the gas stream reacts with the lime or limestone slurry to form calcium sulfite ($CaSO_3 \cdot 2H_2O$) and calcium sulfate ($CaSO_4$). Wet lime scrubbing is capable of achieving 98+% control. Wet scrubbing is currently used on approximately 73% of exhaust gas at both Coal Creek units. A new replacement wet scrubber is a technically feasible retrofit option. Modifications to the existing scrubbers in order to improve its capture and/or control efficiency are also technically feasible. Both options, entire replacement of and upgrades to the existing scrubbers, are considered separately in this evaluation.

Novel Multi-Pollutant Control: TurboSorp®

TurboSorp® is a dry FGD technology in which the flue gas is pushed through an open chamber reactor. The flue gas enters the reactor through a nozzle with venturi geometry for optimum distribution of gas flow. The fluidized bed of particles circulates above the venturi inlet inside the vessel and water is injected to maintain outlet temperatures in the range of 45ºF to 55ºF above saturation temperature. Recycled particles from the baghouse along with hydrated lime are injected at this location to control outlet SO_2. The stream is then passed through a fabric filter or ESP to remove large particulate and finally exits through the stack.

This technology has been considered for Coal Creek as a potential method for treating the current scrubber bypass streams from Units 1 and 2. TurboSorp® could provide the benefits of a dry stack and additional particulate control. A booster fan would be required at the outlet to control the gas flow rate, and the system would also require installation of a hydrator or pug mill to facilitate the lime hydration process. Test plants are currently operating in Europe, but TurboSorp® has not been commercially demonstrated in the United States. Though not considered technically feasible due to its lack of commercial availability at this time, TurboSorp® may be considered further in future control technology assessments.

Additional novel controls including ECO and the Pahlman process for NOx and SO_2 are included in Section 4.2.2.

5.3 Evaluate the Effectiveness of Feasible SO_2 Options

Based on the degree of SO_2 emissions control currently achieved at Units 1 and 2, Table 5-2 describes the expected emissions from each of the remaining feasible control options.

Table 5-2 Control Effectiveness of Technically Feasible SO_2 Control Options

Control Technology	Expected Control Efficiency	Controlled Emissions lb/MMBtu	Controlled Emissions ton/year
Scrubber Replacement[10]	95%	0.106	2,735.7
Scrubber Modification + Coal Drying	94%	0.128	3,310.2
Spray Dry Baghouse	90.0%	0.212	5,471.4
Existing Scrubber + Coal Dryer	83.1%	0.358	9,263.1
DSI Baghouse	70.0%	0.635	16,414.3

With respect to scrubber modifications, a variety of upgrades have been evaluated for the Units 1 and 2 scrubbers. They range in efficiency from 93.9% to 96.0% as illustrated in Appendix I, and include options that will meet the presumptive SO_2 limit of 0.15 lb/MMBtu. Many of the technically feasible options require the replacement or upgrade of the stacks due to the demands of wet stack conditions. A wet stack is a technically feasible option as illustrated in Appendix E, and the evaluated modifications represent both wet and dry stack options. In addition to being evaluated individually, coal drying was incorporated into some of the evaluated scrubber modification options.Full scale coal drying ~~is~~ will be implemented (see Appendix K for detailed analysis report), and as a results, the volume of the flue gas will be significantly reduced, thus requiring fewer modifications to accommodate the currently bypassed gas flow. Appendix I includes information on scrubber modification options provided by URS Corporation. Other modification options include:

- Replacement/addition of spray headers
- Replacement/addition of nozzles
- Installation of trays or liquid distribution rings (LDRs)
- Addition of a fifth scrubber module
- Expansion of the existing absorbers

Treatment of the existing bypass with a separate control was also considered. All of the modifications will require new mist eliminators in the absorbers and all wet scrubbing options will necessitate stack modifications. These options and the applicable combinations have been evaluated individually, and the economic details are included in

---

[10] *Survey of State-of-the-Art Emissions Control Systems* (1010762) published in 2006 by EPRI states that new absorbers can achieve control efficiencies of 98+%. However, given the type of coal and necessary retrofit the existing plant, 95% control could be expected from a new scrubber at Coal Creek. (See 2/23/07 letter for additional justification).

Appendix A. For the sake of clarity, the range of control efficiencies and impacts of the eight evaluated modifications are referred to under the classification of "scrubber modifications."

A number of operational variables can affect the performance of SO_2 control technologies. Gas velocities, duct and stack geometry all play a role in determining deposition in the stack and scrubber modules, resulting in varied removal efficiencies. As a result of existing plant configurations, retrofit scrubber modifications may not achieve the optimum velocities and geometries. Therefore, the control efficiencies and emission rates presented above are design rates only and represent best case operational expectations. Coal sulfur content[11], equipment reliability and maintenance will also play a large part in the control of actual emissions.

Due to the fact that Coal Creek Station is a mine-mouth plant, there are limited opportunities for coal blending. SO_2 emissions will depend heavily on mine operations which introduces a high degree of variability. While coal sulfur content may seem to vary little over short periods of time, a change in mining area could produce a drastic and immediate change. On an annual basis, the average may remain low if only one or two months out of twelve have a high sulfur content, but 30-day rolling average limits must account for the potential of a high sulfur content on the short term basis. This variability must be considered when determining an appropriate emission limit. The technology evaluations presented in Section 5.4 are based on recent emission inventories and design removal efficiencies. When compared to more historical or future predicted coal sulfur contents for Falkirk Mine, the recent sulfur content has been in the mid range. Any future SO_2 emission limit needs to account for the higher end of the expected sulfur content, and realistic operational conditions that can result in removal efficiencies lower than the design basis.

5.4 Evaluate the Impacts of Feasible SO_2 Options

The economic and environmental/non-air quality impacts of the remaining controls are illustrated below.

5.4.1 Economic Impacts

Table 5-3 details the expected costs associated with each technology based on pre-BART historical baseline emissions, the EPA cost model and site specific information. The detailed cost analysis for each technology is provided in Appendix A[12].

---

[11] See section 6.2 and Appendix C for further coal sulfur content and emission rate documentation.

[12] Cost estimates do not represent detailed engineering estimates. Based on market prices and site specific conditions, cost can vary by 20+%.

Table 5-3 SO_2 Control Cost Summary, per Unit Basis

Control Technology	Installed Capital Cost (MM$)	Annualized Operating Cost (MM$/yr)	Pollution Control Cost ($/ton)	Incremental Control Cost ($/ton)
Scrubber Replacement	$204.72	$30.76	$2,114	$33,498
Scrubber Modification + Coal Drying*	$76.22	$11.52	$824	$281
Spray Dry Baghouse	$181.18	$29.22	$2,472	Inferior
Existing Scrubber + Coal Dryer	$71.20	$9.84	$1,226	NA-Base
DSI Baghouse	$48.75	$12.52	$14,313	Inferior

The incremental control costs listed in Table 5-3 represents the incremental value of each technology as compared to the technology with the next highest level of control. Control technologies listed as "inferior" do not represent cost effective options in comparison to the dominant control technologies on an incremental dollar per ton basis. In this analysis, dominant controls are located on the least cost envelope, as illustrated graphically in Figure 5-1.

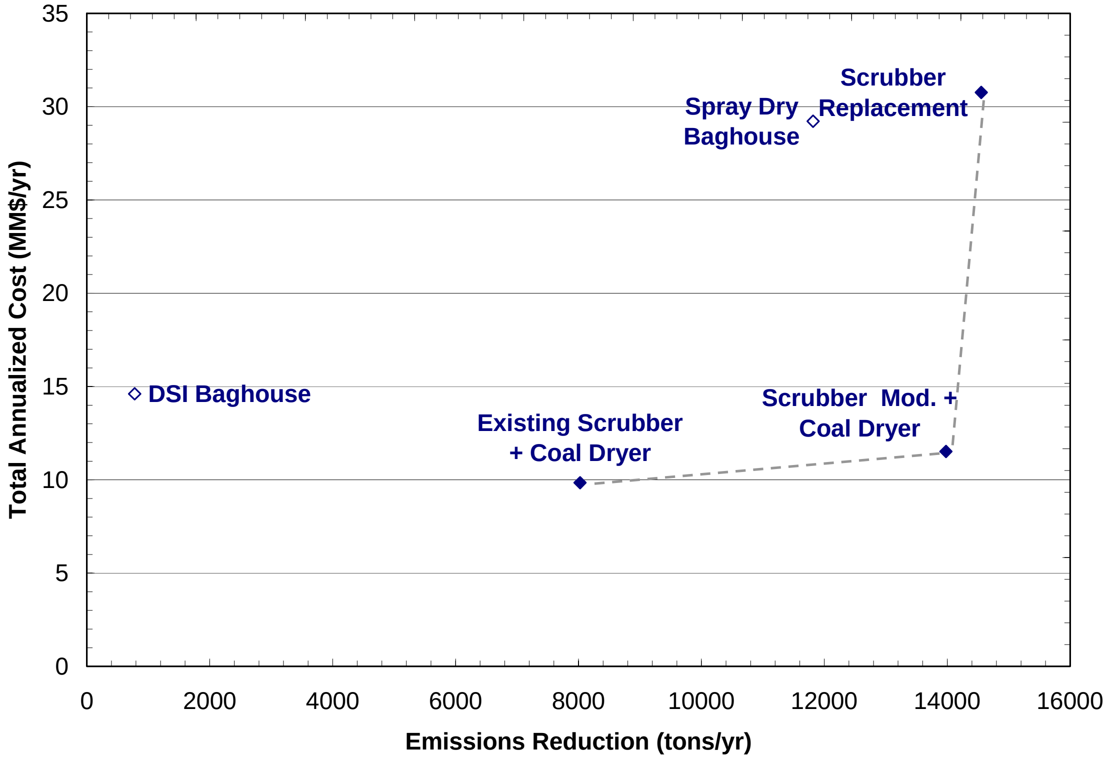

Figure 5-1 Incremental SO_2 Analysis The remaining feasible technologies are illustrated on the basis of emission reduction in tons per year and total cost in millions of dollars per year. Dominant and inferior controls are represented by darkened or empty diamonds respectively. The average cost and emission reduction are show for scrubber modifications.

---

* Cost of options involving coal drying revised to reflect the installed capital and annualized O&M costs of full scale dryer operation.

Based on the BART final rule and other similar regulatory programs like CAIR, cost-effective SO_2 controls are in the range of $1,000 to $1,300 per ton removed as illustrated in Appendix B. Accordingly, the retrofit options of DSI baghouse, spray dry baghouse, and scrubber replacement should be precluded from BART consideration on the basis of both average cost effectiveness and incremental cost effectiveness. All three technologies represent significant capital investments that are not justified on a cost per ton or incremental cost basis.

5.4.2 Energy and Environmental Impacts

The energy and non-air quality impacts for scrubber replacement and modification, dry scrubbing options, and coal drying are presented in Table 5-4.

Table 5-4 SO_2 Control Technology Impacts Analysis

Control Option	Energy Impacts	Other Impacts
Scrubber Replacement	- Additional blower capacity requires increased energy use.	- Extensive process downtime for installation, requiring replacement power. - Stack modifications required. - Additional water consumption and wastewater generation.
Scrubber Modification with Coal Drying	- Minimal energy impacts.	- Stack modifications required. - Outage/replacement power required for installation. - Additional water consumption and wastewater generation.
Dry Scrubbing (Spray Dry/DSI Baghouse)	- Additional blower capacity requires increased energy use.	- Extensive process downtime for installation, requiring replacement power[13].

5.5 Proposed BART for SO_2

Based on the above analysis and the visibility impacts found in Section 7.0**,** GRE is proposing to eliminate the current bypass and scrub 100% of the flue gas stream, with the potential to maintain wet stack operation. This scenario results in a proposed BART emission limit of 0.15 lb/MMBtu station wide cap per unit on a 30-day rolling average period. Compliance with the proposed BART limit will be demonstrated using the existing continuous emissions monitoring system (CEMS).

The proposed emission limit is intended to account for a short term range of operational conditions and coal sulfur content. On an annual basis, it is likely that both Units will operate below the 0.15 lb/MMBtu limit. The visibility modeling results support the proposed BART on dollar per deciview and total deciview improvement bases. Section 7.3 shows that aside from the addition of a new scrubber which has been ruled out by the factors described in Section 5.4, the proposed BART is the most cost effective

---

[13] Replacement power is only required for fully retrofit dry controls designed to handle the full flue gas flow. Control options designed to treat only the current scrubber bypass (including TurboSorp) will not have this requirement.

option and provides a large degree of visibility improvement. For the year 2002, the 98th percentile total visibility improvement for the two stations combined will be over 1.8 Δ-dV compared to baseline.

It must be noted that while modifications to the existing scrubber modules can achieve control efficiencies near what is expected from a newly designed scrubber, a number of operational differences still exist. New scrubbers have a great deal of redundancy and flexibility built into their design. For example, multiple levels of spray headers allow operators to put individual spray headers into service or take them out of service as conditions dictate. In contrast, the Coal Creek Station scrubbers have fewer redundancies and are therefore more likely to experience emission spikes caused by operational configuration.

Coal Creek Station requires room for operational changes that may occur between outages. The scrubbers are designed to minimize operational upsets, however all control technologies, including scrubbers, can experience operational degradation between outage opportunities. Examples such as scaling of the mist eliminators, nozzle breakage, and plugging or scaling of spray pumps and lime slurry equipment can all result in a removal efficiency less than the design removal. Additionally, Coal Creek scrubber modification design will be limited by space constraints of the existing module and building, namely, no footprint exists for additional spray pumps. These factors indicate that while the existing modules will be upgraded, their design and resulting operation will not be the same as would typically be expected from a new scrubber. This implies that a design emission rate cannot be directly translated into an operational emission limit.

Based on the results of the coal dryer study (Appendix J), the final SO_2 control strategy for Coal Creek will include coal drying in addition to the installation of trays or new LDRs and high flow MEs. GRE's goal is to meet or operate below BART presumptive levels while maintaining the highest degree of operational flexibility. In an effort to utilize the best available technology at the time of purchase, GRE will continue to evaluate which technology will provide the requisite removal efficiencies to meet the BART presumptive levels and provide GRE with greatest operational flexibility. Coal drying will provide the benefit of reducing the coal moisture content by about 8%. A decreased flue gas volume coupled with the separation of the heavier material in the 1st stage of the drying process has provided evidence of additional pollutant reductions. (CO_2, NOx, Hg) These numbers have been extrapolated from the prototype experiment but the full scale demonstration project will provide the final refined values.

6.0 Condensable Particulate Matter (CPM) BART Analysis

Based on EPA's interpretation that 'total particulate' includes condensable particulate matter (CPM) and at NDDH's request, GRE provides an estimate of CPM from Units 1 and 2 at Coal Creek Station. It is important to note that ND utilities are not required to test for CPM. They are only required to test for particulate using Methods 5 or 17, depending on plant permit requirements. Coal Creek's Title V permit includes a particulate limit for Units 1 and 2 and compliance is demonstrated based on a correlation curve with opacity that was developed using EPA Method 17. Since GRE does not have stack test data for CPM, a literature review was conducted to estimate CPM emissions based on a correlation to tested filterable values. Unfortunately, there is wide variability in CPM emissions when correlated to filterable emissions, regardless of the methodology selected. Some of the variability it associated with Method 202 and sulfate interference. Since CPM exists in several forms such as ammonia salts and sulfur containing particles, Method 202 cannot compensate for sulfate levels, and consequently overestimates CPM emissions. AP-42 is another methodology that provides a linear relationship between sulfur content and CPM emissions, which is arguably inaccurate, especially at higher sulfur concentrations. Nevertheless, for the purpose of this BART analysis, CPM emissions are approximated and assessed according to BART requirements.

6.1 Identify CPM Control Options

It is generally accepted that CPM is largely formed by ammonia salts and sulfur containing particles. In the absence of ammonia from NO_X controls, no ammonium salts are expected in Unit 1or 2, indicating that the majority of CPM is in the form of sulfuric acid mist (SAM). In general, the inorganic portion of CPM far exceeds the organic portion and is composed primarily of sulfates, which emanate from SO_2. Sulfuric acid mist is formed from sulfur trioxide (SO_3) reacting with water in exhaust streams. SO_3 (and SO_2) is formed when sulfur present in the coal is oxidized by either process conditions or by combustion. Accordingly, the majority of control options for CPM are the SO_2 control technologies described previously in Section 5.0 and listed in Table 6-1 below.

Table 6-1 Available CPM Control Technologies.

CPM Control Options
Wet Electrostatic Precipitator
Dry Sorbent Injection
Spray Dry Absorber
Wet Lime/Limestone Absorber

6.2 Eliminate Infeasible CPM Control Options

Wet Electrostatic Precipitator

In applications where a wet electrostatic precipitator (WESP) is used for particulate removal, it may also be used for SAM removal. A WESP uses a water spray to remove particulate matter from the ESP collection plates. For SAM removal, caustic is added to the water spray system, allowing the spray system to function as an SAM absorber. As indicated in Section 3.0, WESP control is a technically feasible but economically infeasible control option. CPM emissions do not significantly change the economic analysis. As such, WESP is economically infeasible for CPM control. If added to the particulate analysis in Section 3, CPM emissions do not significantly change the economic impacts. No additional PM controls are necessary.

Dry Sorbent Injection (DSI)

Dry sorbent (pulverized lime or limestone) is directly injected into the duct upstream of the fabric filter. SAM reacts with sorbent and the solid particles are collected with a fabric filter. This process was developed as a lower cost option to conventional spray dry absorption (SDA) technology. DSI is technically feasible for controlling CPM. However, as indicated in Section 5.0, DSI represents a lower degree of control than will be achieved by the proposed SO_2 BART controls for Coal Creek Station.

Spray Dry Absorption

Spray dryer absorption is a dry scrubbing system that sprays a fine mist of lime slurry into an absorption tower where the pollutants (SO_2 and SAM) are absorbed by the droplets. The absorption of the SO_2 and SAM leads to the formation of calcium sulfite ($CaSO_3 \bullet 2H_2O$) and calcium sulfate ($CaSO_4$) within the droplets. The liquid-to-gas ratio is such that the heat from the exhaust gas causes the water to evaporate before the droplets reach the bottom of the tower. This leads to the formation of a dry powder which is carried out with the gas and collected with a fabric filter. Dry scrubbing presents a lower degree of control than will be achieved by the proposed SO_2 BART controls for Coal Creek Station.

Wet Lime/Limestone Scrubbing

Wet lime/limestone scrubbing involves scrubbing flue gas stream with a slurry comprised of lime (CaO) or limestone ($CaCO_3$) in suspension. The process takes place in a wet scrubbing tower located downstream of a PM control device to prevent the plugging of spray nozzles and other problems caused by the presence of particulates in the scrubber. The SO_2 and SAM in the gas stream reacts with the lime or limestone slurry to form calcium sulfite ($CaSO_3 \bullet 2H_2O$) and calcium sulfate ($CaSO_4$). Coal Creek Station currently uses wet scrubbing for SO_2 control, and modifications to the existing scrubber system are the proposed BART control. Coal Creek's scrubber modifications will also provide a corresponding reduction to CPM.

6.3 Evaluate the Effectiveness of Feasible CPM Options

A number of methods exist with which to estimate CPM emissions. However, consistent and accurate CPM estimates vary widely due in large part to the uncertainties currently associated with CPM emissions measurements as presented below.

EPA's AP-42 emission factor uses a linear relationship between CPM and the sulfur content of coal. Historical coal sulfur contents have ranged 0.29% to 1.21% for Coal Creek Station with an average of 0.63%. There are two issues relevant to the uncertainty associated with using AP-42 emission factors: how well they represent the results of Method 202 measurements and the known artifacts in the inorganic portion of Method 202. (Namely, condensable sulfates are formed in the aqueous measurement process that would not otherwise form CPM in the atmosphere. These sulfates are generally termed "pseudo particulates" and their formation results in inflated CPM values when using Method 202[14].)

Five tests from coal-burning boilers in various locations provide some indication of the relationship between Method 202 measurements and AP-42 calculations. These sites all used wall fired boilers and pulverized coal and were equipped with a particulate control (ESP or fabric filter) but had no NO_X or SO_2 controls.

In the AP-42 calculations, CPM varies linearly with sulfur content. However, Method 202 measurements do not yield such a linear relationship. This suggests that the AP-42 correlation with coal sulfur is not appropriate. There is not sufficient data to assess if CPM measurements corrected for pseudo particulates would have a linear relationship with coal sulfur content. At higher sulfur contents, AP-42 calculations appear to overestimate CPM compared to Method 202, which already overestimates CPM. For very low sulfur content coal Method 202 may provide the more conservative estimate.

Since GRE does not have Method 202 test data from its boilers, CPM emissions are estimated by using a ratio of 4:1 for CPM to filterable PM (Method 5) based on the literature data presented in both Figure 6-1 and Table 6-2 below. The bar graph and table below summarizes the sulfur content, Method 202 CPM and AP-42 CPM, as well as the ratio of condensable to filterable PM using these two techniques from these five sites. The tests give a range of condensable to filterable PM ratios of 1.44-6.69 using Method 202, with an average ratio of 3.61.

---

[14] A comparison of Method 202 with a modified version to correct for pseudo particulates was performed at the Xcel Energy (previously Northern States Power) Black Dog Station, which at the time of the test fired pulverized coal at 0.25% sulfur content with wall-fired burners. The boilers were equipped with electrostatic precipitators for particulate control, but did not have ammonia-based NOX controls or SO2 controls. The comparison was accomplished by measuring CPM with standard Method 5 and Method 202 techniques and then repeating the measurements using a cold filter in the Method 5 train to simulate conditions for formation of CPM in the atmosphere. At Method 5 temperatures, sulfate based CPM can pass through the collection filter. A cold filter will capture these sulfate and sulfuric acid particulates so that any sulfate measured in the impingers of Method 202 may be considered pseudo particulates. This comparison indicates as much as an 83% overestimation of CPM using Method 202.

Table 6-2 Filterable and Condensable PM Comparison[17,18]

Source	Average Coal Sulfur Content	AP-42 CPM (lb/MMBtu)	Method (M) 202 CPM (lb/MMBtu)	Ratio of Condensable (M 202) to Filterable, (M 5) PM	Ratio of Condensable (AP-42) to Filterable, (M 5) PM
Logan Generating Company, L.P. Cogen Facility	1.13	0.083	0.0208	4.56	18.20
PSE & G - Mercer Station Unit 1	0.75	0.045	0.0373	3.00	3.61
PSE & G- Mercer Station Unit 2	0.75	0.045	0.0563	6.69	5.34
Deseret Generation and Trans. Coop.- Bonanza Power Plant	0.47	0.017	0.0096	1.44	2.55
Xcel Energy Black Dog Station	0.25	0.01	0.0437	2.36	0.54
Xcel Energy Black Dog Station – corrected for pseudo particulates (Modified M 202)	*0.25*	*0.01*	*0.0076*	*0.41*	*0.05*
Average Ratio CPM: Filterable				**3.61**	**6.05**

As described above, the existing methodologies for approximating CPM emissions all have their limitations. The Electric Power Research Institute (EPRI) is currently working with the EPA to revise Method 202 in an effort to produce more accurate CPM emission estimates. For the sole purpose of approximating (CPM) from its lignite-fired boilers for this BART analysis, GRE has chosen to multiply its filterable particulate matter (PM), as determined using EPA Method 5 test data, by a factor of 4. This ratio is based on literature data comparing the results of CPM measured by EPA Method 202[15] to filterable particulates as measured by EPA Method 5. It is also reflective of recent BACT permit limits[16], which show a range of CPM ratios from roughly 2 to 4 times the corresponding PM limit. Accordingly, the proposed CPM emission factor will conservatively estimate CPM emissions for the purposes of this BART evaluation.

As shown in Figure 6-1, a modified Method 202 can correct for pseudo-particulates. It is shown that Method 202 alone can overestimate CPM by as much as 83%, on a relatively low sulfur coal.

---

[15] CPM may be directly measured using EPA Method 202, or it may be estimated using EPA's AP-42 emissions factor document. Method 202 measures the amount of particulates that condense in water-filled impingers in the "back half" of a Method 5 stack sampling system.

[16] CPM information sources for CFB boiler emission limit determinations. Email from Tom Bachman <tbachman@nd.gov> of NDDH, 15 June 2006.

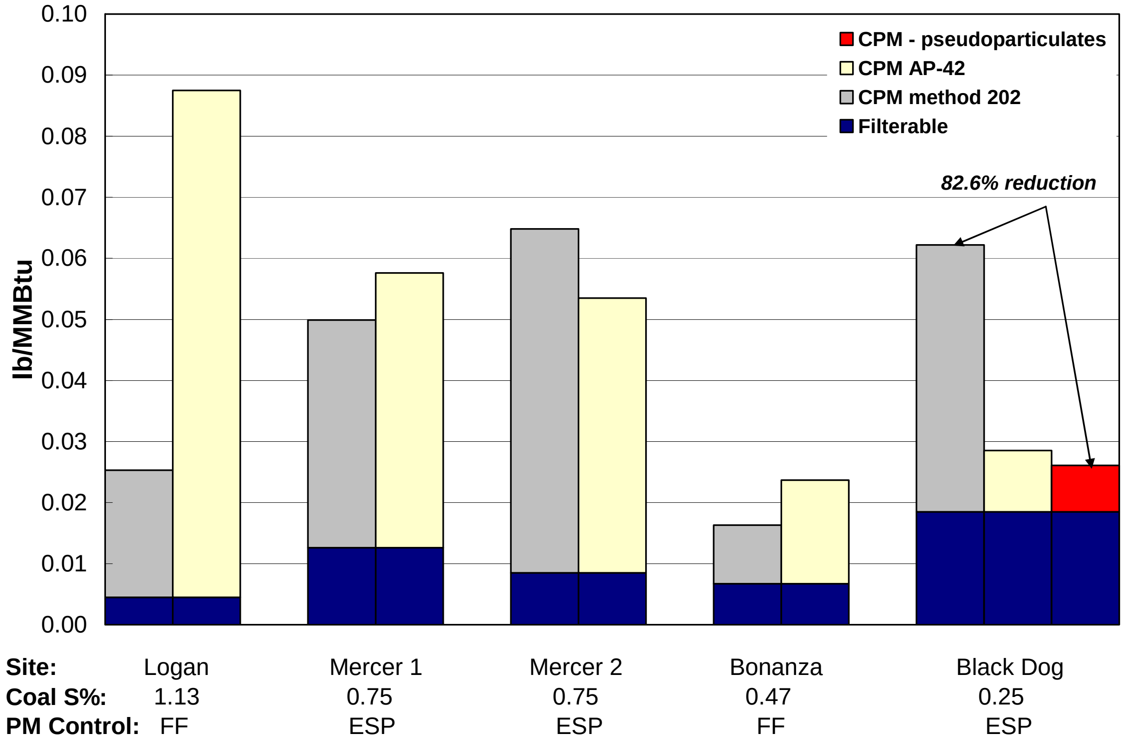

Figure 6-1. Comparison of Method 202 and AP-42. Breakdown of particulate matter is illustrated for 5 power plants[17,18].

Table 6.2 provides CPM estimates using Method 202 and also attempts to correct for pseudo-particulate.

Table 6-3 Annual CPM Emissions Estimate Based on Modified Method 202 Approximation

Unit 1 Method 5 Result (lb/MMBtu)	PM (filterable) Emissions	CPM w/ pseudo-particulates (lb/MMBtu)	CPM w/o pseudo-particulate (lb/MMBtu)	CPM w/ pseudo-particulates (ton/yr)	CPM w/o pseudo-particulate (ton/yr)
0.03	799.0 tpy[19]	0.12	0.02	3,196.0 tpy	556.1

6.4 Evaluate the Impacts of Feasible CPM Options

Uncontrolled SO_2 emissions for a single unit are calculated to be 56,435 tons per year. As illustrated in Table 6-3 CPM emissions are estimated at approximately

---

[17] "In Stack Condensible Particulate Matter Measurements and Issues" by Louis A. Corio and John Sherwell in the Journal of Air & Waste Management Association: 50:207-218.

[18] "Measurement of Condensible Particulate Matter: A Review of Alternatives to EPA Method 202, EPRI, Palo Alto, CA: 1998. Report TR-111327.

[19] Annual emissions are based on past actual operations for Coal Creek Units 1 and 2. 8,856 annual operating hours with a utilization rate of 100%. (0.03 lb/MMBtu x 6019 MMBtu/hr x 8856 hr/yr/2000 = 799.0 tpy)

3,196 tons per year, only 5.7% of the SO_2 emissions. If corrected for pseudo-particulates, CPM emissions may be as low as 556.1 tons per year, or only 1% of the SO_2 emissions. Detailed economic and environmental impacts for the available control technologies have been presented in Section 5.4. With either the corrected or uncorrected value, the incorporation of CPM will not significantly change the SO_2 economic evaluation. Further, as discussed in Section 3 and as modeled in Section 7, existing PM controls at the permit limit of 0.1 lb/MMBtu are considered BART. With an uncorrected CPM emission rate (0.12 lb/MMBtu) estimated at 4 times filterable PM (0.03 lb/MMBtu), both units are operating only slightly above the filterable emission rate (0.1 lb/MMBtu), which has been modeled and contributes only 0.06 Δ-dV per unit to regional haze (see Section 7.5). Therefore, comparable to the SO_2 determination, CPM emissions do not significantly change the PM determination in Section 3.

6.5 CPM Visibility Impacts

As illustrated in Section 3.5, visibility impairment due to particulate matter is negligible in comparison to the contributions attributed to sulfates and nitrates. A comparison of Coal Creek's Unit 1 Method 5 results (0.03 lb/MMBtu) and permitted emission rate (0.1 lb/MMBtu) showed a 0.06 Δ-dV 98th percentile addition to visibility impairment. As stated above, it is assumed that total particulate emissions (uncorrected condensable + filterable) will be 5 times the filterable contribution, or in this case, 0.15 lb/MMBtu, given the uncertainties with the methodologies. Extrapolation from the existing data points indicates that the total visibility impairment attributed to CPM is less than 0.08 Δ-dV. These results indicate that total particulate emissions (uncorrected condensable + filterable) will have a negligible influence on overall visibility impacts. Therefore, even if CPM emissions are as high 4 times filterable PM, the modeled visibility impairment would not be significant and additional SO_2 and PM controls are not economically justifiable.

6.6 Proposed BART for CPM

GRE has reviewed, summarized and discussed the limitations of various methodologies for estimating CPM emissions. GRE proposes no additional control for CPM as supported by the visibility analysis in Section 6.5. It is recognized that proposed BART SO_2 controls will reduce CPM, or specifically, sulfuric acid mist (SAM) as the major component of CPM. Coal Creek Station will reduce SAM emissions by as much as 98% through proposed scrubber improvements.

7.0 Visibility Impacts Analysis

As indicated in EPA's final BART guidance[20], states are required to consider the degree of visibility improvement resulting from the retrofit technology in combination with other factors, such as economics and technical feasibility, when determining BART for an individual source.

The CALPUFF program models how a pollutant contributes to visibility impairment with consideration for the background atmospheric ammonia, ozone and meteorological data. Additionally, the interactions between the visibility impairing pollutants NOx, SO_2 and PM_{10} can play a large part in predicting impairment. It is therefore important to take a multi-pollutant approach when assessing visibility impacts.

7.1 Assessing Visibility Impairment

The visibility impairment contribution for different emission rate scenarios can be determined using the CALMET, CALPUFF, POSTUTIL, and CALBART modeling templates provided by the North Dakota Department of Health (NDDH). The North Dakota BART modeling protocol[21] describes the CALPUFF model inputs including the meteorological data set and background atmospheric ammonia and ozone concentrations along with the functions of the POSTUTIL and CALBART post processing elements. The CALBART output files provide three methods with which to assess the expected post-BART visibility improvement: the 98th percentile, 90th percentile, and the number of days on which a source exceeds an impairment threshold.

As defined by federal guidance and Section 33-15-25-01 of the North Dakota Air Pollution Control Rules, [22] a source "contributes to visibility impairment" if the 98th percentile of any year's modeling results meets or exceeds the threshold of five-tenths of a deciview (dV) at a Federally protected Class I area receptor. The pre-BART evaluation of this criterion conducted by the North Dakota Department of Health identified Coal Creek Station as a BART eligible source[23] that does cause or contribute to visibility impairment at the four North Dakota Class I areas. In addition to establishing whether or not a source contributes to impairment on the 98th percentile, the severity of the visibility impairment contribution or reasonably attributed visibility impairment can be gauged by assessing the number of days on which a source exceeds 0.5 dV. Finally, the determination of reasonable progress along the predicted glide path can be assessed using the 90th percentile prediction.

[20] Federal Register / Vol. 70, No. 128 / Wednesday, July 6, 2005 / Rules and Regulations p. 39106.

[21] *Protocol for BART-Related Visibility Modeling Analyses in North Dakota*, Final Version, November, 2005.

[22] Chapter 33-15-25 is a new rule on public notice through May 15, 2006.

[23] Subject to BART notification from NDDH is included in Appendix D.

7.2 Predicting 24-Hour Maximum Emission Rates

Pursuant to verbal guidance from NDDH staff and to be consistent with use of the highest daily emissions for pre-BART visibility impacts, the post-BART emissions to be used for the visibility impacts analysis should reflect a maximum 24-hour average basis.

The highest daily emissions for PM/PM_{10} were maintained from pre-BART modeling. The highest predicted NOx emission rate is based on pre-BART average emission rates and highest day variability. The pre-BART NOx modeled emission rate (0.29 lb/MMBtu) was approximately 30% higher than the average NOx emissions from historical emission inventories (0.22 lb/MMBtu). As illustrated in , the highest expected emission rate for the proposed BART control of an additional level of SOFA was assessed by adding a 20% variability factor to the design emission rate of 0.15 lb/MMBtu.

Table 7-1 NOx Predicted 24-hour Maximum Emission Rates

Control Strategy	Design Rate (lb/MMBtu)	30-day Rolling Emission Rate (lb/MMBtu)	24-hour Max. Emission Rate		Basis[24]
			Unit 1 (lb/hr)	Units 1 & 2 (lb/hr)	
Pre-BART Baseline	--	--	1,772.3	3,594.7	Actual emissions data from 2000 – 2002. Represents the highest NOx emission rate per calendar day.
Foster Wheeler SOFA/LNB Option 2	0.17	0.19	1,227.6	2,456.5	Design emission rate with 10% variability for 30-day rolling and 20% variability for 24-hr max.
Foster Wheeler SOFA/LNB Option 1	0.15	0.17	1,083.1	2,167.5	
SNCR	0.11	0.12	776.2	1,553.4	
SCR with Reheat	0.04	0.05	310.5	621.4	
LTO	0.02	0.02	155.2	310.7	

---

[24] Emission rates for Unit 1 calculated using 6,015 MMBtu/hr rating. Unit 1 & 2 emissions use 12,037 MMBtu/hr combined rating.

SO_2 emission rates are highly dependant on coal sulfur content. Accordingly, an analysis of past actual and future predicted sulfur content is used to determine expected SO_2 emission rates. Figure 7-1 indicates that 2.6 lb/MMBtu is the maximum expected SO_2 emission rate with respect to 30- day block averages.

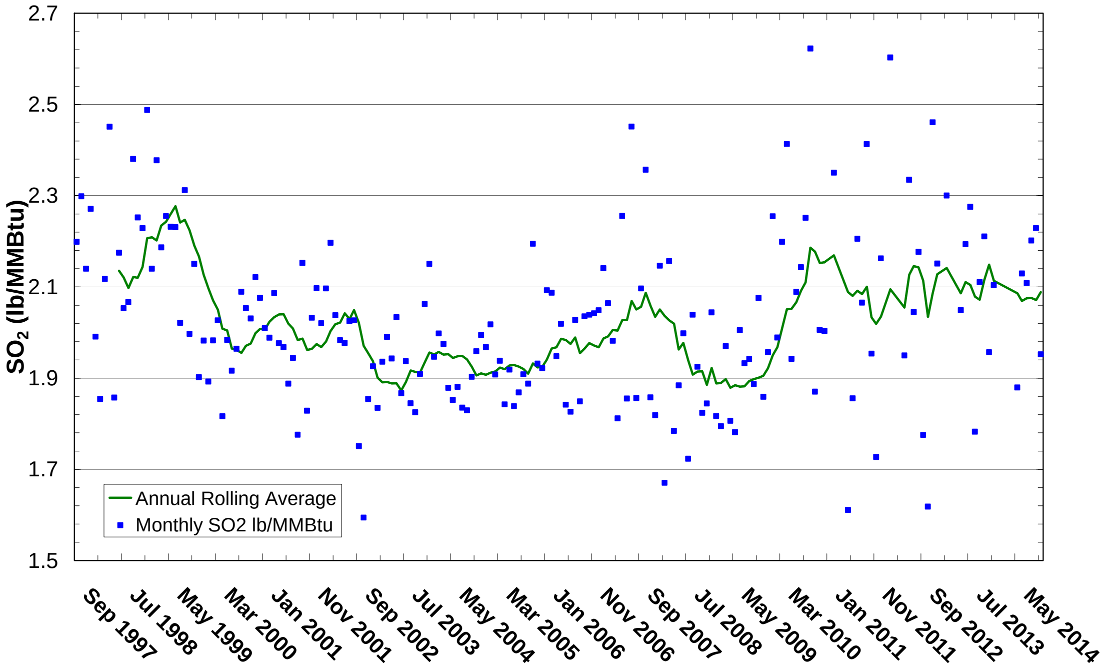

Figure 7-1 Past Actual and Future Predicted Monthly lb SO_2/MMBtu. Coal Creek sampling data is used to determine the 30-day block monthly average sulfur content from 1997 through 2006 and the Falkirk Mine Plan provides monthly predicting for future sulfur content from 2006 through 2014.

A statistical comparison of 30-day block and 30-day rolling past actual data (Appendix C) demonstrates that 14% variability should be used to determine a rolling emission rate based on a block average. This information, in combination with the design emission rates for both a new scrubber and scrubber modifications[25] is used to establish the 30-day rolling emission rates.

Since the SO_2 BART solution will be some modification of the existing scrubber, it is logical to utilize existing operational and maintenance parameters to predict the highest daily emissions. The scrubber is currently cleaned once every 7 days for a period of 4 hours during which time emissions are approximately 1.0 lb/MMBtu. Figure 7-2 illustrates the post-BART operational pattern that will be required to maintain 30-day rolling average emissions of 0.15 lb/MMBtu under current scrubber cleaning conditions. This indicates that under normal operation, the scrubber will be performing below the proposed limit of 0.15 lb/MMBtu.

---

[25] SO_2 modeling was performed for scrubber replacement and scrubber modifications only because scrubber replacement is the only evaluated SO_2 control which will provide lower emissions than the proposed BART control.

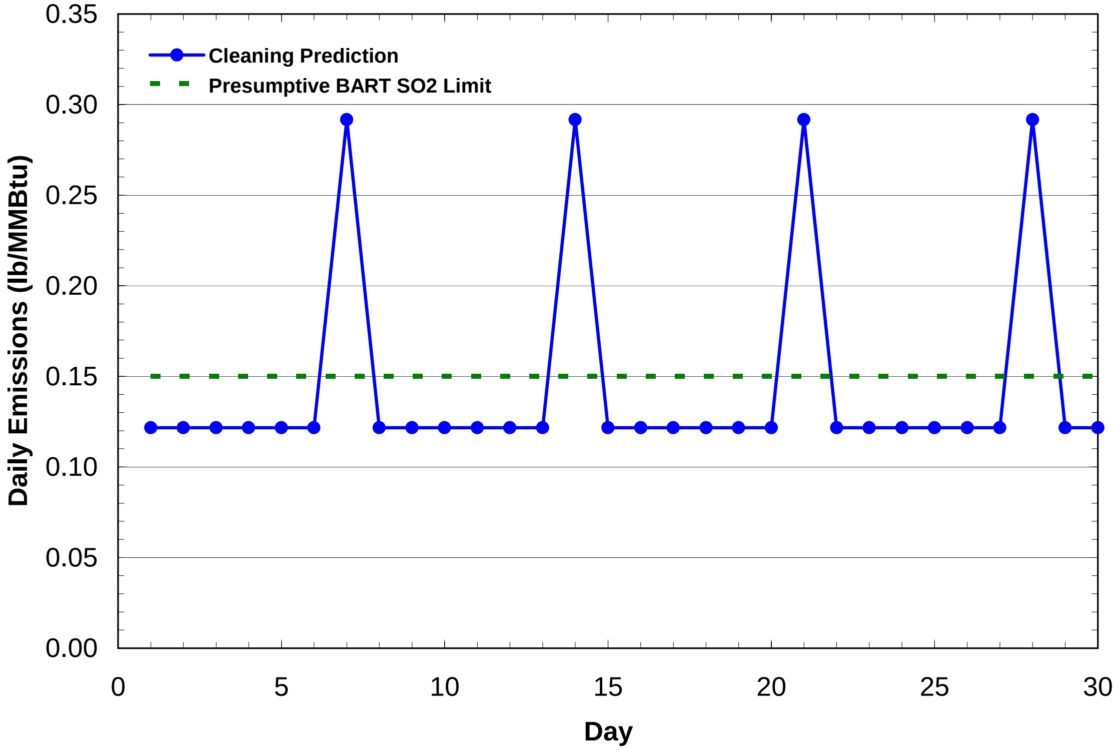

Figure 7-2 Maximum SO_2 Emission Prediction Emissions required to maintain 0.15lb/MMBtu on a 30 day rolling average based on current scrubber maintenance procedures.

A 70% variability was added to the 30-day rolling emission rate for a new scrubber to predict the 24-hour maximum emission rate. This is an engineering estimate based on a comparison of Coal Creek's pre-BART actual annual emissions and 24-hour maximum emissions. Table 7-2 presents a summary of SO_2 emission rates.

Table 7-2 SO_2 Predicted 24-hour Maximum Emission Rates

Control Strategy	Design Reduction	30-day Rolling Emission Rate (lb/MMBtu)	24-hour Maximum Emission Rate		Basis
			Unit 1 (lb/hr)	Unit 1 & 2 (lb/hr)	
Pre-BART Baseline	--	--	5,733.5	10,702.8	Actual emissions data from 2000 – 2002. Represents the highest SO_2 emission rate per calendar day.
Scrubber Modification	95.1%[26]	0.06	1,756.4	3,514.8	Resign reduction at 2.6 lb/MMBtu block 30-day sulfur content + 14% variability for 30-day rolling. Individual methods for determining 24-hour max emissions are described above.
Scrubber Replacement	98.0%	0.15	610.8	1,222.4	

Table 7-3 describes the pre and post-BART model input parameters. Other stack parameters such as exit temperature, height, elevation and diameter were not changed and can be found in the protocol[21].

---

[26] Average percent reduction for evaluated scrubber modifications.

7.3 Modeled Results

Visibility impairment was modeled using the meteorological data for the years 2000, 2001 and 2002 for the predicted post-BART emission scenario. To illustrate the individual in cumulative visibility impacts, Unit 1 alone and Units 1 and 2 in combination were modeled. As indicated by the results, reaction chemistry caused by limited background atmospheric ammonia results in a Δ-dV reduction for Units 1 and 2 together that is less than double the dV reduction for Unit 1 alone. Results for the 90th, 98th and number of days above 0.5 dV at Lostwood Wilderness Area (WA) and Theodore Roosevelt National Park (TRNP) North, South and Elkhorn Ranch units are included in

Table 7-4 through Table 7-6. Additionally, Figure 7-3 illustrates scenarios 1 through 15 on a $/dV basis. The figure focuses on year 2002 modeling results because it is the year that showed the most severe pre-BART visibility impairment.

[1] Average improvement represents the 90th percentile comparison to the base case (Scenario 0) averaged for the 4 Class 1 areas.

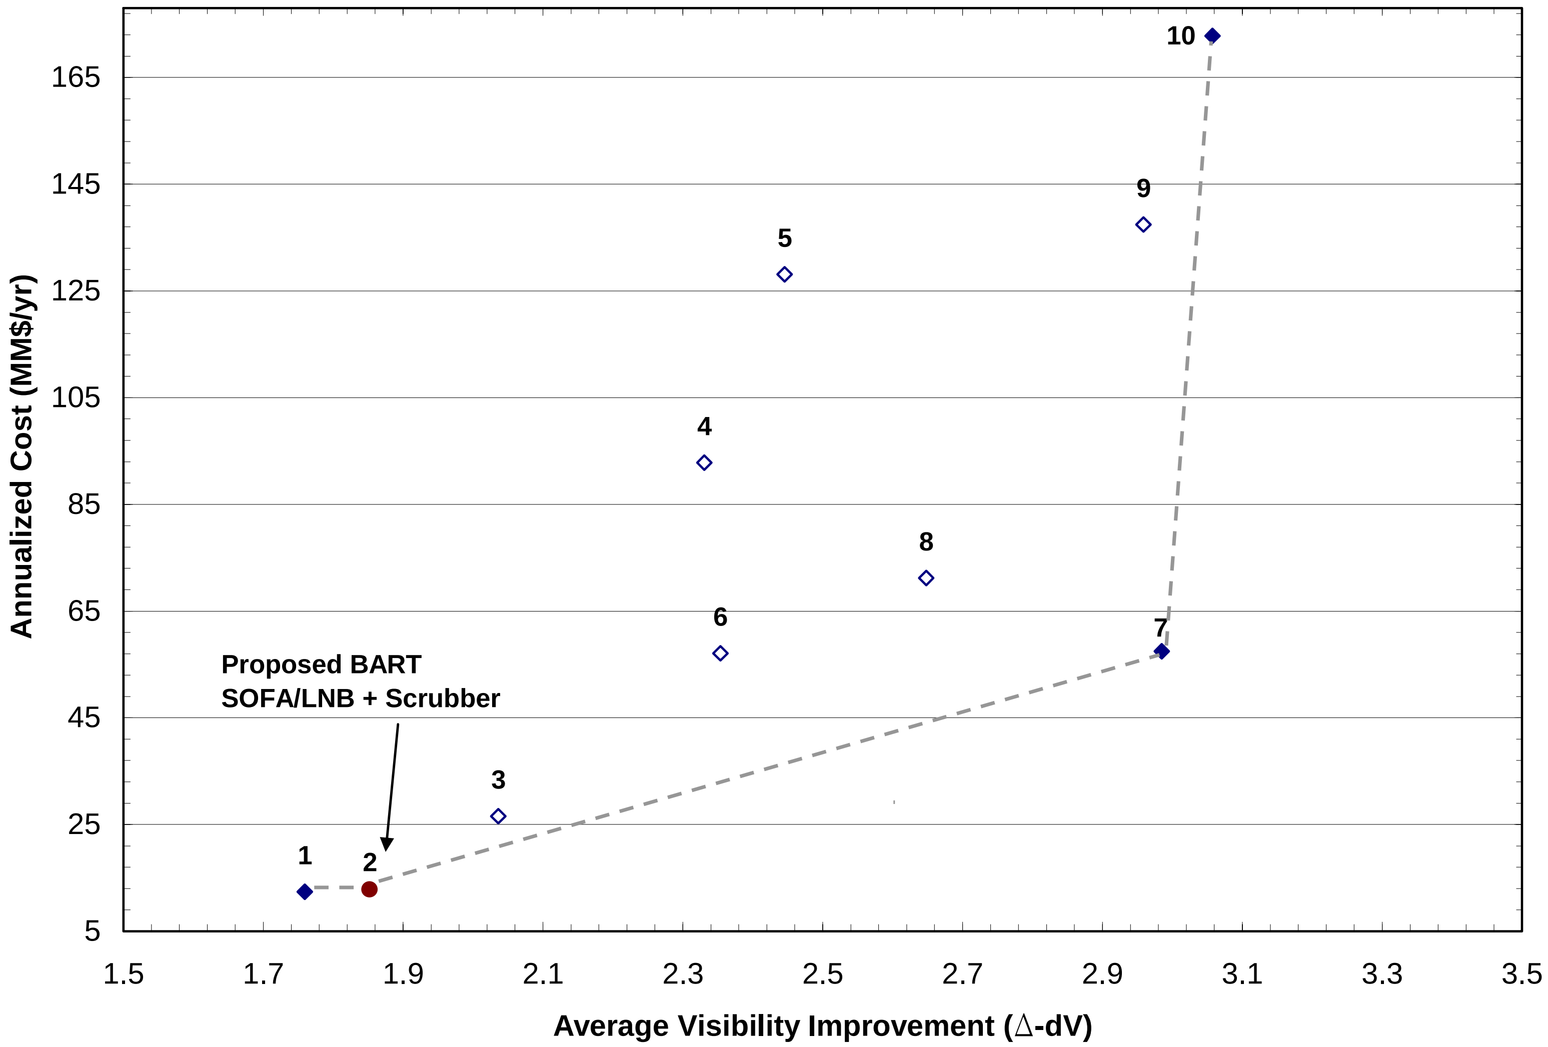

Figure 7-3 Dollar per Deciview Analysis. Scenarios 1 through 10 are plotted for the 98th percentile of 2002 based on the total annualized cost for installation and operation on both Units and the average visibility improvement for the 4 Class 1 areas. Dominant controls are presented as filled icons and inferior controls are represented as empty icons.

As illustrated by the dollar per deciview analysis in Figure 7-3, the proposed BART of scrubber modifications with an additional level of SOFA (Scenario 2) is support by the visibility modeling results. This graph also indicates that a change in NOx emission rate of 0.02 lb/MMBtu (comparison of Scenarios 1 and 2) only results in a change of about 0.1 Δ-dV on a 98th percentile comparison. As noted in Section 5.4.1, scrubber replacement (Scenarios 7 and 10) does not represent a feasible control option, therefore, from a visibility standpoint, Scenario 2 if the next best control.

7.4 Visibility Impacts of the Proposed BART

Scenario 2 represents a significant reduction in modeled visibility impairment in the four Class 1 Areas. As one example, on average, for 2002 98th percentile, the total visibility improvement for the two stations combined will be over 1.8 Δ-dV. Figure 7-4 illustrates the expected visibility improvement for the proposed BART of using current PM_{10} emissions in addition to meeting presumptive NOx and SO_2 limits as compared to the pre-BART baseline (Scenarios 0 and 2). The year 2002 results were used because the highest degree of impairment was demonstrated in that year.

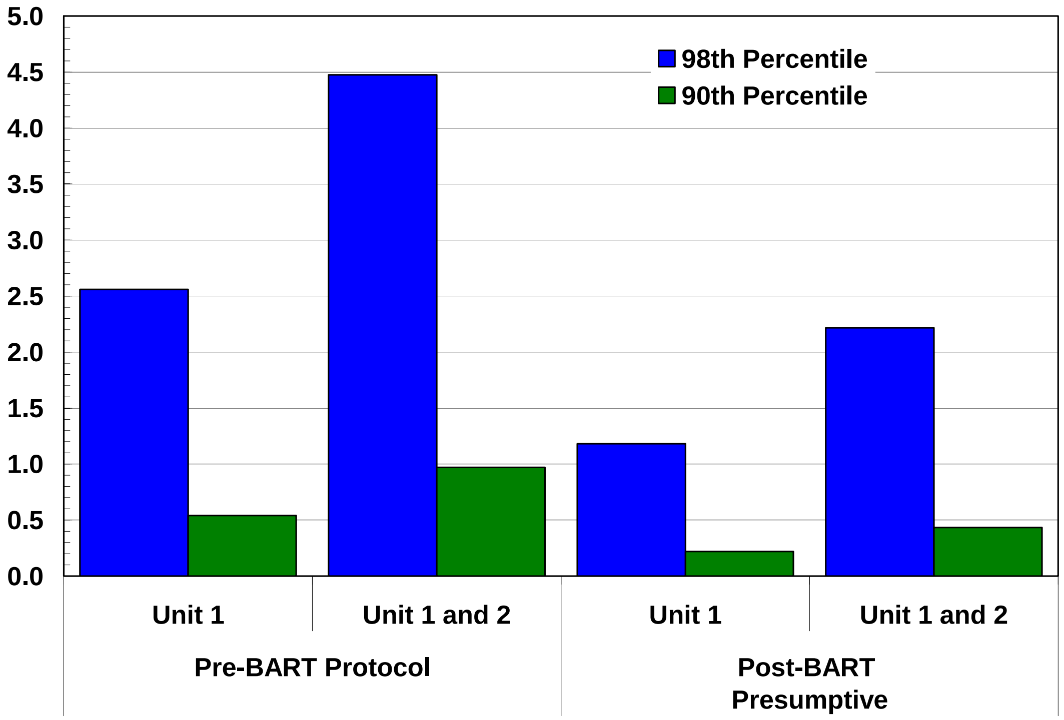

Figure 7-4 Visibility Improvement Predicted visibility improvement at post-BART presumptive emissions illustrated on a 90th and 98th percentile comparison to post-BART emissions at TRNP's South Unit.

8.0 Summary of Proposed BART

Based on the evaluations presented above, Scenario 2 is considered BART for Coal Creek Station. With respect to particulate controls, GRE will maintain the current PM performance standard of 0.1 lb/MMBtu for the existing ESP. The PM analysis presented in Section 3.0 confirms that additional PM controls are not economically justified and would provide negligible deciview reductions in Class 1 areas.

For NOx controls, GRE establishes LNB with and additional level of SOFA as described in Section 4.0. SNCR, SCR and LTO are ruled out on cost per ton bases along with operational, energy and environmental impacts. The LNB/SOFA combination will provide 20% to 30% reduction on a 30-day and annual basis at an emission rate of 0.17 lb/MMBtu.

For SO_2, GRE proposes to modify the existing scrubbers. The proposed emission limit of 0.15 lb/MMBtu on a 30-day rolling average is based on historical and future predicted operation and fuel sulfur content variability. A final decision on the scrubber modifications required to achieve the presumptive BART emission rate of 0.15 lb/MMBtu will be made pursuant to the evaluation of coal drying as applied to Coal Creek Unit 1.

In combination, the proposed BART controls will provide an average visibility improvement of over 1.8 Δ-dV compared to the pre-BART baseline that will significantly contribute to the state's effort in meeting its reasonable progress goals under the Regional Haze Rule.

Notes & Assumptions

1. Total Direct Capital Cost per GRE cost estimate (CCS BART Evaluation.xls). Assumed no indirect capital cost included in estimate.
2. Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 3
3. ESP Maintenance costs Eq 3.45 EPA Cont Cost Manual Section 6 Chapter 3
4. ESP Maintenance Materials Eq 3.45 EPA Cont Cost Manual Section 6 Chapter 3
5. Existing PM emission rate per avg Method 5 test results of 0.030 lb/MMBtu, projected PM emission rate is at typical BACT limit 0f 0.015 lb/MMBtu per RBLC
6. Used an ESP SCA grid factor of 553 ft^2/1000 acfm per GRE, D. Stockdill.
7. Assumed WESP size is 20% of IAPCS model calculated size for electricity and spray water use.
8. Process, emissions and cost data listed above is for one unit.
9. For units of measure, k = 1,000 units, MM = 1,000,000 units e.g. kgal = 1,000 gal

Notes & Assumptions

1. Sept 2005 Cost Estimate Procedure from **BOC Gases**
2. Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 5.2 Chapter 1 (absorbers)
3. Liquid/Gas ratio = 10 L/G = Gal/1,000 acf
4. Water Makeup Rate/Wastewater Discharge = 20% of circulating water rate
5. Check O2 Prices
6. Presumptive BART limits use as basis for emission reductions in NOx control cost analysis (e.g. NOX limit for lignite is 0.29lb NOx /MMBTU) Using emission reduction feasible in recent BACT determinations (70% or higher) can significantly reduce the $/ton control cost down to values approaching the BART economic feasibility values for presumptive BART.
7. Flow rate, duty and costs listed above for one unit.
8. Process, emissions and cost data listed above is for one unit.
9. For units of measure, k = 1,000 units, MM = 1,000,000 units e.g. kgal = 1,000 gal

Notes & Assumptions

1 Estimated Equipment Cost per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2
2 Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2
3 Capital Cost per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.36 -2.43
4 Reagent Use per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.32 - 2.35
5 SCR Catalyst Volume per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.18 - 2.24
6 SCR Reactor Size per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.25 - 2.31
7 SCR Catalyst Replacement per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.50 - 2.53
8 SCR Electrical Demand per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.48
9 SCR Maintenance Costs EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.46
10 Presumptive BART limits use as basis for emission reductions in NOx control cost analysis (e.g. NOX limit for lignite is 0.29lb NOx /MMBTU) Using emission reduction feasible in recent BACT determinations (70% or higher) can significantly reduce the $/ton control cost down to values approaching the BART economic feasibility values for presumptive BART
11 Reheat cost based on 180 F temperature from scrubber exhaust
12 Process, emissions and cost data listed above is for one unit.
13 For units of measure, k = 1,000 units, MM = 1,000,000 units e.g. kgal = 1,000 gal

Notes & Assumptions

1. Sept 2005 Cost Estimate from Foster Wheeler, Option 1. Assumed price listed is for one unit. Costs in spreadsheet are for one unit
2. Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 2 (Used PM Scrubber which has lowest installed cost multiplier)
3. Assumed 0.1 hr/shift operatior and maintenance labor for LNB
4. Presumptive BART limits use as basis for emission reductions in NOx control cost analysis (e.g. NOX limit for lignite is 0.29lb NOx /MMBTU) Using emission reduction feasible in recent BACT determinations (70% or higher) can significantly reduce the $/ton control cost down to values approaching the BART economic feasibility values for presumptive BART
5. Process, emissions and cost data listed above is for one unit.
6. For units of measure, k = 1,000 units, MM = 1,000,000 units e.g. kgal = 1,000 gal

Coal Sulfur Content Variability

Sulfur Content Statistical Variability Analysis

For the purpose of establishing representative SO_2 emission rate predictions, past actual and future predicted coal sulfur content data for Falkirk Mine was analyzed. Table 1 presents an analysis of Coal Creek Station's past actual daily coal sulfur content. The analyzed data set includes 3,136 daily readings covering the time period from September 1997 through mid-May 2006, and is used to illustrate the variability between a 30-day rolling and 30-day block average. Past actual and future predicted mine plan 30-day block data presented in Section 7.2 of the report are recreated below in Figure 1. In order to include at least 98% of expected scenarios and appropriately determine an operational limit on a 30-day rolling average from the 30-day block averages, 14% variability must be assessed. This provides a degree of comfort with the operational limit and expected variability determined from past operational data.

The data presented in Figure 1 is calculated from core samples using a Falkirk mine plan modeling program. The predicted as delivered (AD) pounds of SO_2 per MMBtu is derived from the model. Consequently, the predicted AD pounds of SO_2 per MMBtu will change as the mine plan changes. The mine planning model uses grids generated from drilling and coring data. The in situ sulfur and Btu grids are built using the quality analysis from core samples. Once this is complete, a dilution factor is added in to get the AD sulfur and AD Btu. The dilution factor is needed to account for non-coal (clay) material which is present in the delivered coal as a result of the mining process. The amount of dilution used in the model is periodically adjusted by comparing the model predictions to past actual delivered quality reported by GRE.

The statistical analysis presented in Figure 1 is based on the 2004 mine plan which was available at the time of initial BART analysis submittal. Mine plans are variable in nature, and are therefore used only as an estimation tool, not a definitive statement of future emissions. The individual core sample IDs and characteristics will not be provided as supporting information to this graphic. It is virtually impossible to obtain a representative sample of the coal characteristics using core samples, and this model is only used to plan the mining operation and not to certify the sulfur content or heating values of future coal deliveries. The core samples cannot provide guaranteed estimates for quantities of the coal that will possess the specific characteristics of that core sample; only that some quantity of coal underground has those characteristics. The data provided by the mine plan model is used to incorporate a prediction of future worst case conditions, which in combination with past actual data, assists with the evaluation of SO_2 control technologies.

Bowers vs. SWAPCA	Bowers vs. SWAPCA	300	300	1000	1000	954-1134 was ruled too much, in favor of 256-310 for SO2. This did consider incremental value. Sections XVII to XIX
WRAP Trading Program Methodology	WRAP			3000		
	EPA - Referenced by Wrap					References EPA-600S\7-90-018. Low is <$500/ton, Moderate is $500-3000/ton, High is over $3000/ton

The dollars per ton estimates cited above were obtained from BART guidance, documentation of similar regulatory programs such as CAIR, and relevant court decisions. These materials indicate that most EPA sanctioned documents, including the final BART ruling, concretely support an average expected reasonable cost range of $1,300 to $1,800 per ton of NOx removed and a range of $1,000 to $1,300 per ton of SO_2 removed. The BART presumptive limits were set based on cost effective controls that were on average less than these ranges. As an example, the presumptive SO_2 limit was established based on an average cost effectiveness of less than $1,000/ton. As the cost analysis extends into RPO, WRAP and other regional planning documentation, the cost ranges become more variable and difficult to predict. For ease of comparison, the federally established ranges for NOx and SO_2 were used as a BART cost threshold basis.

RE: Great River Energy – Coal Creek and Stanton Stations
Supplemental Information for Cost Effectiveness under BART

Dear Mr O'Clair:

As follow-up to our June 4, 2007, meeting with you and Mr. David Glatt, this document serves to outline information relevant to determining an appropriate cost effectiveness threshold for evaluations under Best Available Retrofit Technology (BART). Great River Energy (GRE) submits this information as an addendum to the BART analyses and proposal documents that have been submitted to the North Dakota Department of Health (NDDH) for GRE's Coal Creek and Stanton stations. This information and proposal is for your consideration, and we look forward to continuing our dialogue with you on this matter.

Cost effectiveness is one of several important factors evaluated to determine BART in accordance with U.S. Environmental Protection Agency (EPA) rules and guidance. The EPA is specific in its assignment of presumptive BART emission rates and cost effectiveness expectations.[1] Alternative cost effectiveness values referenced through Section 309 of the Clean Air Act are of interest, but are not as specifically tailored to the goals of the BART rules.

The NDDH has suggested a value deemed cost effective for purposes of economic impacts under BART. This value stems from a reference in the 2004 proposed rule for BART determinations.[2] Specifically, the proposed BART Rule references a draft technical support document[3] (TSD) for

---

[1] Technical Support Document for the Best Available Retrofit Technology (BART) Notice of Final Rulemaking – Setting BART SO_2 Limits for Electric Generating Units: Control Technology and Cost Effectiveness, April 2005. Note that scatter plot evaluations for NOx and SO_2 illustrate that presumptive levels are established from large electricity generating units (EGUs) to ensure the highest visibility reduction.

[2] Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations; Proposed Rule; F.R. Vol. 69, No. 87, May 5, 2004, p. 25198

[3] Western Regional Air Partnership Regional Haze BART (Trading Program Option) TSD 6A, Draft: July 16, 1999

the Western Regional Air Partnership's (WRAP) Annex[4] to a report submitted to the EPA by the Grand Canyon Visibility Transport Commission (GCVTC) in 1996.[5]

The cost effectiveness ranges stated in this WRAP TSD reference an EPA assessment of NOx and SO_2 controls for coal-fired boilers that was published in 1990.[6,7] While the information presented is of interest to BART, a straight inflation adjustment from an analysis performed in the late 1980s and published in 1990 does not provide an accurate reflection of current pollution control technologies and associated capital and operating cost effectiveness.

The 1990 EPA document presents a range of control costs that vary by coal sulfur content, boiler type, and generating capacity. It further states that cost estimates rely heavily on site-specific parameters and that both cost and pollutant removal efficiency should be balanced when selecting a control technology for a given boiler. At the time of the report, many technologies considered for BART, including selective non-catalytic reduction (SNCR) for NOx, were not commercially available and are therefore not reflected in the analysis. With the wide variety of specific control costs presented in the document, the range of $500 to $3,000 presented as moderate in the WRAP TSD is a subjective number that broadly incorporated all NOx and SO_2 costs for every type and size of utility.

The document states that $3,000 was used as an approximation to exclude controls that meet BACT level emissions. While BACT controls have been accepted as BART in many cases, the opposite is not necessarily true. Therefore, while BACT average and incremental cost effectiveness thresholds may be reviewed while determining BART cost effectiveness, the EPA's BART Rule and TSDs as well as associated visibility improvements should ultimately be the determinative guidance.

The WRAP TSD was produced under the assumption that BART may not be required for EGUs, which is the premise of the WRAP trading program. Further, in the executive summary to the WRAP annex, it is explained that the goal of WRAP is to employ reductions that are "better than BART" to achieve greater reductions than dictated by reasonable progress goals.

For these reasons, WRAP cost estimates include more than just "BART-eligible sources." As a final WRAP comment, note that the WRAP Annex explicitly sets program penalties at $5,000/ton of excess emissions.[8] This penalty is established at "three to four times greater than the expected market trading price," which is, by definition, an expected cost effectiveness of approximately $1,200/ton to $1,600/ton.

[4] Voluntary Emissions Reduction Program for Major Industrial Sources of Sulfur Dioxide in Nine Western States and A Backstop Market Trading Program, September 29, 2000

[5] Report from Grand Canyon Visibility Transport Commission to the United States Environmental Protection Agency, June 1996

[6] Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations; Proposed Rule; F.R. Vol. 69, No. 87, May 5, 2004, p. 25198.

[7] Assessment of Control Technologies for Reducing Emissions of SO_2 and NOx from Existing Coal-Fired Utility Boilers, EPA-600/7-90-018, September 1990

[8] Voluntary Emissions Reduction Program for Major Industrial Sources of Sulfur Dioxide in Nine Western States and A Backstop Market Trading Program, September 29, 2000, p. 47

Given the outdated nature of the EPA control assessment that is at the root of WRAP's $500 to $3,000/ton range, it is critically important to rely on more recent cost documentation as provided by the EPA in the BART Rule and associated technical support documents and as provided in GRE's BART analyses reports to the NDDH.

With respect to cost effectiveness as defined in the BART Final Rule,[9] the expected control costs range from $900/ton to $2,400/ton for SO_2 removal and from $300/ton to $1,300/ton for NOx, with most NOx estimates at less than $1,000/ton. Again, these estimates rely heavily on boiler type, capacity, and the fuel burned. The following two excerpted figures illustrate not only the EPA's intent to evaluate BART cost effectiveness on the type and size of boiler, but also confirms that average cost effectiveness is established at a much lower level than that suggested by the NDDH. As an example, highlighted in the two excerpted figures are the rows that would apply to Stanton Station.

FIGURE 1

Unit capacity (MW)	Tons (K) of SO_2 emitted in 2001	Percent of BART eligible coal-fired unit's 2001 emissions	Calculated average cost effectiveness for MW grouping ($/ton SO_2 removed)	Percent of estimated removable BART SO_2 emissions from coal-fired units*

Wet-bottom	Bituminous	6	378
Cyclones (with SCR)	All	56	900

In the determination of NOx control cost effectiveness the NDDH should also be cognizant of determinations made by other states in EPA Region 8. As an example, in Colorado's final BART guidance[10] it has been stated that no post-combustion NOx controls will be required, precluding the need to consider SNCR and selective catalytic reduction (SCR) as potential control options.

---

[9] Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations; Final Rule; F.R. Vol. 70, No. 128, July 6, 2005, p. 39133-39135

[10] Colorado BART, March 16, 2006

In the proposed BART Rule[11] the EPA also states that post-combustion NOx controls should not be necessary, other than on cyclone units.

The BART Final Rule further supports that visibility impacts are a key component of the BART determination. If one control technology provides a significant improvement in visibility over another, the State may and should consider this information in its BART determination Under this assumption, one cost effectiveness threshold would not be appropriate for all units because there would be varying degrees of visibility improvements.

In terms of visibility improvement, a 0.5 deciview (dV) level has already been determined by the EPA to be a "contribution threshold" for states in determining BART-eligible sources that cause or contribute to visibility impairment and thus become "subject to BART." It can be asserted that any change in impairment from an individual facility with BART-eligible sources less than 0.5 dV can and should be deemed insignificant by a state. In the 2005 document from the NDDH addressing regional haze status[12] the NDDH determined that a newly permitted coal-fired ethanol production facility and a new 175-MW power plant that will be located closer to Class I areas than GRE's facilities would not adversely affect visibility in the North Dakota Class I areas. The fact that these two projects have already been deemed insignificant supports a *de minimis* contribution threshold.

We understand that regional-scale dispersion modeling for BART is pending. Until this analysis is completed it is unknown whether North Dakota will meet its reasonable further progress goals Accordingly, before requiring emission controls beyond BART, the regional-scale dispersion modeling analysis should be completed with source attribution assessments including those from North Dakota, other contributing states and Canadian sources with their projected reductions. If it can be shown that sources outside the United States are preventing North Dakota Class I areas from meeting their glide path goals, consideration should be given to revising the natural background goal to account for sources that cannot be controlled under the EPA regional haze rules.

Cost effectiveness thresholds have been determined for many other regulatory programs similar to BART. However, BART has the distinct goal of improving/reducing regional haze and is unique in its consideration of visibility impacts. Regardless of the references used to determine cost effectiveness thresholds, it is obvious that pollutant specific thresholds are supported by the EPA. GRE maintains that based on the EPA BART Rule with ranges of $900/ton to $2,400/ton for SO_2 removal and $300/ton to $1,300/ton for NOx removal, and associated references presented in this document, a value of $1,500/ton or less is appropriate for determining cost effectiveness for both NOx and SO_2 control technologies under BART.

Ms. Dianne Stockdill
Environmental Coordinator
Great River Energy
2875 Third Street SW
Underwood, ND 58576

Dear Ms. Stockdill:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Great River Energy Coal Creek Generating Station Units 1 and 2 are BART-eligible sources. Completed visibility modeling for the Coal Creek Station (Units 1 and 2 combined) indicates that the maximum 98th percentile delta-deciview prediction for the facility exceeds the BART screening threshold of 0.5 deciviews. Therefore, Coal Creek Units 1 and 2 are subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Coal Creek Generating Station. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188. We look forward to working with you to develop appropriate BART control strategies for Coal Creek Units 1 and 2.

Sincerely,

Steve Weber for

Terry L. O'Clair, P.E.

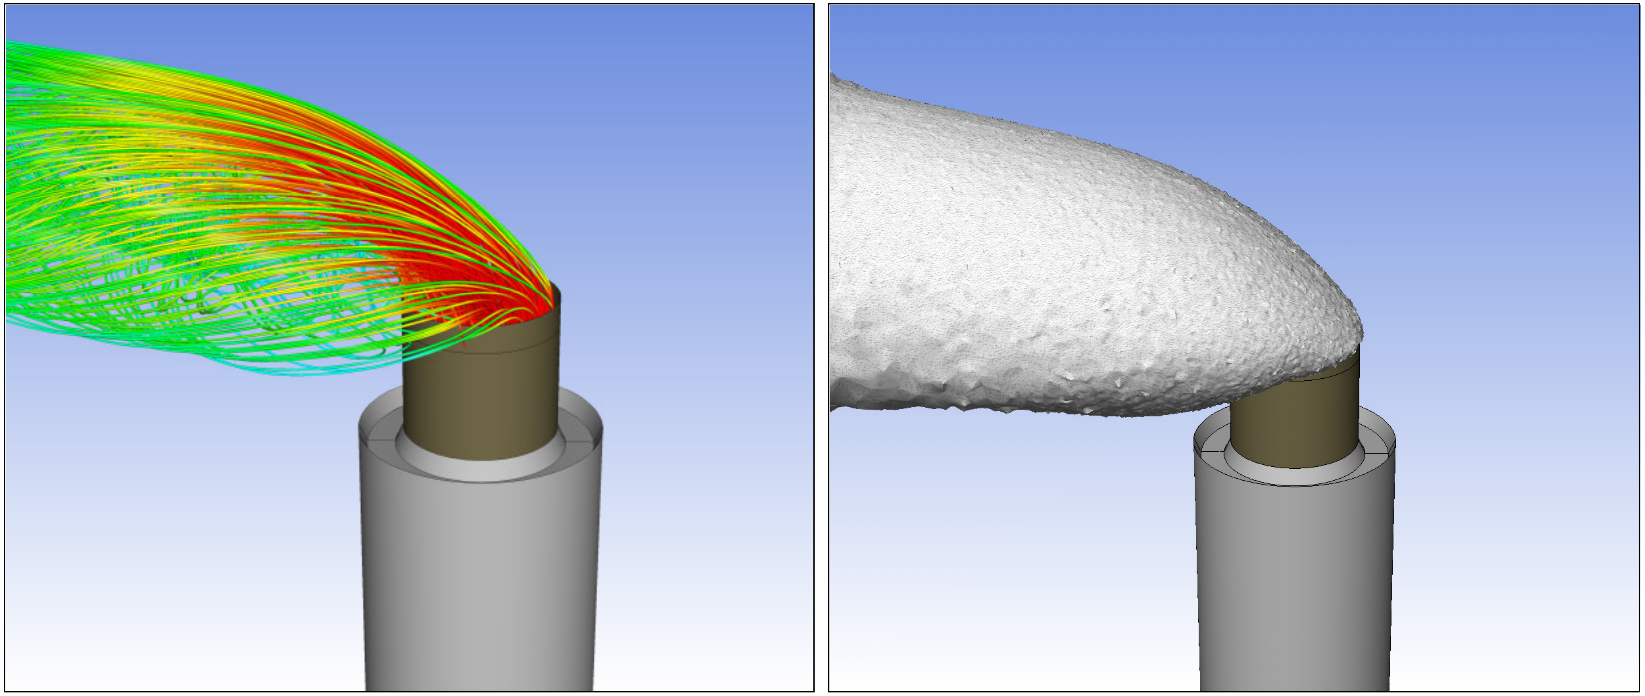
Wet Stack Study

Computational Fluid Dynamics Model of a Wet Stack in North Dakota

590 MW Unit at Full Load



Summary of Results

- The CFD model predicts a bifurcated plume for all cases.

- Predicted plume downwash:
  - 13 Feet Below Top of Liner Extension for 38 MPH wind speed at –7 degree F
  - 16.5 Feet Below Top of Liner Extension for 63 MPH wind speed at –17 degree F

- A 20 foot liner extension is sufficient to prevent stack gas from contacting shell under the worst case met condition.

- The model predicts the potential for ice formation along outer band of plume downwash on liner extension.

- The stack design philosophy is to manage, but not prevent, ice formation.

- Ice formation is managed through the use of an inverted rain cap on the stack shell.

- The model predicts increased vortex shedding in the wake behind the stack for the 63 MPH wind case. This creates additional undulations in the predicted plume shape for the 63 MPH case relative to the 38 MPH case.

CFD Cases

Case 1:
- Wind Speed = 38 MPH at Stack Height
- Ambient Air Temperature = - 7 deg. F

Case 2:
- Wind Speed = 63 MPH at Stack Height
- Ambient Air Temperature = - 17 deg. F

Modeled Flue Gas Conditions (All Cases)

- 1,947,000 acfm at 138 deg. F
- 590 MW at Full Load
- Corresponds to 55 ft/sec gas velocity inside stack
- Effect of buoyancy is included in CFD model

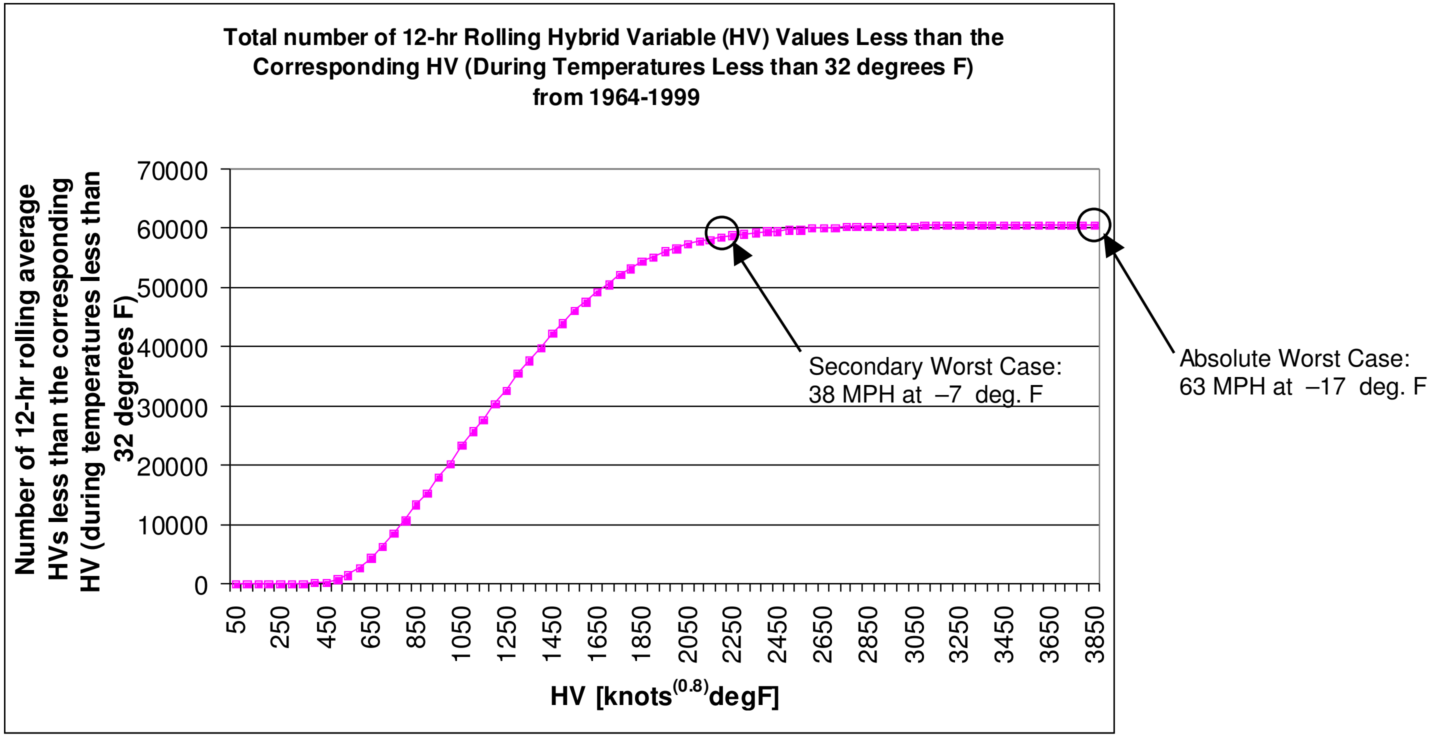
Modeling Assumptions (All Cases)

- Plane of symmetry at stack centerline for geometry and boundary conditions
- Liner extension is assumed to be perfectly insulated

Determination of Worst Case Met Conditions

- Based worst case met condition on wind speed and temperature
  - Reviewed 35 years of Minot met data: 1964 through 1999
  - Computed wind speed at stack height based on wind speed at ground level
  - Heat transfer proportional to [(Wind Speed)$^{0.8}$] * [138 - Temperature] = Hybrid Variable, HV
  - Prepared an occurrence distribution plot of 12 hour rolling average of HV for 35 year period

- Identified two met conditions based on 12 hour rolling average Hybrid Variable
  - Absolute worst case for entire 35 year period: Wind Speed at stack height = 63 MPH, Temperature = -17 F
  - Secondary worst case representing 99 % of 35 year period: Wind Speed at stack height = 38 MPH, Temperature = -7 F



Secondary Worst Case:
38 MPH at –7 deg. F

Absolute Worst Case:
63 MPH at –17 deg. F

TLN3 SYSTEM ASSESSMENT AND RECOMENDATIONS FOR LOWER NOx OPERATION

GREAT RIVER ENERGY
UNDERWOOD, NORTH DAKOTA
COAL CREEK UNIT 1

FWNAC Contract No. 65-117436
September 9, 2005

Prepared By: Brad Moulton & John Grusha

NOTICE

Summary:

Foster Wheeler was on site at Great River Energy (GRE) Coal Creek Station August 16-18, 2005 for the purpose evaluating the current TLN3 system performance, for future NOx reduction potential. This consisted of conducting a series of tests that would both identify the effectiveness of various NOx reduction adjustments and subsystems, determine any barriers, and gather data that would help predict and quantify the benefits of specific modifications for additional NOx reduction. Several recommendations are summarized and offered to Great River Energy's for review and consideration.

The primary evaluation tests consisted of the following:

1. Static pressure measurements at the SOFA elevations were taken at varying conditions to determine SOFA flows and the effect on NOx levels.
2. Main windbox/furnace DP was increased to evaluate forcing more air to the SOFA windboxes.

The effect of operating oxygen levels and main burner tilts was not examined however there is potential here.

Separated Overfire Air flow measurements:

Separated overfire air (SOFA or SSAS 13 and 14) static pressure measurements were taken at each corner (both elevations). These readings were used to evaluate current overfire air flow rates versus the initial design and what it takes to increase the flow. Furnace draft measurements were taken at the observation doors near each SOFA corner, to determine the DP across the nozzle tips. Knowing the DP, nozzle tip flow area and k factors, velocity and flow can be determined. The measured overfire air flows are summarized in the following table:

		Corner Flows, lb/hr

Table 1 –Separated Overfire Air Flow Rates for Individual Corners Under Various Conditions

The original overfire air system was designed for 20% at 5.0 in w.c. Some variances exist between corners but overall the current measured flow rates match initial predicted values closely. The first test consisted of raising the windbox/furnace DP from 4.0 to 4.5 in w.c. This increased the SSAS/ SOFA flow from 17.5 to 18.75% (table 1). Further SOFA flow increase was seen at 5.0 in w.c, however at this condition, the main windbox dampers were at their low limit of

10% open. (This is a plant- imposed limit for nozzle tip cooling considerations.) Further closure would have diverted more secondary air to the overfire air.

The next series of test consisted of evaluating SOFA tilt angle versus NOx. The lowest NOx emissions were at a SOFA tilt angle of +12 degrees. Further increasing SOFA tilts to +25 caused an increase in NOx. This was not expected and is suspected to be due to the apparent flow resistance being created by the "up-tilt" of the nozzle tips. Measured flow rates show a slight decrease in overfire air flow.

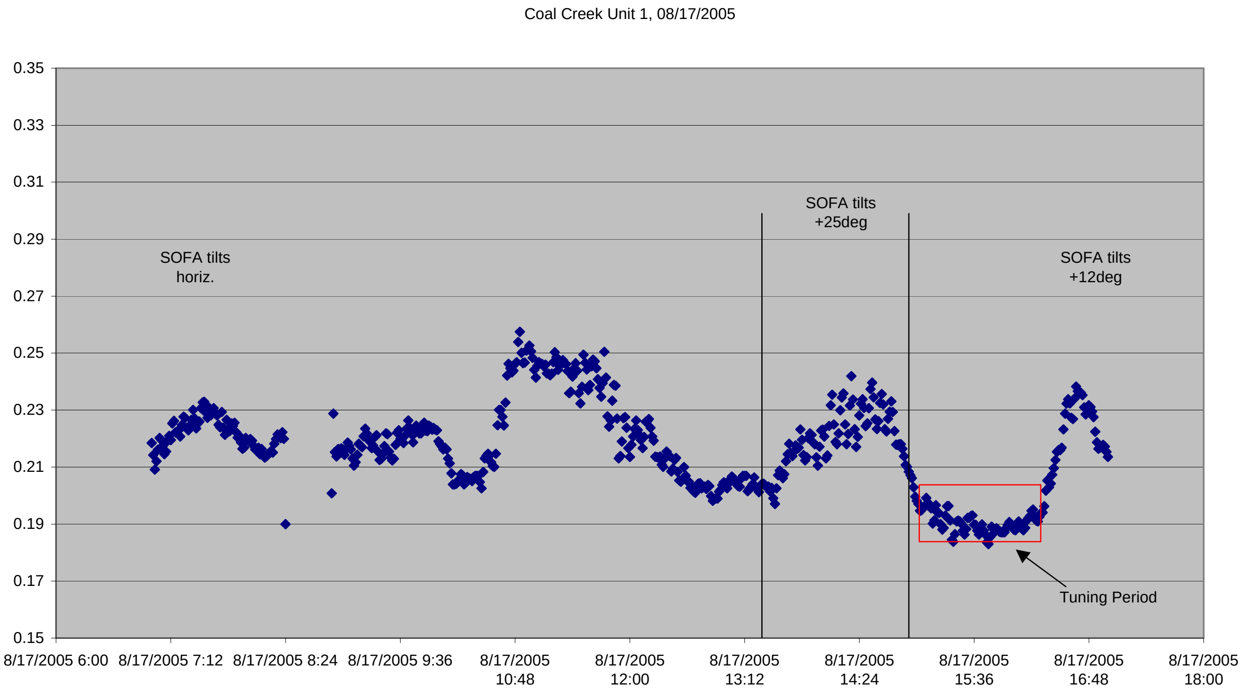

Figure 1: NOx versus Various Operating Conditions

NOx testing/tuning conducted on the last day of the visit (August 18, 2005) showed that opening up the close-coupled overfire air (CCOFA or SAS 11 and 12 compartments) reduced NOx emissions by approximately 0.02 lbs/MBtu.

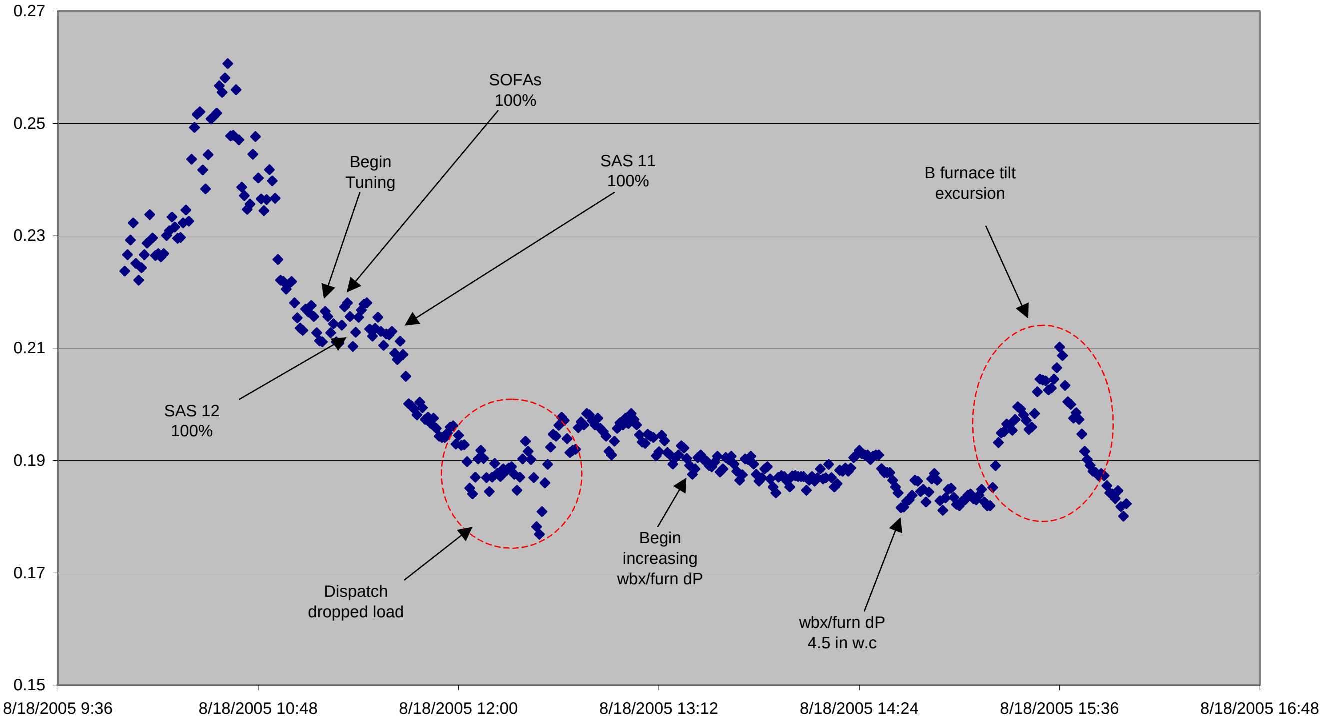

Figure 2. - NOx versus Various Operating Conditions – August 18th

Consistent sub 0.19 lb/MBtu NOx values were achieved with the SOFA and CCOFA compartments at 100% open. As figure 3 shows, only a load disruption and subsequent ramp up caused NOx values above 0.19 lb/MBtu for the better part of the entire afternoon. At these emission levels, main windbox tilts had a pronounced affect on NOx.

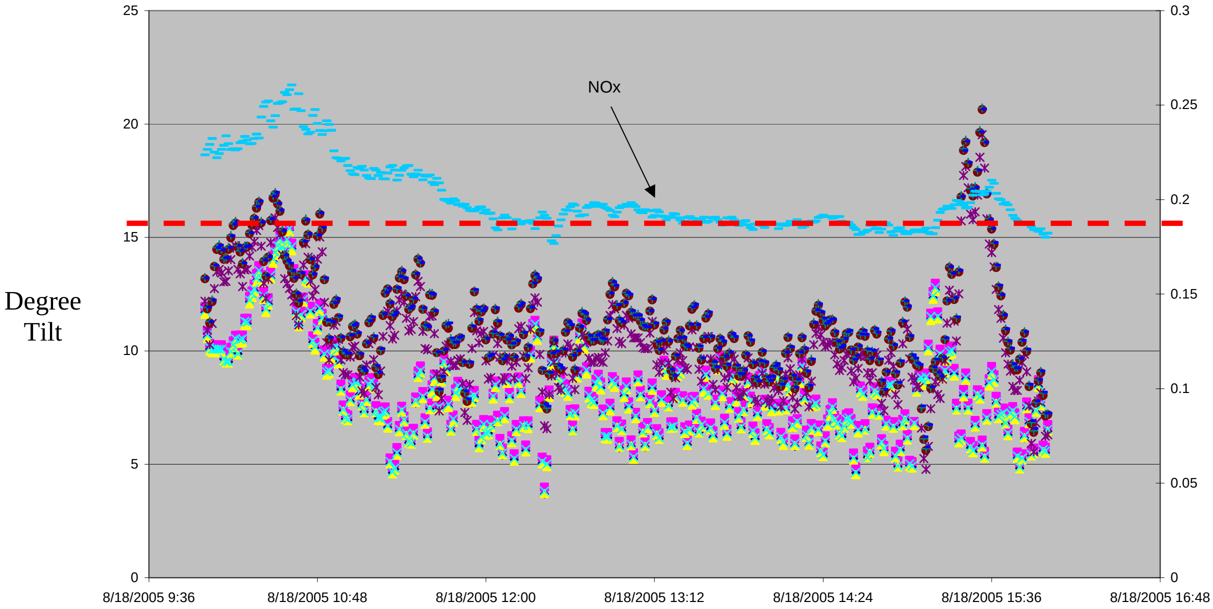

Figure 3. – NOx versus Main Windbox Tilts Over an Extended Period

The above graph shows the NOx and tilts as a function of time. As more overfired air was introduced into the furnace to lower NOx (by opening up the SAS 11 and 12), the main burner tilts were lowered while still controlling steam temperatures. It is clearly evident that fluctuations in NOx coincide with tilt perturbations. The rather drastic increase in NOx around 15:36 was caused by the raising of the A furnace tilts followed by the more marked increase in the B furnace tilts (above 20 degrees).

Recommendations

Based on this evaluation we offer three options that could be applied depending on Great River Energy's short and long-term goals

A. Current Operation:

Based on these evaluation tests, unit #1 should be able to operate at MCR closer to 0.19 lb /MBtu NOx level, with no modification but a few operational changes. This is approximately a 15% reduction from current levels

1. SOFA tilts should be set at + 12 degrees
2. The CCOFA curves (SAS 11 and 12) should be modified so they are 100% open at full load. Specifically they should be optimized to go 100% open at 90 % load, which will match the tested load condition during the time of the Foster Wheeler visit.
3. Further reduction in NOx may be realized by making modifications to the existing steam temperature control logic. Currently, the tilts modulate a fair

amount, which causes fluctuations in NOx of approximately ±0.01 lb/MBtu (over the range observed). (It should be noted that main windbox tilts were not optimized for NOx during this visit.)

4. Lower NOx should be realized with main windbox tilts lower, however some parametric testing would be needed to assess how steam temperatures are affected. Some changes to sootblowing cycles may be warranted to allow lower tilt operation.
5. Operation with a pulverizer out of service would also significantly aid toward maintaining higher overfire air levels. Besides lower NOx emissions it would provide improved DP control and more open auxiliary air dampers.

B. Modifications for 0.17 lbs NOx/MBtu:

Reducing NOx levels closer into the 0.17 levels would require diverting more secondary air to both the CCOFA and SOFA levels. We believe this NOx level could be still be achieved with the current SOFA windboxes and some additional modifications in the main windboxes.

Specifically our model shows that the following changes would be required.

New reduced flow area horizontally adjustable boundary air nozzle tips and new oil nozzle tips would be required. These are required to maintain nozzle tip velocities and nozzle tip cooling being lost due to diverting more secondary air to the SOFA, but also to maintain windbox to furnace DP and damper control. Besides staying cooler, they would also be less prone to slagging for a longer service life. This would be designed to our latest double shroud design standards.

Larger venturi over the coal and auxiliary air dampers would also be required in the main windboxes. These would reduce damper leakage and allow the auxiliary dampers to be at a more open position then current dampers for the same DP. Currently, increased staging is limited by the 10% limit on main windbox auxiliary dampers and the flow restrictions of the existing SOFA nozzle tips.

The following equipment (per unit) would need to be installed:

Item	Quantity	Description
1	Thirty two (32)	Reduced flow area, double shroud front removable section boundary air nozzle tips with full tilt and yaw capability. Matl: 309 SS
2	Twenty four (24)	Reduced flow area, tilting oil nozzle tips. Matl: 309 SS
3	One Hundred Twenty (120)	Venturi damper plates, one for each fuel air and boundary air compartment to further reduce the damper/area tip ratio. Matl. Carbon Steel
4	One lot	Revised SAMA drawings

5	Two Hundred (200) hours	Startup and optimization support for Reevaluating the damper curves regarding impact on the combustion process, furnace slagging, etc. Examination of boiler operational parameters including windbox-furnace DP, boiler O2, fuel/air staging and main burner tilt control.

For budgeting purposes, we estimate approximately $500,000 for the above scope on a D&S basis and approximately another $500,000 for installation.

C. Modifications for 0.15 lbs NOx/MBtu:

From the recent testing and our modeling, long term, NOx levels in the 0.15 lb/MBtu range will not be achieved without substantially increasing separated overfire air flow. At the current 20% SOFA air staging, the lower furnace is bright and free of “sparklers”. An additional 10 % staging could be appreciated with minimal boiler performance issues.

To achieve this objective, Foster Wheeler would recommend installing an additional level of SOFA windboxes and associated tube panels, ducts, hanger, etc. The challenge is to get the added SOFA flow, taking into account the high primary air flow percentage with all mills in service. For this we would be looking a duct arrangement that “scoops” secondary air from the secondary air ductwork rather than rely on windbox backpressure through venturi and nozzle tips. We would need to study the take-offs for this and CFD model the design to confirm the expected results.

The objective with this proposed modification is to divert the existing CCOFA air to the new SOFA windboxes. Separated overfired air is nearly twice as effective in reducing NOx as compared to close-coupled overfire air (CCOFA). Because of this fact, the existing CCOFA nozzles would be downsized and venturis added to the CCOFA dampers to achieve this objective.

Specifically, the following equipment (per unit) would need to be installed:

Item	**Quantity**	**Description**
1	Eight (8)	Separated SOFA windboxes sized for approximately 10% of total combustion air, with tilting and yawable double shroud nozzle tips and static pressure taps for air flow measurement, etc. Windbox material: Carbon Steel; Nozzle tip material: 309SS.
2	One (1) lot	Complete secondary air duct system for the SOFA system including ducts, hangers expansion joints, flow diverting vanes or scoops, and associated support steel.
3	Sixteen (16)	Reduced flow area, double shroud CCOFA nozzle tips. Matl: 309 SS

4	Sixteen (16)	Venturi damper plates, one for each CCOFA compartment to optimize the damper/area tip ratio. Matl. Carbon Steel
5	One session (1)	CFD modeling of secondary and OFA ducting to optimize duct design
6	Eight (8)	Waterwall tube panels to incorporate SOFA.
7	Five Hundred (500) hours	Startup and optimization support for Reevaluating the damper curves regarding impact on the combustion process, furnace slagging, etc. Examination of boiler operational parameters including windbox-furnace DP, boiler O2, fuel/air staging and main burner tilt control.

For budgeting purposes, we estimate approximately $1,000,000 for the above scope on a D&S basis and approximately another $1,000,000 for installation.

Conclusions:

Lower NOx operation in the range of 0.19 lb/MBtu should be achievable with the current equipment. Only a few operational changes are needed to realize these emission levels. The tilting SOFA nozzle tips have been optimized to produce the lowest NOx possible at +12 degrees with the current equipment.

For NOx emissions, in the range of 0.17 lb/MBtu, it will require additional equipment and operational modifications. Specifically this would include smaller main windbox boundary and oil nozzle tips along with damper venturis. These modifications will allow Coal Creek to "push" more SOFA air, maximizing the modifications within the current constraints of the primary air, existing SOFA ducts and windboxes.

For NOx emissions in the range of 0.15 lb/MBtu, about 10% additional overfire air would be required to reliably achieve these levels. This will require additional separated overfire air by installing an additional level. The objective would be to have the capability of introducing 30% of the total combustion air as separated overfire air.

We hope this information is helpful and are available to discuss this assessment and or other considerations with Great River Energy. Foster Wheeler has thoroughly enjoyed working with the Coal Creek Station and personnel and looks forward to future projects and discussions.

SCR catalyst performance in flue gases derived from subbituminous and lignite coals

Steven A. Benson*, Jason D. Laumb, Charlene R. Crocker, John H. Pavlish

Energy and Environmental Research Center, University of North Dakota, PO Box 9018, Grand Forks, ND 58202-9018, United Sates

Accepted 1 July 2004

Abstract

Lignite and subbituminous coals from the United States of America have characteristics that impact the performance of catalysts used in selective catalytic reduction (SCR) for nitrogen oxide removal and mercury oxidation. Typically, these coals contain ash-forming components that consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. The alkali and alkaline-earth elements are partitioned between reactions with minerals and reactions to form alkali and alkaline-earth-rich oxides during combustion. The particles resulting from the reaction with minerals produce low-melting-point phases that cause a wide range of fireside deposition problems. The alkali and alkaline-earth-rich oxides consist mainly of very small particles (<5 μm) that are carried into the backpasses of the combustion system and react with flue gas to form sulfates, and possibly carbonates. These particles cause low-temperature deposition, blinding, and plugging problems in SCR systems. These coals also contain the very low levels of chlorine that are necessary for mercury oxidation. Slipstream testing was conducted at two selected subbituminous-fired power plants and one lignite-fired power plant to determine the impacts of ash on SCR plugging, blinding, and mercury oxidation. The results indicated a high potential for

Keywords: Coal; Selective catalytic reduction (SCR); Blinding; NO_x; Mercury; Oxidation

---

1. Introduction

Selective catalytic reduction (SCR) for NO_x control and mercury oxidation was investigated using a slipstream reactor at power plants firing subbituminous and lignite coals to determine the potential for ash plugging, catalyst blinding, and mercury oxidation. SCR units lower NO_x emissions by reducing NO_x to N_2 and H_2O. Ammonia (NH_3) is the most common reducing agent used for the SCR of NO_x. The SCR process involves the use of a metal oxide catalyst such as titanium dioxide-supported vanadium pentoxide catalyst (V_2O_5). These units are operated at about 340–370 °C (650–700 °F). Subbituminous and lignitic coals are known for their ability to produce alkali and alkaline-earth sulfate-bonded deposits at low temperature (<1000 °C) in utility boilers. The mechanisms of the formation of low-temperature sulfates have been extensively examined and modeled by the Energy and Environmental Research Center (EERC) in work termed Project Sodium and Project Calcium in the early 1990s [1,2]. Deposit buildup of this type blinds or masks the catalyst, diminishing its reactivity for converting NO_x to N_2 and water and potentially creating increased ammonia slip [3]. Elemental mercury oxidation has been observed in laboratory-, pilot-, and full-scale testing using SCR catalysts [4–6]. In these studies, the metal oxides, V_2O_5 and TiO_2, have been shown to promote the conversion of elemental mercury to oxidized and/or particulate-bound mercury. Full-scale tests in Europe [7] and the United States [8] have indicated that the V_2O_5 and TiO_2 catalyst may promote the formation of oxidized mercury. The ability to oxidize mercury is largely dependent on the composition of the coal [8].

Lignite and subbituminous coals produce ash that plug and blind catalysts [9–12]. The problems currently being experienced on SCR catalysts include the formation of sulfate- and phosphate-based blinding materials on the surface of catalysts and the carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing them on top of the SCR catalysts [3]. The most significant problem that limits the successful application of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates, phosphates, and possibly carbonates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency [3,11–14]. The degree of the ash-related impacts on SCR catalyst performance depends upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design [11–15].

Cichanowicz and Broske [13] conducted tests on a South African and a German Ruhr Valley coal and found that the German Ruhr Valley coal significantly increased the pressure drop across the catalyst because of the accumulation of ash. They found that the German coal produced a highly adhesive ash consisting of alkali (K and Na) sulfates. In addition, they reported that the alkali elements are in a water-soluble form and highly

mobile and will migrate throughout the catalyst material, reducing active sites. The water-soluble form is typical of organically associated alkali elements in coals. The German Ruhr Valley coal has about 9.5% ash and 0.9% S on an as-received basis, and the ash consists mainly of Si (38.9%), Al (23.2%), Fe (11.6%), and Ca (9.7%), with lower levels of K (1.85%) and Na (0.85%) [13]. Cichanowicz and Muzio [14] summarized the experience in Japan and Germany and indicated that the alkali elements (K and Na) reduced the acidity of the catalyst sites for total alkali content (K+Na+Ca+Mg) of 8–15% of the ash in European power plants. Licata et al. also found that alkaline-earth elements such as calcium react with SO_3 on the catalyst, resulting in plugging of pores and a decrease in the ability of NH_3 to bond to catalyst sites. The levels of calcium in the coals that caused blinding ranged from 3% to 5% of the ash. Studies conducted on the impact of alkali elements associated with biomass found that, when biomass is fired, poisoning and blinding of SCR catalysts occurred [16,17].

The slipstream reactors were installed at three power plants. Two of the plants were cyclone fired: one with lignite and one with subbituminous coal. The third plant was a pulverized-coal, tangentially fired unit with subbituminous coal. The slipstream reactors were designed to expose SCR catalysts to flue gas and particulate matter under conditions that simulate gas velocities, temperatures, and ammonia injection of a full-scale plant. The control system maintains catalyst temperature, pulse air to remove accumulated deposits, constant gas flow across the catalyst, and records pressure drops and temperatures. The reactor was operated in an automated mode and can be controlled via modem connection. Testing at each power plant was conducted over a 6-month period. The reactor was inspected and cleaned at 2-month intervals, and a catalyst section was removed for analysis. The

Table 2
Key selection criteria

Field test 1—Columbia Station
Tangentially fired boiler to show differences in ash partitioning as compared to cyclone-fired systems. High-potential-blinding coal in Caballo, which can be burned nearly 100% for the entire test.
Field test 2—Baldwin Station
Plant is cyclone fired. Units are already equipped to do slipstream testing. Plant currently fires a blend of Antelope and tires; plant is willing to fire 100% Antelope. High potential blinding coal in Antelope.
Field test 3—Coyote Station
Cyclone-fired with lignite. High potential blinding with high alkali and alkaline-earth elements. Coal can have very high sodium contents and is known to cause significant low-temperature deposition.

Table 3
Ultimate analysis results (dry basis)

	Antelope	Caballo	Beulah

Oxygen (by difference)	16.61	18.96	20.35

catalysts and associated ash deposits were analyzed to determine the characteristics of the ash on the surface and in the pores. In addition, the mercury speciation in the flue gas upstream and downstream of the catalyst was conducted at 2-month intervals during the testing at the lignite-fired plant. The ability of the SCR catalyst materials to catalyze gaseous elemental mercury (Hg^0[g]) to a more soluble and chemically reactive $Hg^{2+}X(g)$ forms was evaluated, along with the potential increase in particle-associated mercury, Hg(p). Increasing the oxidized and particulate fractions of mercury has the potential to increase the capture efficiency of mercury by conventional control devices such as wet flue gas desulfurization (FGD) scrubbers and electrostatic precipitators (ESPs).

This paper summarizes pressure drop, formation of deposits that blind the surface of the catalyst, and the ability of SCR catalysts to oxidize mercury.

2. Experimental

2.1. Overview of test program and fuel characteristics

A portable SCR slipstream reactor system was designed and constructed to conduct full-scale evaluation of the SCR catalyst ash plugging and blinding and mercury oxidation. A particle-laden flue gas slipstream was isokinetically extracted from the flue gas duct ahead of the air heater at full-scale utilities using an induced-draft fan. Two systems were constructed

Table 4
Ash composition (wt.% equivalent oxide)

Oxide	Antelope	Caballo	Beulah
SiO_2	24.82	26.70	16.50
Al_2O_3	13.55	16.60	13.30

SO_3	16.33	14.40	19.80

so that data may be collected simultaneously from two full-scale sites. Testing was conducted at three boilers, including tests on a cyclone boiler firing Powder River Basin (PRB) coal, a lignite-fired cyclone boiler, and a pulverized coal boiler burning PRB. SCR catalysts were exposed to flue gases and combustion-derived fly ash particles for 6-month time periods to study the blinding effect of fly ash and ash deposits on catalyst performance.

The electric utility units selected for testing are shown in **Table 1**. The plants where the SCR slipstream system was installed included Alliant Energy's Columbia Station, Dynegy's Baldwin Station, and Otter Tail Power Company's Coyote Station. **Table 1** describes the plants, and **Table 2** summarizes the characteristics and selection criteria.

The units tested were selected based on the fuels fired, boiler type, and availability of the unit for sampling. The average composition of the coals fired during the testing is

listed in **Tables 3 and 4**. The subbituminous coals were typically low ash, nominally 4.5% to 5.5% with very high levels of calcium in the ash. In comparison, the lignite contains higher levels of ash and lower calcium but higher levels of sodium. The alkali and alkaline-earth elements are primarily associated with the organic matrix of the coal as salts of carboxylic acid groups [18]. The portion of the ash-forming components that are associated with the organic matrix of the coal for subbituminous coal ranges from 30% to 60% [18]; for the lignite coal, the portion is about 20% to 40%. The remaining ash-forming components consist of mineral grains. For these coals, the percent organically associated is 29% for the Antelope, 36% for Caballo, and 19% for Beulah. The minerals present in the coals determined by computer-controlled scanning electron microscopy (CCSEM) analyses are listed in **Table 5**. The primary minerals present in the subbituminous coals include quartz and various clay minerals with some pyrite and a mineral that is rich in Ca, Al, and P. This mineral has been identified in some coals as crandalite. The primary minerals found in the Beulah coal include clay minerals (kaolinite), pyrite, and quartz.

2.2. SCR slipstream system

The SCR slipstream system consists of two primary components: the control room and the SCR reactor. The reactor section consists of a catalyst section, an ammonia injection system, and sampling ports for NO_x at the inlet and exit of the catalyst section. The control

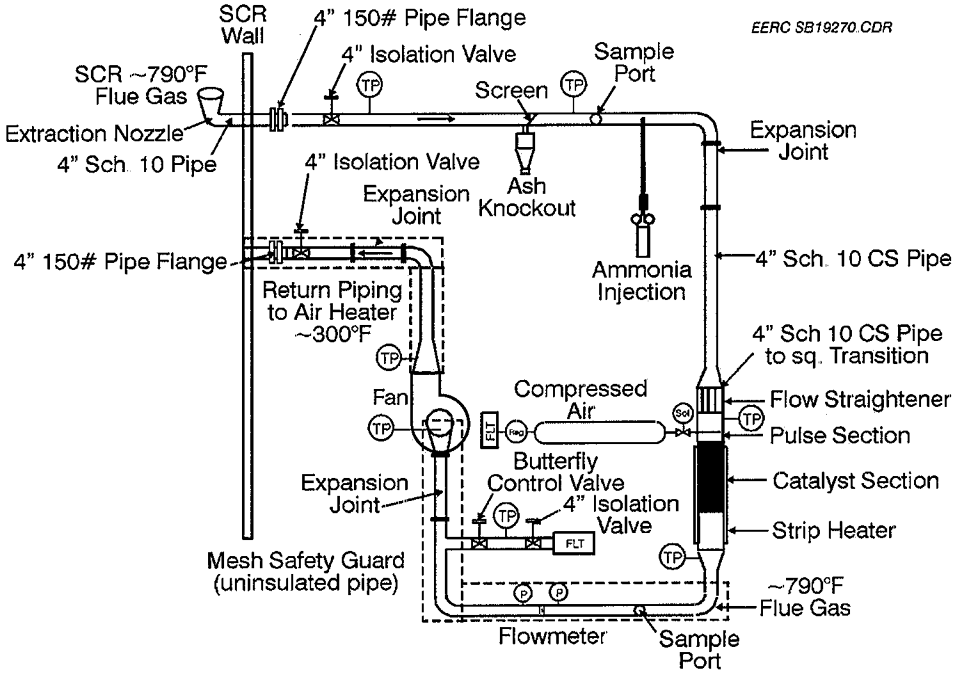

Fig. 1. Schematic diagram of SCR slipstream system.

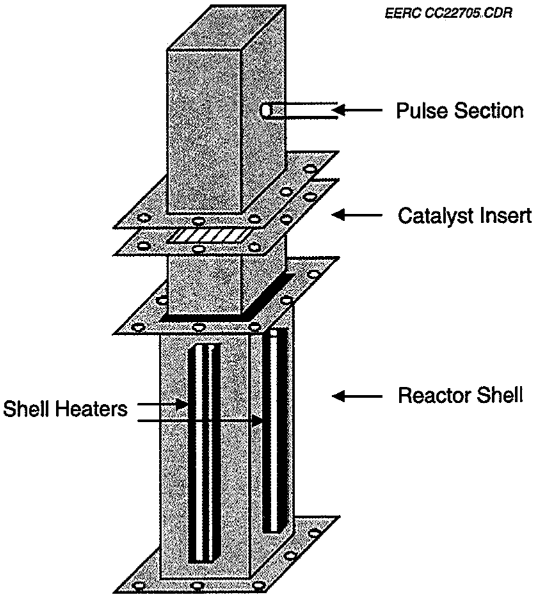

Fig. 2. Diagram of reactor section SCR slipstream system.

room houses a computer system that logs data and controls the gas flow rates, temperatures, pressure drop across the catalyst, and sootblowing cycles. The computer was programmed to maintain constant temperature of the catalyst, gas flow rates, sootblowing cycles, and ammonia injection. The computer is equipped with a modem that

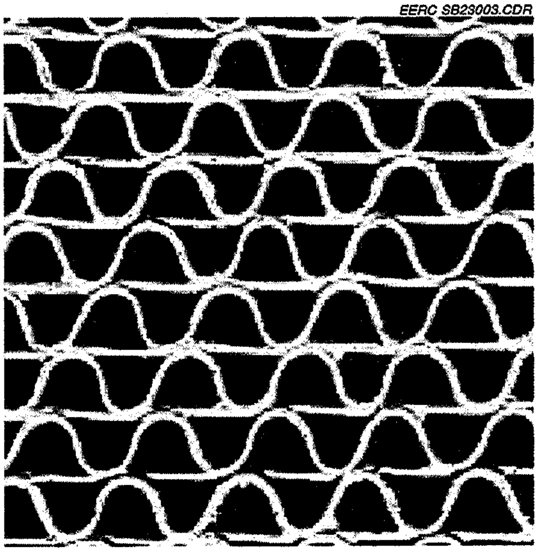

Fig. 3. Haldor Topsoe SCR catalyst showing the gas flow passages.

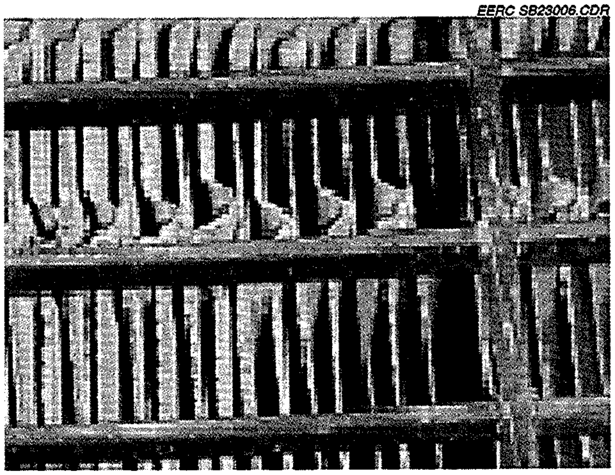

Fig. 4. Babcock Hitachi SCR catalyst showing the gas flow passages.

allowed for downloading of data and modification of the operation of the reactor from a remote computer located at the EERC.

A schematic diagram of the SCR slipstream system is shown in Fig. 1. Flue gas is isokinetically extracted from the convective pass of the boiler upstream of the air heater. The temperature is typically about 790 °F. The flue gases pass through a 4-in. pipe equipped with sampling, thermocouple, and pressure ports. Ammonia is injected into the piping upstream of the reactor section. The reactor consists of a steel housing that is approximately 8.5 in. square and 8 ft long. The reactor section illustrated in Fig. 2 has three components, including a flow straightener, a pulse section or sootblower, and a catalyst test section. A metal honeycomb is used as a flow straightener upstream of the catalyst section and is about 6 in. long. A purge section was installed ahead of the catalyst test section to remove accumulated dust and deposits. The catalyst test section is located downstream of the purge section. The entire catalyst section is insulated and equipped with strip heaters for temperature control. The catalyst test section is 3.28 ft (1 m) in length and houses three catalyst sections. Thermocouple and pressure taps are located in the purge sections for measurements before and after each section.

The induced-draft fan is used to extract approximately 400 acfm (200 scfm) of flue gas from the convective pass of the utility boiler to achieve an approach velocity of 5.2 m/s

Table 6
Selected operating conditions of the SCR catalysts

Plant name	Average SCR inlet temperature (°F)	Average SCR outlet temperature (°F)	Air pulse frequency	Flue gas flow rate (acfm)
Baldwin	645	549	Once per day and on demand	393
Columbia	672	662	Once per day and on demand	385
Coyote	675	667	Once per day and on demand	385

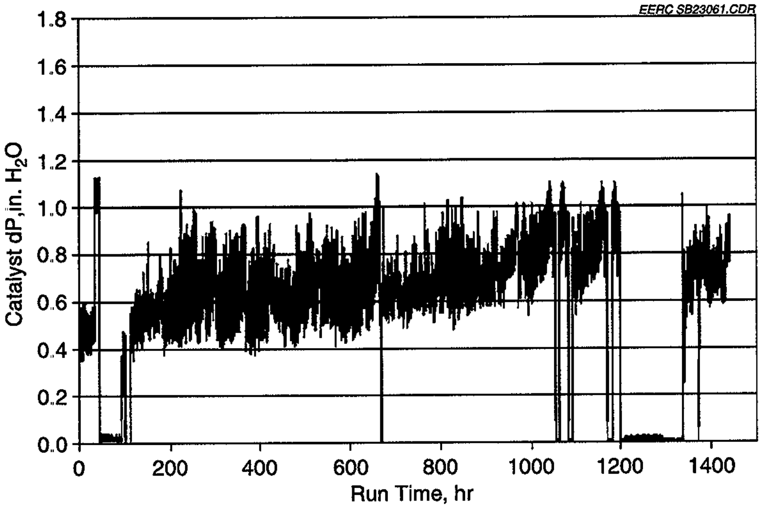

Fig. 5. Catalyst pressure drop at Baldwin Station at 0 to 2 months of operation.

(17.0 ft/s). The total gas flow through the reactor represents a thermal load of approximately 300 kW.

The range of operating conditions for the reactor is listed below:

- Gas temperature: ~700–800 °F
- Gas flow rate: 400–500 acfm
- Approach velocity range: 5.0–5.5 m/s
- Ammonia injection rate: 0.5:1 with NO_x level
- Tempering air for fan: ~50–200 scfm

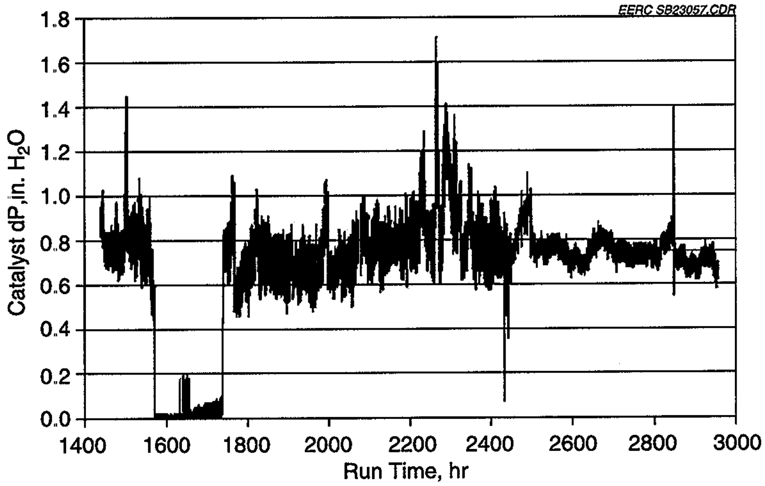

Fig. 6. Catalyst pressure drop at Baldwin Station at 2 to 4 months of operation.

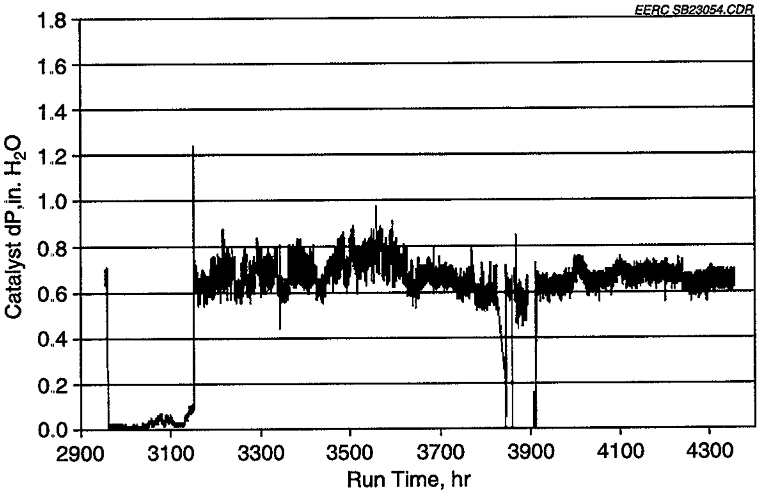

Fig. 7. Catalyst pressure drop at Baldwin Station at 4 to 6 months of operation.

- Catalyst dP: 0.5–1.0 in. water column
- Fan sized for up to 30 in. water column.

2.2.1. SCR catalyst

The catalyst installed at the Baldwin and Coyote Stations was the Haldor Topsoe catalyst. Topsoe's DNX-series of catalysts comprises SCR DENOX catalysts tailored to suit a comprehensive range of process requirements. DNX-series catalysts are based on a corrugated, fiber-reinforced titanium dioxide (TiO_2) carrier impregnated with the active components vanadium pentoxide (V_2O_5) and tungsten trioxide (WO_3). The catalyst is shaped to a monolithic structure with a large number of parallel channels. The unique catalyst design provides a highly porous structure with a large surface area and an ensuing

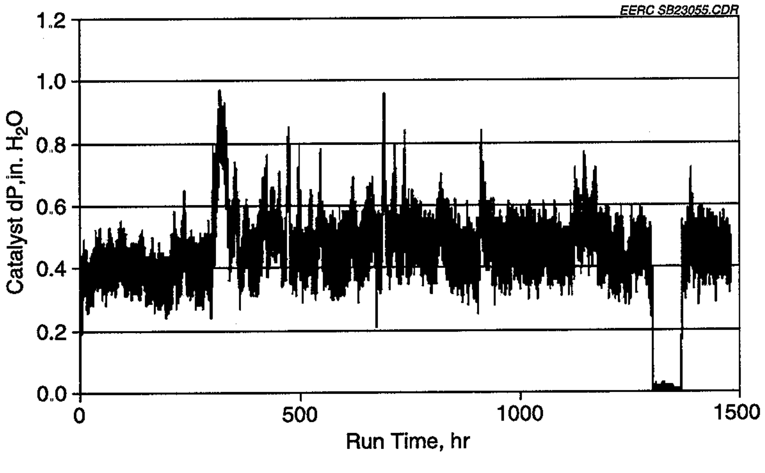

Fig. 8. Catalyst pressure drop at Columbia Station at 0 to 2 months of operation.

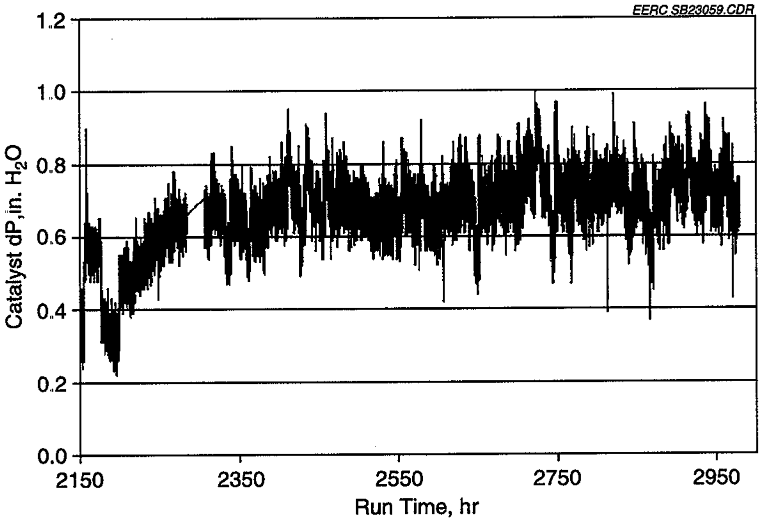

Fig. 9. Catalyst pressure drop at Columbia Station at 2 to 4 months of operation.

large number of active sites. Fig. 3 is an image of the Haldor Topsoe SCR catalyst. The pitch of the catalyst was approximately 6 mm.

The catalyst installed at the Columbia Station was a Babcock Hitachi plate-type catalyst. This catalyst is a TiO_2-based plate catalyst, developed and manufactured by Hitachi. Fig. 4 shows the design of the catalyst. The pitch of the catalyst was approximately 10 mm.

2.2.2. System performance measurement

Upon installation at each utility boiler unit, flue gas temperature, composition, and velocity measurements were obtained using portable equipment. Shakedown testing of the

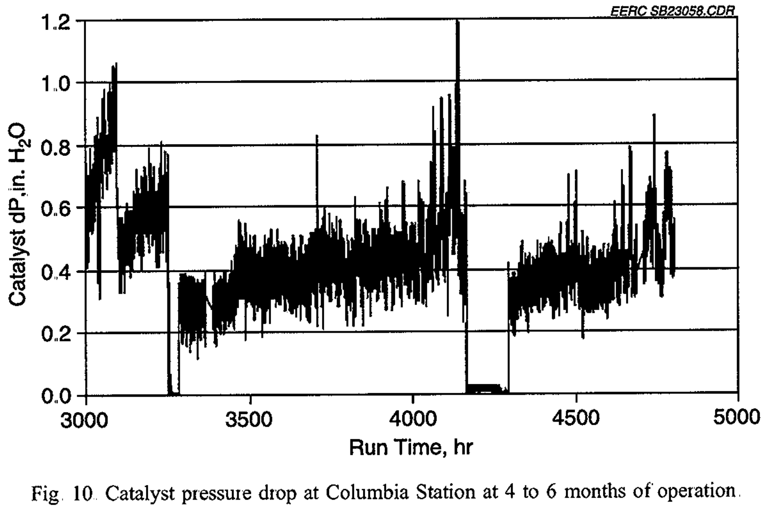

Fig. 10. Catalyst pressure drop at Columbia Station at 4 to 6 months of operation.

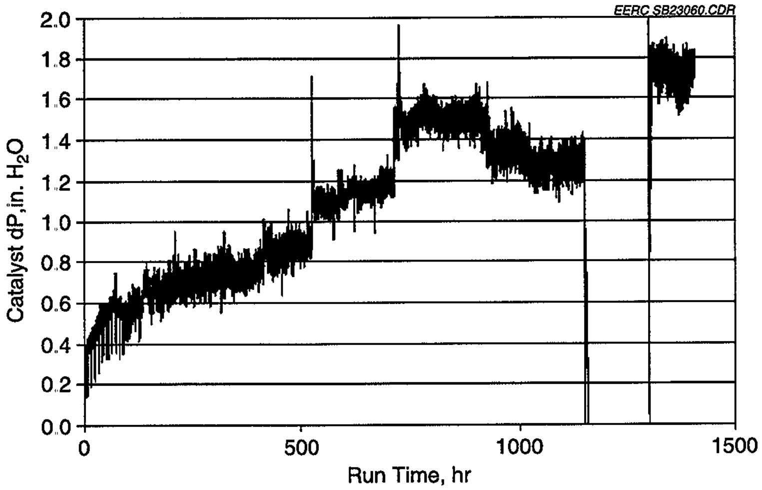

Fig. 11. Catalyst pressure drop at Coyote Station at 0 to 2 months of operation.

unit was conducted to ensure that all components were operating properly and that data were being logged and could be retrieved. After installation and shakedown were completed, the reactor was operated in a computer-controlled, automated mode and monitored on a daily basis to ensure proper operation and data quality. During operation of the SCR slipstream system, catalyst temperature, sootblowing frequency, and pressure drop across the catalyst were monitored and logged. Samples of the exposed SCR catalyst and associated deposits were obtained after exposure to flue gas and particulate for 2, 4, and 6 months. The samples of the catalyst were analyzed to determine the components that were bonding and filling pores, resulting in decreased reactivity.

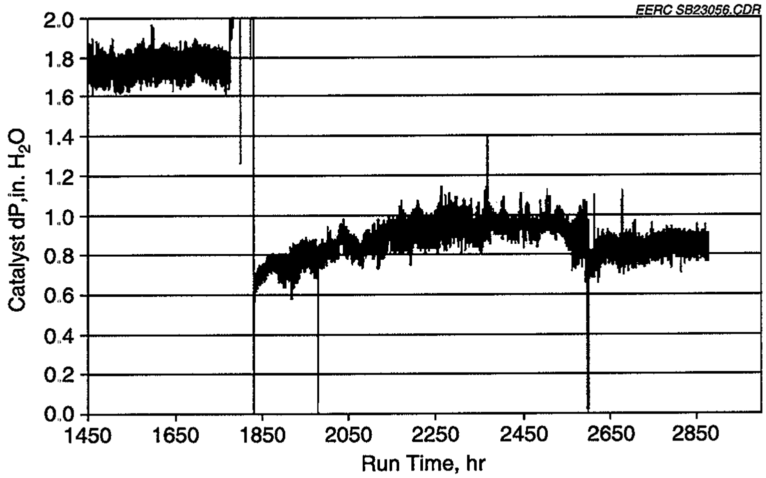

Fig. 12. Catalyst pressure drop at Coyote Station 2 to 4 months of operation.

The characteristics of ash that accumulated on the catalyst were examined using SEM–X-ray microanalysis and X-ray diffraction (XRD) [18]. Correlations between the physical and chemical characteristics of any ash deposits on the SCR test section and entrained-ash sample collected at the chamber inlet and the coal inorganic composition will be made to

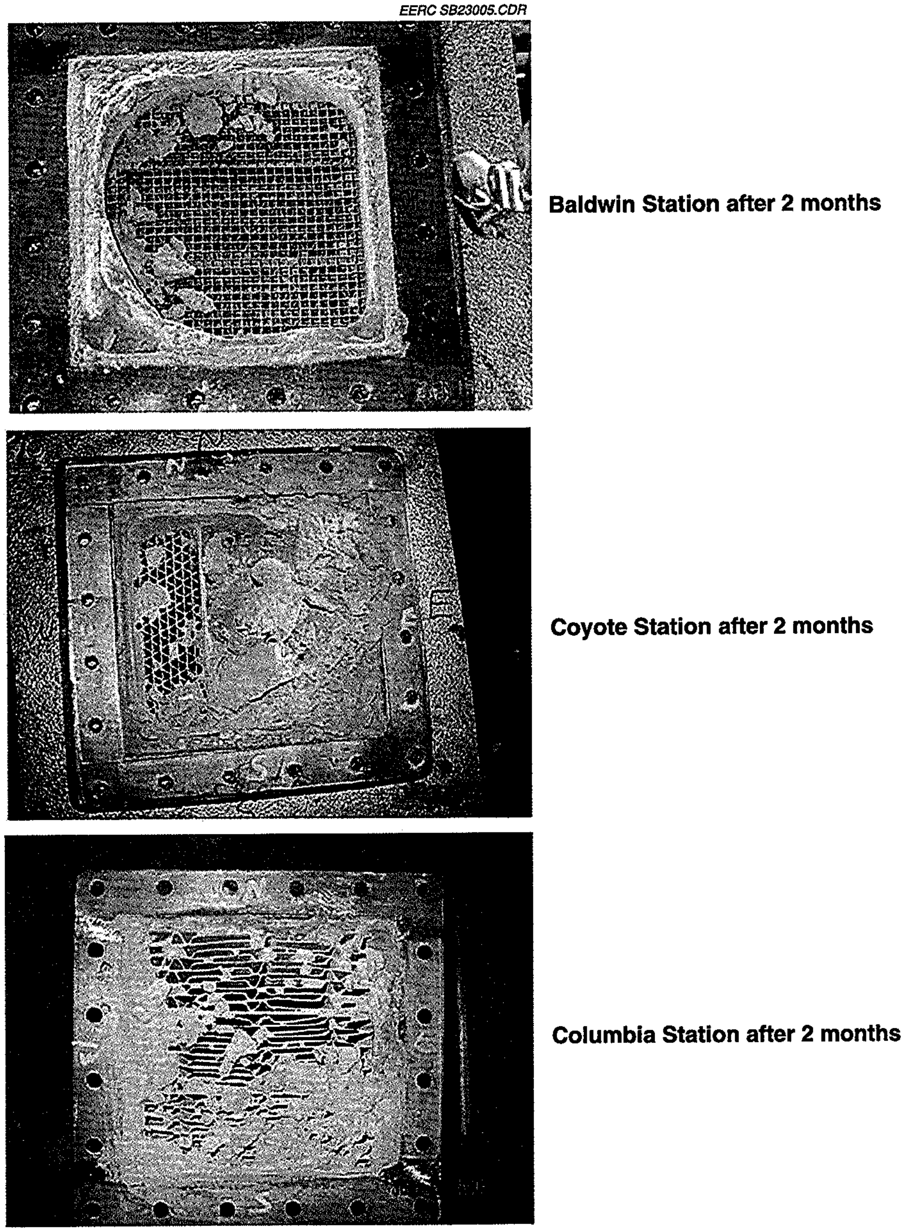

Fig. 13. Pictures of catalyst inlet after about 2 months of testing at each plant.

discern mechanisms of SCR blinding. Entrained ash was collected at Columbia Station only and characterized to composition and size.

2.3. Analysis of flue gas constituents across the catalyst—Ontario Hydro method for mercury speciation

At the Coyote Station, the Ontario Hydro (OH) mercury speciation sampling train was used to determine mercury forms across the SCR test section. The OH extractive mercury speciation sampling technique was used to measure potential mercury conversion across the SCR system over a period of several hours after fresh installation of the SCR test chamber and again just prior to removal of SCR catalyst sections.

The procedure used to conduct the mercury speciation sampling was American Society for Testing and Materials (ASTM) Method 06784-02 entitled "Standard Test Method for Elemental, Oxidized, Particle-Bound and Total Mercury in Flue Gas Generated from Coal-Fired Stationary Sources (Ontario Hydro Method)" [19].

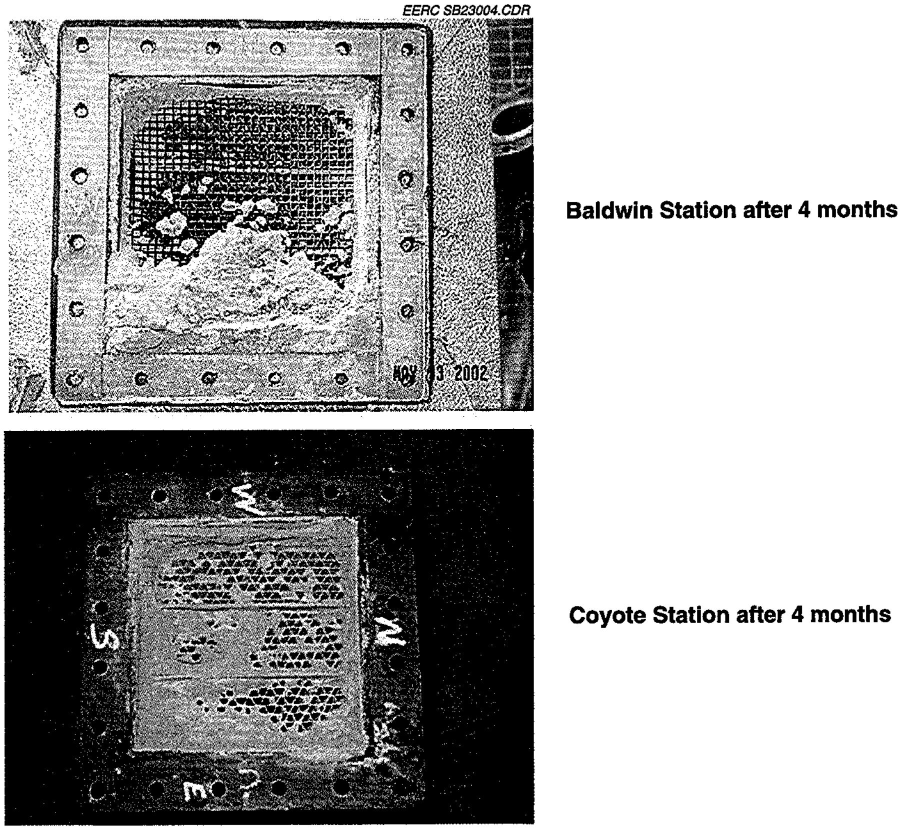

Fig. 14. Pictures of catalyst inlet after about 4 months of exposure to flue gas and particulate.

The OH method follows standard EPA methods for isokinetic flue gas sampling (EPA Methods 1–3 and EPA Method 5/17). A sample is withdrawn from the flue gas stream isokinetically through the filtration system, which is followed by a series of impingers in

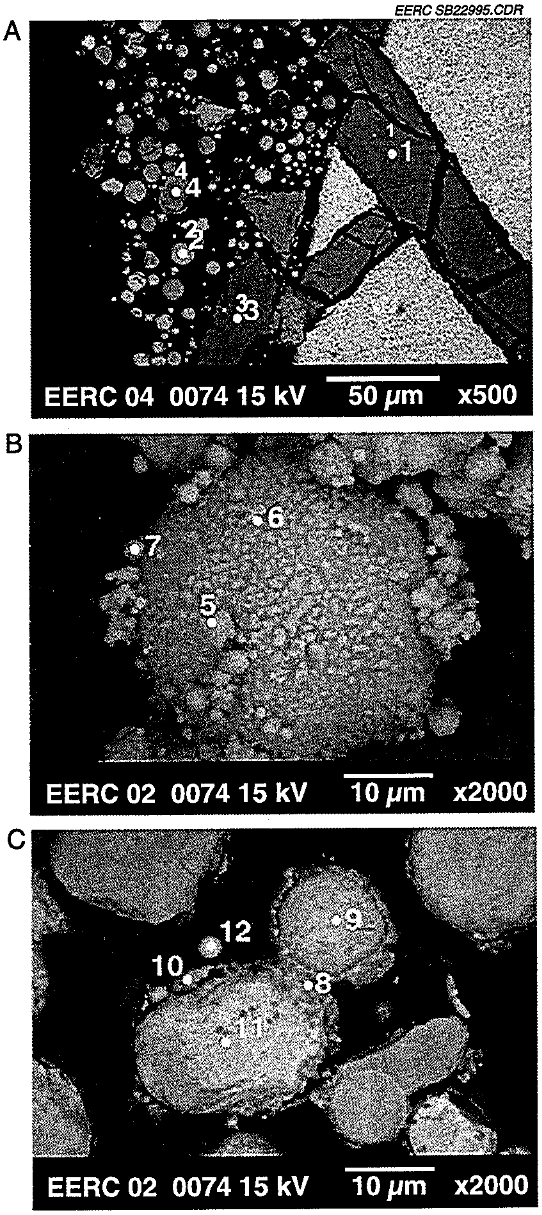

Fig. 15. SEM images of ash collected on catalyst surface at the Baldwin Station after 2 months of exposure. (A) Low-magnification image of ash deposit on catalyst surface, (B) high-magnification image of coated ash particle, and (C) high-magnification image of polished cross section showing coatings on particles.

an ice bath. Particulate-bound mercury is collected on the filter; Hg^{2+} is collected in impingers containing 1 N potassium chloride solution; and elemental mercury is collected in one impinger containing a 5% nitric acid and 10% peroxide solution and in three impingers containing a solution of 10% sulfuric acid and 4% potassium permanganate. An impinger containing silica gel collects any remaining moisture. The filter media is quartz fiber filters. The filter holder is glass or Teflon-coated. An approximate 2-h sampling time was used, with a target sample volume of 1 standard cubic meter.

3. Results and discussion

3.1. Pressure drop

3.1.1. Testing at the Baldwin Station

The reactor was installed at the Baldwin Station and operated for a 6-month time period on the Haldor Topsoe catalyst. The information obtained from testing included pressure drop, sootblowing cycles, and reactor temperatures. Table 6 summarizes the operating conditions of the reactors during the testing periods at all plants. Figs. 5–7 show the pressure drop across the catalyst test periods from 0 to 2 months, 2 to 4 months, and 4 to 6 months, respectively. During the first 2 months of operation, the pressure shown in Fig. 6 was about 0.5 in. of water; at the end of 2 months, the pressure drop was about 0.8 in. of water, indicating plugging had occurred. The air was pulsed a minimum of every 8 h in an attempt to maintain cleanliness. The reactor was monitored on a daily basis, and adjustments in pulsing cycles were made in order to minimize deposit accumulation. However, for the first 2 months, the pressure drop steadily increased. There are several periods where the unit was taken off-line; during those times, the temperature of the catalyst was maintained. At 2-month intervals, a section of catalyst was removed and replaced with a new one.

Table 7

Total	100	100	100	100	100	100	100	100	100	100	100	100

For Months 2 through 4, the pressure drop was highly variable initially but was about 0.8 in. of water. From Months 4 through 6, the pressure drop was maintained between 0.6 and 0.8 in. of water. This is due to the installation of a fresh catalyst section and leaving two thirds of the catalysts in place that partially plugged. The gas velocity in the single section of new, clean catalyst was high because of channeling, and the result of the high gas flow was less deposition and accumulation. Gas velocity has a significant impact on the potential for deposits to form. However, at high gas velocity, low NO_x conversion is likely.

3.1.2. Testing at Columbia

The reactor was installed at the Columbia Station and operated for a 6-month period of time for the Babcock Hitachi catalyst. The information obtained from the testing included pressure drop information, sootblowing cycles, and reactor temperature. Table 6 shows the reactor temperature, air-pulsing cycles, and airflow rates. Figs. 8–10 show the test periods from 0 to 2 months, 2 to 4 months, and 4 to 6 months, respectively. The pressure drop across the SCR upon installation was about 0.4 in. of water and increased to an average of

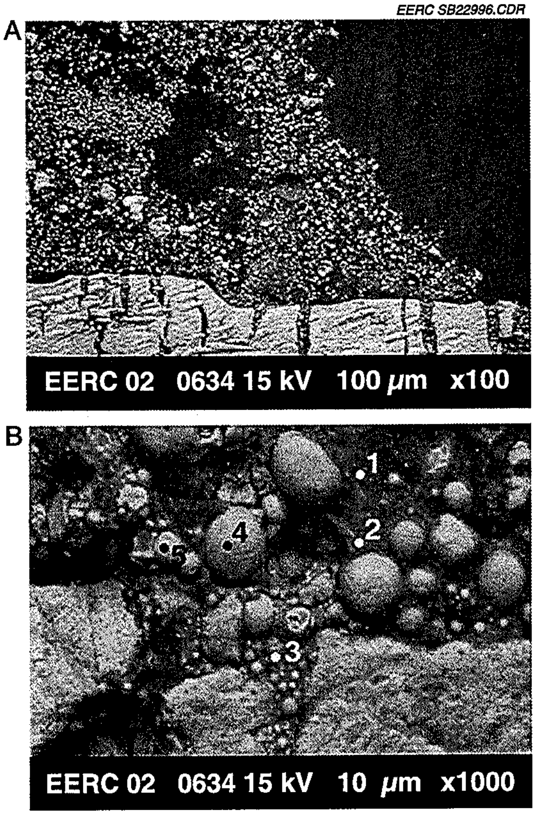

Fig. 16. SEM images of ash collected on catalyst surface at the Baldwin Station after 4 months of exposure. (A) Low-magnification image of ash deposit on catalyst surface, and (B) high-magnification image of polished cross section showing particles in a matrix of calcium- and sulfur-rich materials.

about 0.5 in. of water, but ranged from less than 0.4 to greater than 0.8 in. of water. **Fig. 9** shows the pressure drop for Months 2 to 4. The pressure drop increased from about 0.5 to 0.7 in. of water because of accumulation of ash. **Fig. 10** shows a rapid increase in pressure drop across the catalyst at about 3000 h of operation, and aggressive pulsing brought it down to 0.4 in. of water until the catalyst section was changed out at about 3200 h. After cleaning the reactor and replacing one catalyst section, the pressure drop was about 0.3 but increased to over 0.6 in. of water up to about 4100 h. There was an outage at the plant, and aggressive pulsing of the reactor was conducted; the pressure drop was brought back down to 0.3 but rapidly increased to over 0.5 in. of water within 500 h.

3.1.3. Testing at Coyote

The same reactor that was installed at the Baldwin Station was moved and installed at the Coyote Station. In addition, the same Haldor Topsoe catalyst was used in the reactor. The cleaning cycles, temperatures, and gas flow rates are listed in **Table 6**. The reactor was operated for a 6-month period of time. **Figs. 11 and 12** show the test periods from 0 to 2 months and 2 to 4 months. As this paper is being prepared, the reactor is still operating on-site. The pressure drop across the catalyst upon installation was about 0.4 in. of water. After only 750 h, the pressure drop was 1.5 in. of water, indicating significant plugging. Very aggressive air pulsing was conducted, with little success in removing the deposits. The pressure drop for the catalyst was over two times greater than the pressure drop observed for the Baldwin Station utilizing the same reactor and same catalyst. At about 1700 h, the reactor was cleaned, and a section of catalyst was removed for characterization. The pressure drop after cleaning was about 0.8 to 1.0 in. of water. The pressure drop did not increase as rapidly because of the higher velocities through the clean section of the catalyst.

3.1.4. Visual observations of deposit characteristics

The tops of the catalysts were photographed during inspection and sampling of the catalyst sections. **Fig. 13** shows the ash materials that accumulated on the catalyst inlet after 2 months of operation. The most significant accumulation was noted for the Coyote

(A and B) Low-magnification images of ash deposit on catalyst surface and (C) high-magnification image of polished cross section showing particles in a matrix of calcium- and sulfur-rich materials.

Station, followed by Columbia and Baldwin. The Coyote Station had some larger pieces of ash deposit material on the surface as well as plugging of the catalyst passages. The Baldwin Station showed some obvious deposition along the walls of the reactor and some accumulation on the inlet sections. The Columbia Station showed more significant accumulation and plugging than the Baldwin Station.

After 4 months, the tops of the catalysts were photographed during inspection and sampling of the catalyst sections, as shown in Fig. 14. The most significant accumulation was noted for the Coyote Station and some accumulation for the Baldwin Station.

3.2. Deposit characteristics

The characteristics of the ash materials that collected on the catalyst surfaces and pores were characterized by SEM and X-ray microanalysis and, in selected cases, XRD was used to determine the crystalline phases present. The catalysts were sampled after 2, 4, and 6 months. The sections were sampled, and approximately 2.5-cm squares were mounted for SEM analysis on double-stick tape and in epoxy resin. The double-stick tape samples allowed for characterization of the external morphology of the particles and catalyst surface. The samples mounted in resin were cross-sectioned and polished, which allowed for more detailed and quantitative analysis of the bonding materials and materials that accumulated in the pores of the catalyst.

3.2.1. Plugging deposit characteristics

3.2.1.1. Baldwin Station deposits. Samples of catalyst were removed from the Baldwin Station after exposure to flue gases and particulate after 2, 4, and 6 months. Fig. 15 shows the characteristics of the ash deposit material on the SCR catalyst after 2 months of exposure. This is a polished cross section of a deposit on the surface of the catalyst. Fig. 15A shows particles on the surface of the catalyst that range in size from <1 to 15 μm. The larger particles range from oxides of solely silicon and iron to complex mixtures rich in

aluminum and calcium; aluminum, silicon, and calcium; aluminum, calcium, and iron; and sodium, calcium, aluminum, and silicon. Chemical analysis of selected particles is summarized in Table 7. The samples of ash mounted on double-stick tape allow for the characterization of the external surfaces of the particles. The surface of a typical particle that is accumulating on the surface of the catalyst is shown in **Fig. 15B**. The blebs on the surface are composed of calcium and sulfur, with some iron and minor amounts of sodium and potassium. **Fig. 15C** shows a cross section of the deposited particles showing calcium- and aluminum-rich particles bonded together with a calcium- and sulfur-rich phase. This phase is in the form of calcium sulfate based on XRD analysis conducted on the deposited ash samples.

The 4-month sample from the Baldwin Station showed more extensive sulfation of the alkaline-earth elements present in the deposits. **Fig. 16** shows the images of a polished cross section of an ash deposit on the surface of the catalyst. The deposit formed both on the surface of the catalyst and within the catalyst pores as shown in **Fig. 16A**. **Fig. 16B** shows a higher magnification view of the deposit on the catalyst surface. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The chemical composition of selected points shown in **Table 8** shows high levels of calcium and sulfur. There is much more extensive bonding of the materials with the sulfate matrix as compared to the 2-month sample.

The 6-month sample from the Baldwin Station showed extensive sulfation of the alkaline-earth elements present in the deposits. **Fig. 17A and B** shows regions of the catalyst where all the pores were blocked and a minimal amount of deposit on the surface of the catalyst. **Fig. 17C** shows a higher magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The chemical compositions of selected points that indicate the presence of high levels of calcium and sulfur are listed in **Table 9**. There is much more extensive bonding of the materials with the sulfate matrix as compared to the 2-month sample. In addition, there are some regions of high levels of calcium, aluminum, and sulfur present. The calcium aluminum materials are likely derived from the calcium aluminum phosphate minerals found in the coal fired at this plant.

magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The presence of sodium enhances the bonding and sulfation of the particles to form a strongly bonded matrix.

The 4-month sample from the Coyote Station showed particles adhering to the surface and completely filling and masking the pores in the catalyst as shown in **Fig. 22**. **Fig. 22A** shows the external morphology of the catalyst surface showing the masking of the catalyst surface. Chemical compositions of selected points are shown in **Table 14**. The 4-month sample shows more sulfation than the 2 months of exposure samples. **Fig. 22B and C** shows a higher magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of sodium-, calcium-, and sulfur-rich material, likely in the form of calcium sulfate. The presence of sodium and potassium enhances the bonding and sulfation of the particles to form a strongly bonded matrix. Significant sodium was found in the deposits, as shown in **Table 14**.

3.2.2. Deposit formation mechanisms

The mechanism for the formation of deposits that blind SCR catalysts involves the transport of very small particles rich in alkali and alkaline-earth elements, the surface of the catalyst, and reactions with SO_2/SO_3 to form sulfates. The formation of SO_3 from SO_2 is catalyzed by the SCR; this, in turn, increases the reaction rate of SO_3 to form sulfates. In some cases, the alkali and alkaline-earth elements will also react with CO_2 to form carbonates. XRD analysis shown in **Fig. 23** identified $CaSO_4$ as a major phase and $Ca_3Mg(SiO_4)_2$ and $CaCO_3$ as minor phases.

Lignite and subbituminous coals contain high levels of organically associated alkali and alkaline-earth elements including sodium, magnesium, calcium, and potassium, in addition to mineral phases. The primary minerals present in these coals include quartz, clay minerals, carbonates, sulfates, sulfides, and phosphorus-containing minerals [18].

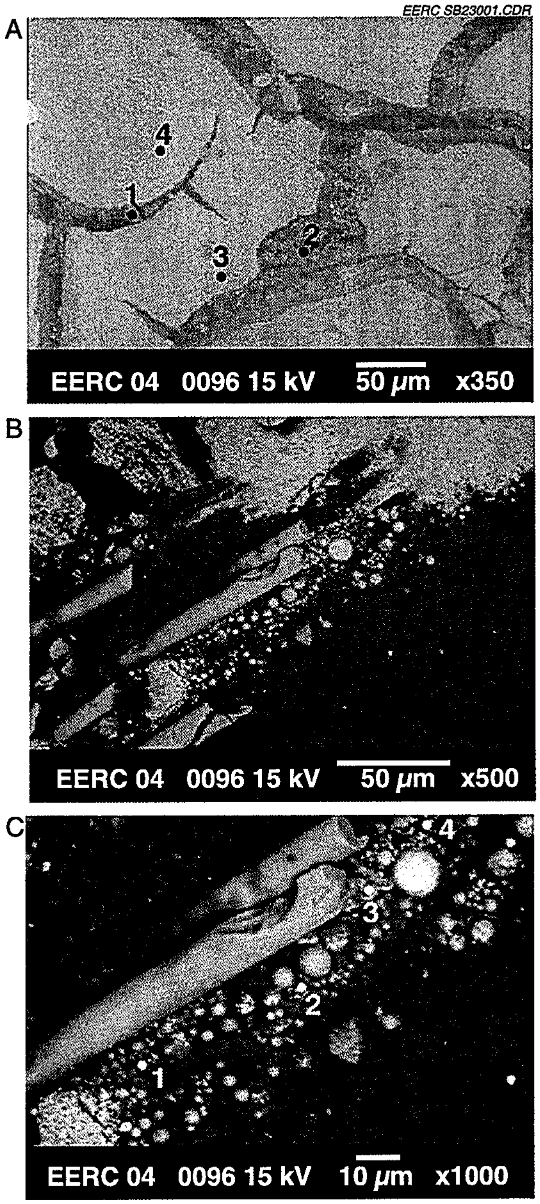

Fig. 21. SEM images of ash collected on catalyst surface at the Coyote Station after 2 months of exposure. (A) Low-magnification image of ash deposit on catalyst surface, (B) low-magnification image of polished cross section showing particles in a matrix of calcium- and sulfur-rich materials, (C) higher magnification image of bonding.

During combustion, the inorganic components in the coal are partitioned into various size fractions based on the type of inorganic component, their association in the coal, and combustion system design and operating conditions. There has been

Table 13
Chemical composition of selected points and areas in **Fig. 21**

Oxide	Point 1	Point 2	Point 3	Point 4
Na_2O	0.9	0.7	1.2	1.0

Total	100	100	100	100

significant research conducted on ash formation mechanisms and relationships to impacts on power plant performance [18–34]. Typically, during combustion the inorganic components associated with western subbituminous and lignite coal are distributed into various size fractions of ash, as shown in Fig. 24. The results shown in Fig. 24 were obtained from isokinetic sampling and aerodynamically size-fractionating ash particles from a full-scale pulverized-coal-fired boiler firing subbituminous coal and analyzing each size fraction. The results show that the smaller size fractions of ash are dominated by partially sulfated alkali and alkaline-earth elements. These ash particles are largely derived from the organically associated cations in the coal. The larger size fraction has higher levels of aluminum and silicon derived from the mineral fraction of the ash-forming component of the coal. Entrained ash was extracted from the Columbia Station at the point of the inlet to the SCR reactor and was aerodynamically classified and analyzed. The composition of the size fractions was compared to the chemical composition of the ash deposited on and in the catalyst, as shown in Fig. 25. The comparison shows that the composition of the particle captured in the SCR catalyst is very similar to the <5-μm size fraction. The deposited material shows significantly more sulfation than the entrained-ash size fraction, indicating that the sulfation process occurs after the particles are deposited in the catalyst.

The mechanism of SCR catalyst blinding when firing lignite or subbituminous coals is shown in Fig. 26 [35]. The requirements for the formation of deposits that blind SCR catalyst include firing a coal that produces significant levels of <5-μm-sized particles. The particles are transported into the pores of the catalyst and subsequently reacted with SO_3 to form sulfates. The sulfate forms a matrix that bonds other ash particles. The SCR catalyzes the formation of SO_3 and thereby increases the rate of sulfation [9,15]. The sulfation of CaO increases the molar volume, resulting in the filling of the pore. For coals that have high sodium contents, formation of low-melting-point phases such as pyrosulfates are possible [36]. Pyrosulfate materials can melt at temperatures as low as 535 °F in coal-fired power systems.

(A) Low-magnification image of ash deposit on catalyst surface, (B) low-magnification image of polished cross section showing particles in a matrix of calcium- and sulfur-rich materials, (C) higher magnification image of bonding.

3.3. Flue gas measurements

3.3.1. Mercury transformations

The ability of mercury to be oxidized across the SCR catalyst was investigated at the Coyote Station. The Coyote Station is fired on North Dakota lignite, and the flue gases are dominated by elemental mercury. Measurement of mercury speciation was conducted using the OH method at the inlet and the outlet of the SCR catalyst. The measurements were made upon installation of the catalyst and after 2 and 4 months of operation. The

Total	100	100	100	100	100	100	100	100	100	100

results of the mercury speciation measurement at the inlet and outlet of the SCR catalyst conducted upon installation are shown in Fig. 27. The inlet and outlet measurements were repeated three times and are shown in Fig. 27. The level of elemental mercury at the inlet was approximately 76% to 92%, with the remaining in the oxidized form ranging from 8% to 24%. Very little was in the form of particulate mercury at the inlet. Measurement of mercury speciation was conducted with the ammonia on and off. The results with the ammonia off showed an increase in the oxidized mercury to 43% of the total mercury occurring across the SCR catalyst. However, when the ammonia was introduced into the

Fig. 24. Simplified illustration of ash partitioning in combustion systems [18].

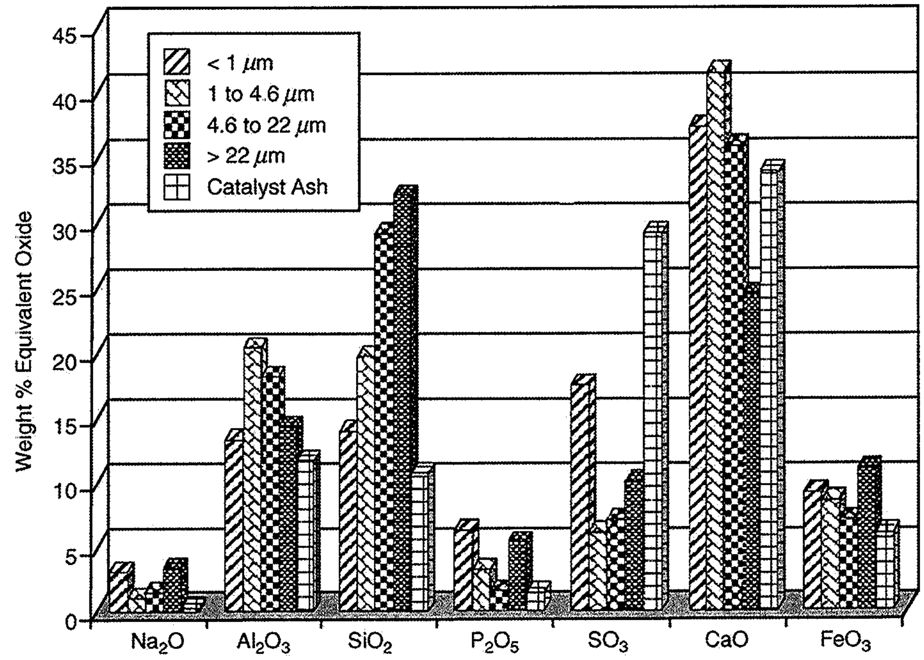

Fig. 25. Comparison of entrained ash and deposited ash on catalyst for Columbia Station.

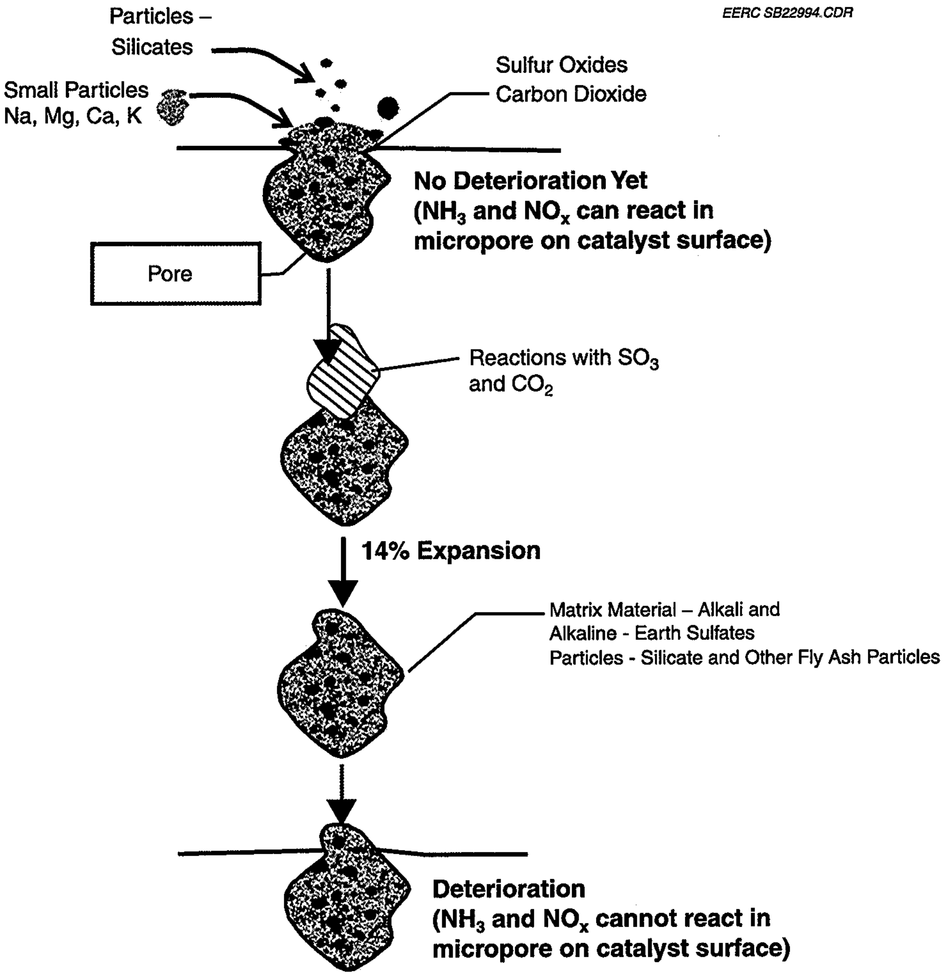

Fig. 26. Mechanism of SCR catalyst blinding via the formation of sulfates and carbonates (modified after Pritchard et al. [35]).

SCR catalyst, the amount of mercury oxidation decreased from 43% to 19%. There was an increase in the particulate mercury from 1.0% to 7.2%.

The mercury oxidation after the SCR catalyst was exposed to flue gas and particulate for 2 months is shown in Fig. 28. The level of oxidized mercury at the inlet ranges from 7.5% to 11.1% of the total mercury. The level of oxidized mercury at the outlet ranged from 7.6% to 14% of the total mercury. The level of particulate mercury increased from a negligible level to 3% of the total mercury at the outlet.

The results of mercury oxidation across the SCR catalyst after 4 months of exposure to flue gases and particulate are shown in Fig. 29. The results show a higher level of oxidized mercury at the inlet as compared to testing conducted at installation and after 2 months. The level of oxidized mercury at the inlet ranges from 32% to 38% of the total,

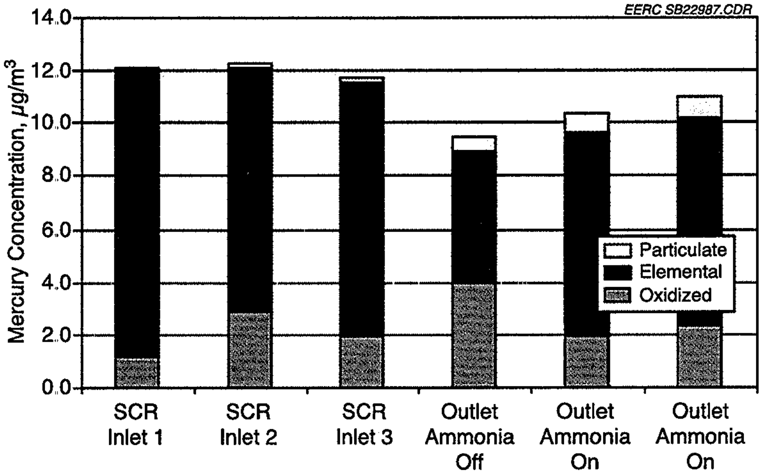

Fig. 27. Mercury speciation measurement at the inlet and outlet of the SCR catalyst upon installation of the catalyst.

with about 5% of the total in the particulate form. The outlet levels of oxidized mercury decrease after passing through the catalyst to about 20% of the total. The level of particulate mercury remained about the same across the catalyst.

4. Conclusions

A slipstream reactor is designed to expose SCR catalyst to coal combustion-derived flue gases and particulate. The system is computer-controlled and operates in an automated

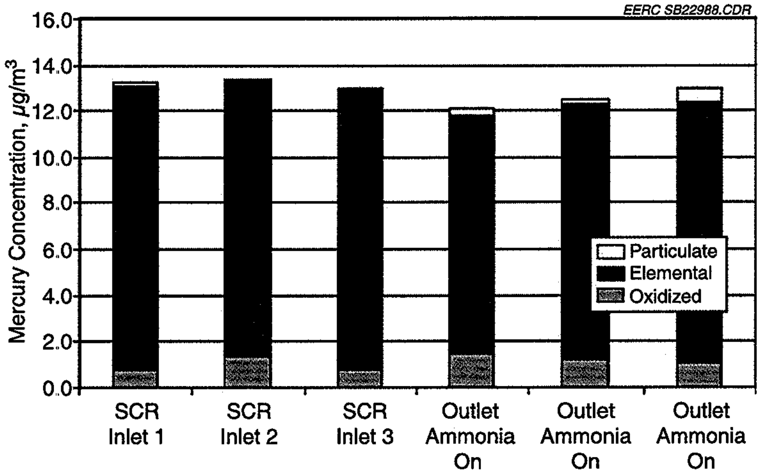

Fig. 28. Mercury speciation measurement at the inlet and outlet of the SCR catalyst after exposure to flue gases and particulate for 4 months.

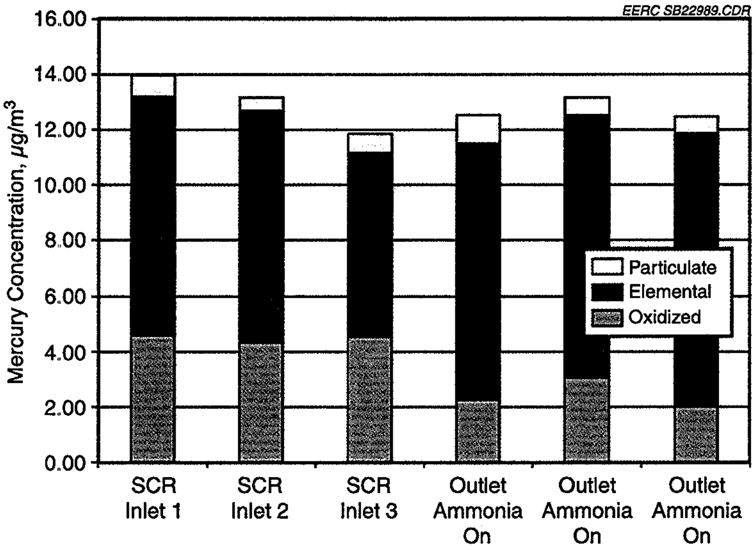

Fig. 29. Mercury speciation measurement at the inlet and outlet of the SCR catalyst after exposure to flue gases and particulate for 2 months.

mode. The system can be operated and monitored remotely through a modem connection. SCR catalyst testing was conducted at two subbituminous-fired plants and one lignite-fired plant. The boiler configurations for the subbituminous-fired plants included a cyclone- and a tangentially fired boiler. The boiler configuration for the lignite plant was a cyclone-fired system.

The pressure drop across the catalyst was found to be the most significant for the lignite-fired plant as compared to the subbituminous-fired plants. Both coals had significant accumulations of ash on the catalyst, on both macroscopic and microscopic levels. On a macroscopic level, there were significant observable accumulations that plugged the entrance as well as the exit of the catalyst sections. On a microscopic level, the ash materials filled pores in the catalyst and, in many cases, completely masked the pores within 4 months of operation.

The deposits on the surfaces and within the pores of the catalyst consisted of mainly alkali and alkaline-earth element-rich phases that have been sulfated. The mechanism for the formation of the sulfate materials involves the formation of very small particles rich in alkali and alkaline-earth elements, transport of the particles to the surface of the catalyst, and reactions with SO_2/SO_3 to form sulfates. XRD analysis identified $CaSO_4$ as a major phase and $Ca_3Mg(SiO_4)_2$ and $CaCO_3$ as minor phases.

Lignite and subbituminous coals contain high levels of organically associated alkali and alkaline-earth elements, including sodium, magnesium, calcium, and potassium in addition to mineral phases. During combustion, the inorganic components in the coal are partitioned into various size fractions based on the type of inorganic component and their association in the coal and combustion system design and operating conditions. The results of this testing found that the smaller size fractions of ash are dominated by partially sulfated alkali and alkaline-earth elements. The composition of the size fractions was compared to the chemical composition of the ash deposited on and in the catalyst. The comparison shows that the composition of the particle captured in the SCR catalyst is very similar to the <5-μm size fraction.

The ability of mercury to be oxidized across the SCR catalyst was investigated at the Coyote Station. The Coyote Station is fired on North Dakota lignite, and the flue gases are dominated by elemental mercury. Measurement of mercury speciation was conducted using the OH method at the inlet and the outlet of the SCR catalyst. These results show limited oxidation of mercury across the SCR catalyst when firing lignite coals. The reasons for the lack of mercury oxidation include the following: no or low chlorine present in the coal and flue gas to catalytically enhance the oxidation of Hg^0, high levels of alkali and alkaline-earth elements acting as sorbents for any chlorine present in the flue gas, and low levels of acid gases present in the flue gas.

This report describes research sponsored by EPRI.

The report is a corporate document that should be cited in the literature in the following manner:

Status and Performance of Best Available Control Technologies, EPRI, Palo Alto, CA: 2005. 1008114.

REPORT SUMMARY

This study is intended to provide a better understanding of the best available control technology (BACT) as required today in permits issued for new coal-fired power plants and to document the actual emissions performance of the emission control technologies on new units. The study focused on controls technologies, data reporting, initial test results, and permitting trends.

Background

EPRI has been working with its members to develop a plan that links near-term, tactically-focused work to the ultimate vision of "The Roadmap for the Electricity Sector." A key element of the plan is the development of Near Zero Emissions (NZE) plants that preserve the coal option. Qualitatively, NZE are defined as emissions virtually equivalent to those from gas-fired power plants except for CO_2.

This investigation is intended to provide a better understanding of best available control technology (BACT) proposed today for emission control as well as the performance of the most recently installed equipment on coal-fired power plants. Due to the time lag between permitting of a new coal-fired power plant and initial operation and emissions performance testing, it was necessary to consider units that have been permitted but not yet started up.

Objectives

- To compare the most recent permitted emissions levels to the actual emissions achieved by the newest plants in the generating fleet
- To provide direction for technology development for near zero emission plants by examining the control capabilities of the most recently installed technologies.

Approach

The project team examined the most recent permits that have been issued. It was necessary to examine permits issued as far back as 1997 in order to find plants that had sufficient operating data to examine with respect to initial operation. The focus of this report is on pulverized coal (PC) boilers and circulating fluidized bed (CFB) boilers in Rankine cycle plants. Integrated gasification combined cycle (IGCC) plants have very different needs because they use species capture devices before the addition of combustion air for both process reasons and because of emission constraints.

Results

Various technologies have been installed for SO_2 and NO_X; however, the fabric filter/baghouse is the overwhelming choice for particulate control. SO_2 control technologies were evenly divided between wet and dry technologies. For NO_X control the CFB units were dominated by selective noncatalytic reduction (SNCR), while the majority of PC units are equipped with low NO_x burners (LNBs) and selective catalytic reduction (SCR). Permitting trends for most emissions suggest an increasing tightening of control, and the initial operating experience shows that most of these units were able to achieve the permit limit. There is increasing interest in fine particulates, though little guidance on measurement methods.

EPRI Perspective

This report provides a distillation of available information on emissions control technologies for coal-fired generating stations. It provides a ready source of information on not only permit limits but also the ability to achieve these limits on start-up. Its summary of trends in permit limitation and rundown of recently installed technologies provide some insights into which technologies are appropriate for consideration when examining the development of NZE power stations.

INTRODUCTION

EPRI has been working with its members to develop a Plan that links the near-term, tactically-focused work to the ultimate vision of "The Roadmap for the Electricity Sector". A key element of the plan is the development of Near Zero Emissions (NZE) plants that preserve the coal option. Qualitatively, NZE is defined as being virtually equivalent to emissions from gas-fired power plants, with the exception of CO_2.

The focus is on pulverized coal (PC) boilers and circulating fluidized bed (CFB) boilers in Rankine cycle plants, as integrated gasification combined cycle (IGCC) plants have very different needs because they use species capture devices for both process reasons (before the addition of combustion air) and emission constraints. However, some of the findings and technologies for PC- and CFB-based plants could apply to the final pollution control systems in the stream of devices in IGCC plants. This investigation is intended to provide a better understanding of best available control technology (BACT) proposed today as well as the performance of the most recently installed equipment on coal-fired power plants. Due to the time lag between permitting of a new coal-fired power plant and initial operation and emissions performance testing, it is necessary to consider units which have been permitted but not yet started up.

2

RECENTLY PERMITTED U.S. COAL-FIRED ELECTRIC UTILITY UNITS

The list of units to include in the study was obtained from two sources:

- The RACT/BACT/LAER Clearinghouse (RBLC) database www.epa.gov/ttn/catc
- The National Coal-Fired Utility Projects Spreadsheet http://www.epa.gov/ttn/catc/dir1/natlcoal.xls

For purposes of this study, "recent" permits will be those issued during the calendar year 1997 or thereafter. Advanced queries were run on the RBLC database to find all facilities permitted in 1997 or after and having a Standard Industrial Classification (SIC) code of 4911 "Electric Services". Additionally, the RBLC listed "process" was examined to eliminate any units that were not coal-fired boilers. Added to this basic list were any additional units from the National Coal-Fired Utility Projects Spreadsheet. From this list, all citations for anything other than new coal-fired boilers were eliminated (e.g. modifications to existing boilers were eliminated). Lastly, all units which did not have an issued permit as of February 2005 were eliminated.

To determine the operational status of each unit, the state agency was contacted.

Included Units

Forty-four units at 31 facilities have been identified as meeting the requirements of this study (25 PC units, 19 CFB units). Twelve units are operational and eight of those have been stack tested. Table 2-1 lists the units included in this study. Table 2-2 summarizes each facility and Appendix A describes each facility in detail. Plants that were excluded from the study are listed in Appendix B.

Controls

PC and CFB boilers employ the types of emission control for the various pollutants that are effective for the boiler configuration and operating conditions. Emission controls can be integral to the combustion process or add-on equipment that is installed downstream of the combustion zone. The types of emission control employed for BACT at recently permitted utility boilers are described below. The specific control equipment utilized for each pollutant at each boiler unit identified in Table 2-1 is listed in Tables 2-3 through 2-6.

SO_2

The primary types of SO_2 control for the units in this study are circulating fluidized bed (CFB) combustion, wet flue gas desulfurization, and semi-dry flue gas desulfurization. Flue gas desulfurization (FGD) refers to the treatment of flue gas to remove the SO_2 which has formed during the combustion of fossil fuels. These controls are described in this section, including the prevalence of each type.

In the CFB combustion process, limestone is added to the boiler furnace, resulting in the removal of SO_2 during the combustion process. A grid supports a bed of coal and limestone in the firebox of the CFB boiler. Combustion air is forced upward through the grid, suspending the coal and limestone bed in a fluid-like motion. The sulfur in the coal is oxidized to SO_2 and consequently combines with calcined limestone to form calcium sulfate ($CaSO_4$). The flyash containing the calcium sulfate is collected in the downstream baghouse.

In the wet FGD process, a slurry of finely ground limestone ($CaCO_3$) in water is recirculated through an absorber tower and placed in turbulent contact with the flue gas. The contact between the flue gas and the slurry cools and saturates the gas stream as SO_2 and other acid gasses are absorbed into the slurry droplets. Calcium sulfate (gypsum) and calcium sulfite are formed in the chemical reaction that occurs in the slurry, which is typically dewatered and removed as a solid waste by-product.

CFB - circulating fluidized boiler

PC - pulverized coal boiler

In the semi-dry FGD process, boiler flue gas is taken from a point downstream of the air heater and introduced into a reactor vessel into which hydrated lime (calcium hydroxide, $Ca(OH)_2$) and water are added. The calcium hydroxide reacts with SO_2 that has been absorbed into the water to form calcium sulfite and calcium sulfate. The heat from the flue gas causes the water to evaporate, cooling the gas and drying the reaction products. The amount of water added to the process is carefully controlled so that the flue gas temperature is maintained safely above the saturation, or dew point, temperature. The reaction product leaves the reactor as fine particles entrained in the flue gas and is collected in the particulate control equipment (usually a baghouse) located downstream of the FGD equipment.

There are two main variants of the semi-dry FGD process: lime spray drying and fluidized bed (or circulating) dry scrubbing. They are differentiated by the type of reactor vessel used and the method in which water and lime are introduced into the reactor. In the lime spray drying process, quicklime (CaO) is slaked with water to form a slurry of calcium hydroxide. The lime slurry is mixed with additional water and sprayed into the reactor as finely atomized droplets. The turbulent mixing of the flue gas and the droplets of slurry promote rapid absorption of SO_2 into the water of the slurry droplets. The flue gas is cooled and humidified as the water evaporates from the droplets, leaving a dry powdered reaction product entrained in the flue gas along with any fly ash that entered the reactor. The entrained particles are collected in an electrostatic precipitator (ESP) or baghouse downstream. To enhance the lime utilization, a portion of the collected product is typically recycled back to the process. It is slurried with water and sprayed into the reactor along with the fresh lime slurry.

In the fluidized bed (or circulating) dry scrubbing process, the flue gas is introduced into the bottom of a reactor vessel at high velocity. The movement of the gas through the reactor suspends particles of fly ash and reaction products from the process that are introduced into the reactor, creating a fluidized bed. Dry, powdered, hydrated lime and/or ash product from the downstream particulate collection device is introduced into the bed within the reactor vessel. Water is sprayed into the reactor near the bottom of the bed under high pressure or mixed with the reagent/ash product before it is added to the reaction vessel. In the moist layer at the surface of the lime particles, calcium hydroxide reacts with the absorbed SO_2 to form calcium sulfite and calcium sulfate. The evaporation of water cools and humidifies the flue gas and maintains the bed in a slightly moist, powdery condition. The continuous motion of the bed prevents solids deposition, and promotes regeneration of the particle surfaces, exposing the lime to additional reaction with SO_2. Particles that are entrained in the flue gas leaving the top of the reactor are collected in an ESP or baghouse downstream. A large portion of the collected particles is recycled to the reactor, sustaining the bed and improving lime utilization.

Five of the 19 recently permitted CFB units identified in this study did not add additional SO_2 controls. The remaining fourteen units employed some variant of semi-dry FGD technology in combination with the SO_2 removal capability of the limestone injection to the CFB boiler.

Thirteen of the 25 recently permitted PC units used semi-dry FGD as their SO_2 control. Wet FGD was used at twelve PC units.

NO_x

The primary types of NO_x control for the units in this study are CFB combustion, selective non-catalytic reduction (SNCR), over-fire air (OFA), low NO_x burners (LNB), and selective catalytic reduction (SCR). These controls are described in this section, including the prevalence of each type.

The CFB combustion process has an inherently low level of NO_x emissions due to the combustion temperature. Combustion in a CFB boiler occurs at relatively low combustion temperatures ranging from 1,500 to 1,800 °F. Because thermal NO_x formation occurs at temperatures greater than 2,000 °F, the lower combustion zone temperatures in a CFB boiler significantly reduces NO_x production.

SNCR is an add-on control technology commonly applied to CFB boilers that utilizes ammonia or urea injection into the flue gas near the furnace exit or in the convective passes. Due to the high temperatures in these zones a catalyst is not needed for NO_x to react with ammonia to form nitrogen gas and water.

Overfire air technology reduces NO_x emissions within the normal combustion zone of the furnace without any chemical additives or alternate fuel. An OFA system reduces the formation of NO_x by inhibiting the immediate availability of oxygen to the fuel. OFA also reduces thermal NO_x by spreading the combustion over a larger volume in the boiler and lowering the combustion temperature in the lower part of the furnace.

An SCR system uses ammonia injected into the flue gas upstream of a catalyst placed downstream of the economizer exit to reduce NO_x to molecular nitrogen and water. The process is termed "selective" because the ammonia preferentially reacts with the NO_x rather than with the oxygen in the flue gas. A catalyst is used to achieve NO_x reduction by chemical reaction with ammonia to form elemental nitrogen and water at appropriate flue gas temperatures. Ammonia for use in an SCR system can come in one of two forms, anhydrous ammonia or aqueous ammonia. Another option is to use a dry urea storage system that generates ammonia on site as needed.

Three of the recently permitted CFB units did not use add on controls for NO_x, while 16 units used SNCR controls.

The controls for PC units were divided up into two groups: SCR, and LNB/ SCR. Three units used SCR, and 24 units used LNB and SCR controls.

PM_{10}

The principal types of PM_{10} control for the units in this study are electrostatic precipitator (ESP), fabric filter/baghouse (FF/BH), and multi clones. These controls are described in this section, including the prevalence of each type.

An electrostatic precipitator (ESP) removes solid or liquid particulate matter from a gas stream by imparting an electrical charge on the individual particle and collecting the charged particle to an oppositely charged surface. Most ESPs used in coal-fired boiler applications are dry, but some high-sulfur coal-fired units are now being permitted with a wet ESP (WESP) located in the saturated flue gas environment down stream of the wet FGD system. The purpose of the WESP is to collect sulfuric acid mist, which is a major component of the condensable fraction of the total particulate emissions. WESPs are not used as the primary particulate control device and either an ESP of a baghouse would be provided upstream of the wet FGD system to remove a majority of the fly ash.

Baghouses collect particulate matter on the surfaces of filter bags. Most of the particles are captured by impaction and sieving on already collected particles, which are present as a dust layer on the bags (dust cake). There are two major types of baghouses: reverse-air and pulse jet. In reverse air baghouse setups, the particulate-laden gas stream enters from the bottom and passes into the inside of the bag. Filtered gas passes through the dust cake on the inside of the bag and is exhausted. In order to clean this type of baghouse, some of the filtered gas is passed in a reverse direction (outside to inside the bag) to remove some of the dust cake. In pulse jet baghouses, the flue gas is passed through the outside of the bags thereby producing the dust cake on the exterior of the bags. These bags are cleaned by injecting a short pulse of compressed air, which removes some of the dust cake.

The multiclone is a mechanical collector sometimes used as a precollector upstream of an ESP, FF, or wet scrubber. These devices can be specified to reduce particle loadings and consequently reduce capital and/or operating costs for downstream equipment.

The primary particulate control technology identified in permits for the 19 recently permitted CFB boilers is a fabric filter (baghouse). Seventeen units used this control. Two CFB units were permitted for an ESP for particulate control.

Fabric filters were also the primary particulate control technology among recently permitted PC boilers, with 17 of the 25 units using this control method. Seven PC units used ESP as the primary particulate controls. ESPs are generally used for high-sulfur coal applications. A multi clone was identified in the permit as the particulate control technology to be used for one unit. Six PC units have been permitted with a WESP for control of the sulfuric acid aerosol downstream of a wet FGD system. Four of these units will use dry ESPs as the primary control upstream of the wet FGD. Two will use a fabric filter.

CO and VOC

VOC and CO emissions at all CFB and PC units are controlled by good combustion practices.

3

EMISSION LIMITS ACHIEVED IN PRACTICE

In order to determine the emissions levels that have been achieved in practice, data was gathered from the Acid Rain data submitted to the EPA.

The data gathered was not sufficient to determine if the pollution control equipment is being operated at its maximum performance level or at a lower level to provide a margin of safety. There are numerous factors that go into such an operating methodology, including the cost (energy, reagents, and maintenance) as well as allowances and compliance averaging periods. Although it seems logical that a "more powerful design" would achieve additional removal at the sacrifice of cost and operational reliability, no concrete data was found to support such a conclusion.

Electronic Data Reporting

The Clean Air Markets division of EPA maintains data from power plants as it is collected from the quarterly electronic data reports (EDRs) submitted by each facility. This database was queried to find the monthly emissions for the units included in this study (http://cfpub.epa.gov/gdm/). Data was pulled for reporting years 2001 through 2003 and is presented in Figures 3-1 through 3-8. The lb/MBtu values for NO_x were provided directly in the retrieved data. The lb/MBtu values for SO_2 were calculated from the retrieved tons SO_2/month and MBtu/month values.

NO_x and SO_2 emission limits that were not given as a 30-day average were converted to a 30-day average using the tpy limits and heat input of the unit. Where a conversion was made, it was noted in the general notes on Tables 2-3 through 2-6 for that facility and pollutant. No Acid Rain data was available for AES Puerto Rico.

Please note that the Acid Rain data is from monthly blocks of data not 30-day rolling averages. This may explain some of the instances where the Acid Rain data shows values higher than the limits.

Initial Test Results

Initial test data was available for eight units, as shown in Table 7. The data was obtained through the state agency or the facility and is for a 3-run average (not a 30-day rolling average). See Figures 3-9 through 3-12. Exceedances are shown for AES Puerto Rico on PM_{10} and TSP; however, results of a repeat stack test were not available from the agency. The limit for AES Puerto Rico was subsequently increased.

Permitting Trends

Permitting trends for SO_2, NO_X, and PM_{10} are shown in Figures 3-13, 3-15, and 3-17. These figures were generated to show trends and differences between the permitted emission limits established for units that are operating versus those that are not yet operating. Figures 3-14, 3-16, and 3-18 show trends and differences between permitted emission limits for PC boilers and CFB boilers.

The data in Figures 3-13 through 3-19 is based on permitted emission limits that are based on a Best Available Control Technology (BACT) analysis (i.e. control equipment capabilities). It does not include emission limits that were established from non-BACT criteria, such as the emission limits in NSPS, Subpart Da. For example, pollutants for some of the units replacing existing units did not exceed emission significance thresholds in the netting analysis. Consequently, these pollutants were able to net out of PSD review for those pollutants and be based a less stringent requirement such as NSPS, Subpart Da.

In regards to SO_2, no significant trends or differences between the permitted emission limits established for units that are operating versus those that are not yet operating were found for either CFB or PC units. Figures 3-13 and 3-14 show that the emission limits for operating and not yet operating units are in the same range with most of the emission limits being in the center of the range. CFB boilers have the largest range of limits ranging from 0.022 to 0.25 lb/MMBtu. The emission limits for PC boilers are concentrated around the 0.10 to 0.15 lb/MMBtu range. Both figures show downward trends in the SO_2 emission rates meaning that SO_2 emission limits are becoming more stringent.

In regards to NO_X, no significant trends or differences between the permitted emission limits established for units that are operating versus those that are not yet operating were found for either CFB or PC units. Figures 3-15 and 3-16 generally show that NO_x emission limits for PC units were slightly lower than for CFB boilers (i.e. about 0.08 lb/MMBtu for PC boiler, and about 0.10 lb/MMBtu for CFB boiler). The figures also show a slight downward trend in the NO_x emission limits for both CFB and PC units.

In regards to PM_{10}, no significant trends or differences between the permitted emission limits established for units that are operating versus those that are not yet operating were found for either CFB or PC units. See Figures 3-17, 3-18, and 3-19.

There is an increasing emphasis on speciation between filterable and condensable particulate matter and the appropriate limits for each. Specifying limits as to filterable only or both filterable and condensable is more common in recent years. In fact, the limit for AES Puerto Rico was changed from 0.015 lb/MMBtu to 0.03 lb/MMBtu in order to account for the condensable fraction of the particulate emissions.

Figures 3-18 and 3-19 show emission limits for "filterable" and "filterable and condensable" PM_{10} emissions. There are no distinct trends in the emissions data. With the exception of a couple outliers, the emissions limits for both types of PM_{10} are in the 0.015 to 0.02 lb/MMBtu range.

4
SUMMARY AND CONCLUSIONS

This investigation is intended to provide a better understanding of the best available control technology (BACT) being required today in permits issued for new coal-fired power plants and to document the actual emissions performance of the air pollution control technologies installed on new units that have recently begun operation. The study focused on four areas: emission controls used, electronic data reporting, initial test results, and permitting trends.

Controls

The types of emission control employed for BACT at recently permitted utility boilers were examined. Permitted SO_2, NO_x, PM_{10}, and CO and VOC controls were compiled from 44 units at 31 facilities. This included 25 PC units and 19 CFB units.

For CFB boilers, 26 percent of the facilities used no additional SO_2 controls. The other 74 percent used some variant of semi-dry FGD technology in combination with the SO_2 removal capability of the limestone injection to the CFB boiler. Semi-dry FGD and wet FGD were the two SO_2 control technologies used at PC facilities, with half of the units using each technology (13 semi-dry and 12 wet).

A majority of CFB units used SNCR to control NO_x emissions and three of the facilities did not use supplemental NO_x controls. Eighty-eight percent of the PC units used LNB and SCR controls, while 12 percent used SCR.

The primary particulate control technology identified in permits for CFB and PC boilers is a fabric filter (baghouse). Out of 44 total units, just seven PC units and two CFB units used ESPs for particulate control and one unit was permitted with a multiclone for particulate control.

VOC and CO emissions at all CFB and PC units are controlled by good combustion practices.

Electronic Data Reporting

Data from power plants as it is collected from the quarterly electronic data reports (EDRs) submitted by each facility was queried to find the monthly emissions for the units included in this study (http://cfpub.epa.gov/gdm/). Monthly data was downloaded for reporting years 2001 through 2003 for the eight operating new units that had data available. In general, the monthly average emissions of SO_2 and NO_x for each unit were consistently below the permit limits for the facilities with the exception of a few outliers.

Initial Test Results

Initial stack test data was available for eight units. The data was obtained through the state agency or the facility and is for a 3-run average (not a 30-day rolling average). All of the facilities met the permit limits for PM_{10}, TSP, CO and VOC, with the exception of the TSP test results dated 3/3/2003 for AES Puerto Rico. This limit was subsequently increased via a permit modification.

Permitting Trends

Permitting trends for SO_2, NO_X, and PM_{10} were generated to show trends and differences between the permitted emission limits established for units that are operating versus those that are not yet operating. Trends and differences between permitted emission limits for PC boilers and CFB boilers were also examined. Data based on permitted emission limits that are based on a Best Available Control Technology (BACT) analysis (i.e., control equipment capabilities) were used.

In regards to SO_2, no significant trends or differences between the permitted emission limits established for units that are operating versus those that are not yet operating were found for either CFB or PC units. The emission limits for operating and not yet operating units are in the same range with most of the emission limits being in the center of the range. CFB boilers have the largest range of limits ranging from 0.022 to 0.25 lb/MBtu. The emission limits for PC boilers are concentrated around the 0.10 to 0.15 lb/MBtu range. The results displayed a downward trend in the SO_2 emission rates meaning that SO_2 emission limits are becoming more stringent.

In regards to NO_X, no significant trends or differences between the permitted emission limits established for units that are operating versus those that are not yet operating were found for either CFB or PC units. The NO_x emission limits for PC units were slightly lower than for CFB boilers (i.e., about 0.08 lb/MBtu for PC boiler, and about 0.10 lb/MBtu for CFB boiler). The results indicated a slight downward trend in the NO_X emission limits for both CFB and PC units.

In regards to PM_{10}, no significant trends or differences between the permitted emission limits established for units that are operating versus those that are not yet operating were found for either CFB or PC units.

There is an increasing emphasis on speciation between filterable and condensable particulate matter and the appropriate limits for each. Specifying limits as to filterable only or both filterable and condensable is more common in recent years. In fact, the limit for AES Puerto Rico was changed from 0.015 lb/MBtu to 0.03 lb/MBtu in order to account for the condensable fraction of the particulate emissions.

There are no distinct trends in the emissions data for "filterable" and "filterable and condensable" PM_{10} emissions. With the exception of a couple outliers, the emissions limits for both types of PM_{10} are in the 0.015 to 0.02 lb/MBtu range.

A
FACILITY INFORMATION

CFB

AES Puerto Rico (2 units)

State: PR *EPA* 2 *Operational:* yes (& tested)
MW: 2 units at 227 MW each (Net) *MBtu/Hr:* 2461.35 MBtu/hr each - 2 units *Number Of Units:* 2
Permit Date: 9/18/1998 *Permit* AES-PRCP
Fuel: bituminous coal

AES-PRCP shall combust the following fuels: Low sulfur coal with a maximum sulfur content of 1.0% by weight.

Energy Services of Manitowoc

State: WI *EPA* 5 *Operational:* no
MW: 64 MW *MBtu/Hr:* 270 MBtu/hr *Number Of Units:* 1
Permit Date: 12/3/2003 *Permit* 02-RV-147
Fuel: coal, petroleum coke, and/or paper pellets
Facility Notes: SO_2, NOx, and PM10 are non-BACT; CO is BACT

EnviroPower IL - Benton (2 units)

State: IL *EPA* 5 *Operational:* no
MW: 2 units at 250 MW each (nominal net output) *MBtu/Hr:* 2,550 MBtu/hr each - 2 units *Number Of Units:* 2
Permit Date: 7/3/2001 *Permit* I.D. #: 055802AAG , Application #: 00080042
Fuel: coal tailings and coal

Coal mine tailings will be taken from the mine tailing piles at the former Old Ben 24 mine site as well as from other sites in southern Illinois.

Indeck-Elwood LLC (2 units)

State: IL *EPA* 5 *Operational:* no
MW: 2 units at 330 MW each (gross) *MBtu/Hr:* 2,900 MBtu/hour each - 2 units *Number Of Units:* 2
Permit Date: 10/10/2003 *Permit* ID #: 197035AAJ, Application #: 02030060
Fuel: coal, petroleum coke, coal tailings

The boilers would be fired on coal as their primary fuel and petroleum coke and coal tailings as supplemental fuels. (The boilers are designed to use coal mixed with up to 20 % petroleum coke and waste coal as their primary fuel.)

JEA Northside #1 & #2 (2 units)

State: FL ***EPA*** 4 ***Operational:*** yes (& tested)
MW: 2 units at 297.5 MW each ***MBtu/Hr:*** 2,764 MBtu/hr each - 2 units ***Number Of Units:*** 2
Permit Date: 7/14/1999 ***Permit*** PSD-FL-265
Fuel: coal, petroleum coke
Facility Notes: SO_2 based on NSPS: other pollutants based on BACT

Kentucky Mountain Power, LLC (EnviroPower) (2 units)

State: KY ***EPA*** 4 ***Operational:*** no
MW: ***MBtu/Hr:*** 2,550 MBTU/hour each - 2 units ***Number Of Units:*** 2
Permit Date: 5/4/2001 ***Permit*** V-00-045
Fuel: coal and coal refuse

Red Hills (Choctaw Generation Limited Partnership) (2 units)

State: MS ***EPA*** 4 ***Operational:*** yes (initial testing waived)
MW: ***MBtu/Hr:*** 2,475.6 MBTU/hr each - 2 units ***Number Of Units:*** 2
Permit Date: 8/25/1998 ***Permit*** 0400-00011
Fuel: lignite
Facility Notes: RBLC indicates NOx is non-BACT; the other pollutants are BACT

Sevier Power (Nevco Energy)

State: UT ***EPA*** 8 ***Operational:*** no
MW: 270 MW ***MBtu/Hr:*** 2532 MBtu/hr ***Number Of Units:*** 1
Permit Date: 10/12/2004 ***Permit*** DAQE-AN2529001-04
Fuel: bituminous coal

Seward Reliant (2 units)

State: PA ***EPA*** 3 ***Operational:*** yes (not tested)
MW: 521 MW (net nominal) ***MBtu/Hr:*** 2,532 MBtu/hr each (nominal), atmospheric CFB - 2 units ***Number Of Units:*** 2
Permit Date: 10/19/2001 ***Permit*** PA-32-040B
Fuel: coal refuse and/or run-of-mine (raw) coal, up to 35% maximum on an annual basis
Facility Notes: non-BACT for SO_2, NOx, PM10; BACT for CO, NSR for VOC

Southern Illinois Coop (Marion Generating Station)

State: IL ***EPA*** 5 ***Operational:*** yes (& tested)
MW: 120 MW ***MBtu/Hr:*** 1402 MBtu HHV/hr ***Number Of Units:*** 1
Permit Date: 6/15/2001 ***Permit*** 00070030- 199856aac
Fuel: coal refuse, coal, petroleum coke
Facility Notes: non-BACT for SO_2, NOx, PM10, and VOC; BACT for CO

Spurlock (E. KY Power Coop)

State: KY ***EPA*** 4 ***Operational:*** no
MW: 270 MW ***MBtu/Hr:*** 2,500 MBTU/hour ***Number Of Units:*** 1
Permit Date: 8/4/2002 ***Permit*** V-97-050 (Revision 1)
Fuel: coal

Toledo Edison Co. - Bayshore Plant

State: OH ***EPA*** 5 ***Operational:*** yes (& tested)
MW: ***MBtu/Hr:*** 1,736 MBtu/hr ***Number Of Units:*** 1
Permit Date: 10/21/1997 ***Permit*** 04-01056
Fuel: pet coke, coal CFB boiler fired primarily with petroleum coke (1736 MMBTU/hr rating) and use of coal (1764 MMBTU/hr rating) as a backup fuel
Facility Notes: non-BACT for SO_2, NOx, PM10, VOC; BACT for CO

PC

Corn Belt Energy

State: IL ***EPA*** 5 ***Operational:*** no
MW: 91 MW ***MBtu/Hr:*** 900 MBtu/hr ***Number Of Units:*** 1
Permit Date: 12/17/2002 ***Permit*** Application #: 1070028, I.D. #: 107806AAC
Fuel: bituminous coal and coal tailings 10450 btu/lb, , Elkhart Mine Road, Mine-Mouth Project, Elkhart, Logan County
Facility Notes: The project is being pursued by Corn Belt in conjunction with a clean coal combustion grant from the United States Department of Energy (USDOE). 365 day "shakedown" period when only nsps limits apply

Council Bluffs (Mid America)

State: IA ***EPA*** 7 ***Operational:*** no
MW: 790 net MW ***MBtu/Hr:*** 7,675 MBtu/hr ***Number Of Units:*** 1
Permit Date: 6/17/2003 ***Permit*** 03-A-425-P
Fuel: PRB

Elm Road Generating Station (WE-Energies) (2 units)

State: WI ***EPA*** 5 ***Operational:*** no
MW: 2 units at 615 MW each ***MBtu/Hr:*** 6180 MBtu/hr each - 2 units ***Number Of Units:*** 2
Permit Date: 1/14/2004 ***Permit*** 03-RV-166
Fuel: bituminous coal -washed Eastern United States Pittsburgh #8

Hawthorn 5 (KCP&L)

State: MO ***EPA*** 7 ***Operational:*** yes (& tested)
MW: 570 MW ***MBtu/Hr:*** 6,000 MBtu/hr ***Number Of Units:*** 1
Permit Date: 8/17/1999 ***Permit*** 888
Fuel: PRB 8350

Holcomb Unit #2 (Sand Sage Power, LLC)

State: KS ***EPA*** 7 ***Operational:*** no
MW: 660 MW ***MBtu/Hr:*** 6,501 MBtu/hr ***Number Of Units:*** 1
Permit Date: 10/8/2002 ***Permit*** Source ID #: 0550087
Fuel: PRB

Intermountain Power Unit #3

State: UT ***EPA*** 8 ***Operational:*** no
MW: nominal 950-gross MW (900-net MW) ***MBtu/Hr:*** 9,050 MBtu/hr ***Number Of Units:*** 1
Permit Date: 10/15/2004 ***Permit*** DAQE-AN0327010-04
Fuel: bituminous or blend of bituminous and up to 30% subbituminous

Longview Power (GenPower)

State: WV ***EPA*** 3 ***Operational:*** no
MW: 600 MW ***MBtu/Hr:*** 6,114 MBtu/hr ***Number Of Units:*** 1

Permit Date: 3/2/2004 ***Permit*** R14-0024
Fuel: bituminous coal 2.5% sulfur (nominal)

Plum Point Power Station
State: AR ***EPA*** 6 ***Operational:*** no
MW: 550-800 MW (nominal) ***MBtu/Hr:*** 8,897 MBtu/hr ***Number Of Units:*** 1
Permit Date: 8/20/2003 ***Permit*** 1995-AOP-R0
Fuel: PRB
Facility Notes: MMBtu/hr for the boiler was found in the predetermination document for Longview

Prairie State (2 units)
State: IL ***EPA*** 5 ***Operational:*** no
MW: 1500 MW ***MBtu/Hr:*** 7,450 MBtu/hr (each) ***Number Of Units:*** 2
Permit Date: 1/14/2005 ***Permit*** 189808AAB
Fuel: bituminous coal mine mouth; Illinois coal; 4% sulfur; 8,780 btu/lb

Rocky Mountain Power (Hardin Generator Project)
State: MT ***EPA*** 8 ***Operational:*** no
MW: 113 MW (nominal) ***MBtu/Hr:*** 1,304 MBtu/hr ***Number Of Units:*** 1
Permit Date: 6/11/2002 ***Permit*** 3185-00
Fuel: coal

coal owned by the Tribe of Crow Indians from the Absaloka Mine. The mine, which is owned by Westmoreland Resources, Inc., is located approximately 30 miles east of Hardin. Using the heat content of 8,700 Btu/lb of Absaloka Mine coal, as provided by Westmoreland Resources, Inc., the coal-firing rate will be approximately 75 ton/hr and 656,500 tpy.

Roundup (Bull Mountain) (2 units)
State: MT ***EPA*** 8 ***Operational:*** no
MW: 2 units at 390 MW each (nominal) ***MBtu/Hr:*** 4,013 MBtu/hr each (Max short term heat input to boiler); 2 units - 3,737 mmBtu/hr each (Max long term heat input to boiler) - 2 units ***Number Of Units:*** 2
Permit Date: 7/21/2003 ***Permit*** 3182-00
Fuel: coal

Coal for the main boilers will be supplied by the BMP Investments Incorporated coal mine that is located on the adjacent property immediately to the east of the power plant location. (Bull Mountain Mine)

Santee Cooper/Cross #3 & #4 (2 units)
State: SC ***EPA*** 4 ***Operational:*** no
MW: 2 units at 600 MW each ***MBtu/Hr:*** 5,400 MBTU/hr (normal pressure rating), 5,700 „BTU/hr (overpressure rating) each - 2 units ***Number Of Units:*** 2
Permit Date: 8/5/2004 ***Permit*** 0420-0030-CI-R1
Fuel: coal, synfuel and petcoke blended up to 30% by weight as fuel

coal, including synfuel, and petcoke blended up to 30% by weight as fuel. For this permit, the term "coal" and requirements pertaining to coal shall also include the following synthetic fuel-altered coal (synfuel): - coal with HES binder (petroleum emulsion - MSDS identification AMI-403) - coal with NALCO 9838 binder (water based vinyl polymer)- coal with Dow Latex DL 298NA (latex based emulsion in water) Boilers 03 and 04) The owner/operator shall maintain daily monitoring of the petcoke blend ratio. This blend shall not exceed 30% by weight blend petcoke. The petcoke blend ratio shall be calculated daily by measuring the weight of the petcoke burned as well as the weight of the entire coal/petcoke mixture. Records of daily petcoke blend ratios shall be submitted to the Manager of the Technical Management Section, Bureau of Air Quality along with the quarterly CEMS reports.

Facility Notes: NOx and SOx are non-BACT, the rest are BACT

Thoroughbred (2 units)

State: KY ***EPA*** 4 ***Operational:*** no, Permit under litigation
MW: 2 units at 750 MW each ***MBtu/Hr:*** 7,446 MBTU/hour each - 2 units ***Number Of Units:*** 2
Permit Date: 10/11/2002 ***Permit*** V-02-001 Revision 1
Fuel: bituminous coal

Tucson - Springerville (2 units)

State: AZ ***EPA*** 9 ***Operational:*** no
MW: 2 units at 400 net MW each ***MBtu/Hr:*** 4,200 MBtu/hr each - 2 units ***Number Of Units:*** 2
Permit Date: 4/29/2002 ***Permit*** 1001554
Fuel: PRB
Facility Notes: Netted for NOx and SO_2, non-BACT for SO_2 and NOx; BACT for PM10, CO and VOC

Two Elk

State: WY ***EPA*** 8 ***Operational:*** no
MW: 280 MW (nominal) ***MBtu/Hr:*** 2,960 MBtu/hr ***Number Of Units:*** 1
Permit Date: 5/29/2003 ***Permit*** CT-1352B
Fuel: PRB

Whelan Energy Center Unit 2- Hastings

State: NE ***EPA*** 7 ***Operational:*** no
MW: 220 MW ***MBtu/Hr:*** 2,211 MBtu/hr ***Number Of Units:*** 1
Permit Date: 3/30/2004 ***Permit*** 58048
Fuel: PRB has a minimum heat content of approximately 8,100 Btu/lb (from NDEQWhelanFactSheet58048f02doc.pdf)

Wisconsin Public Service - Weston 4

State: WI ***EPA*** 5 ***Operational:*** no
MW: 500 MW ***MBtu/Hr:*** 5,173 MBtu/hr ***Number Of Units:*** 1
Permit Date: 10/19/2004 ***Permit*** 03- RV- 248
Fuel: PRB

WYGEN I (Black Hills)

State: WY ***EPA*** 8 ***Operational:*** yes (& tested)
MW: 80 MW ***MBtu/Hr:*** 1,014 MBtu/hr ***Number Of Units:*** 1
Permit Date: 9/6/1996 (5/17/2004) ***Permit*** CT-1236
Fuel: PRB
Facility Notes: Modified Permit CT-1236A reflects the as-build WYGEN 1 facility and to revise the short term SO_2 limit for the PC boiler from a 2 hour block average to a 3 hour block average. The as-built modifications consist of the installation of a boiler baghouse instead of a precipitator, installation of a Spray Dryer Absorber instead of a Circulating Dry Scrubber, and modifications to the material handling dust collectors.

WYGEN II (Black Hills)

State: WY ***EPA*** 8 ***Operational:*** no
MW: 500 MW ***MBtu/Hr:*** 5,145.7 MBtu/hr ***Number Of Units:*** 1
Permit Date: 9/25/2002 ***Permit*** CT-3030
Fuel: PRB

Export Control Restrictions

Access to and use of EPRI Intellectual Property is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or permanent U.S. resident is permitted access under applicable U.S. and foreign export laws and regulations. In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI Intellectual Property, you acknowledge that it is our obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case by case basis an informal assessment of the applicable U.S. export classification for specific EPRI Intellectual Property, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes. You and your company acknowledge that it is still the obligation of you and your company to make your own assessment of the applicable U.S. export classification and ensure compliance accordingly. You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of EPRI Intellectual Property hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

The Electric Power Research Institute (EPRI)

The Electric Power Research Institute (EPRI), with major locations in Palo Alto, CA, and Charlotte, NC, was established in 1973 as an independent, non-profit center for public interest energy and environmental research. EPRI brings together member organizations, the Institute's scientists and engineers, and other leading experts to work collaboratively on solutions to the challenges of electric power. These solutions span nearly every area of power generation, delivery, and use, including health, safety, and environment. EPRI's members represent over 90% of the electricity generated in the United States. International participation represents over 10% of EPRI's total R&D program.

URS SO_2 Control Evaluation

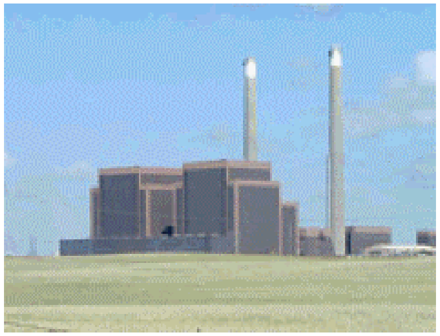
Reduction of SO_2 Emissions at Coal Creek

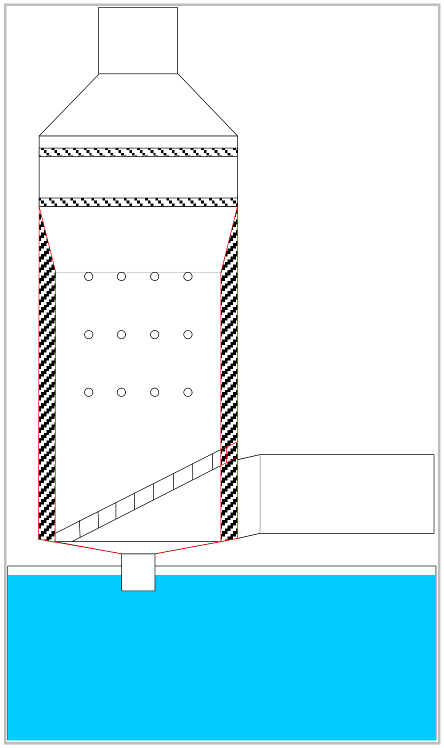
URS

GRE Coal Creek Units 1 & 2

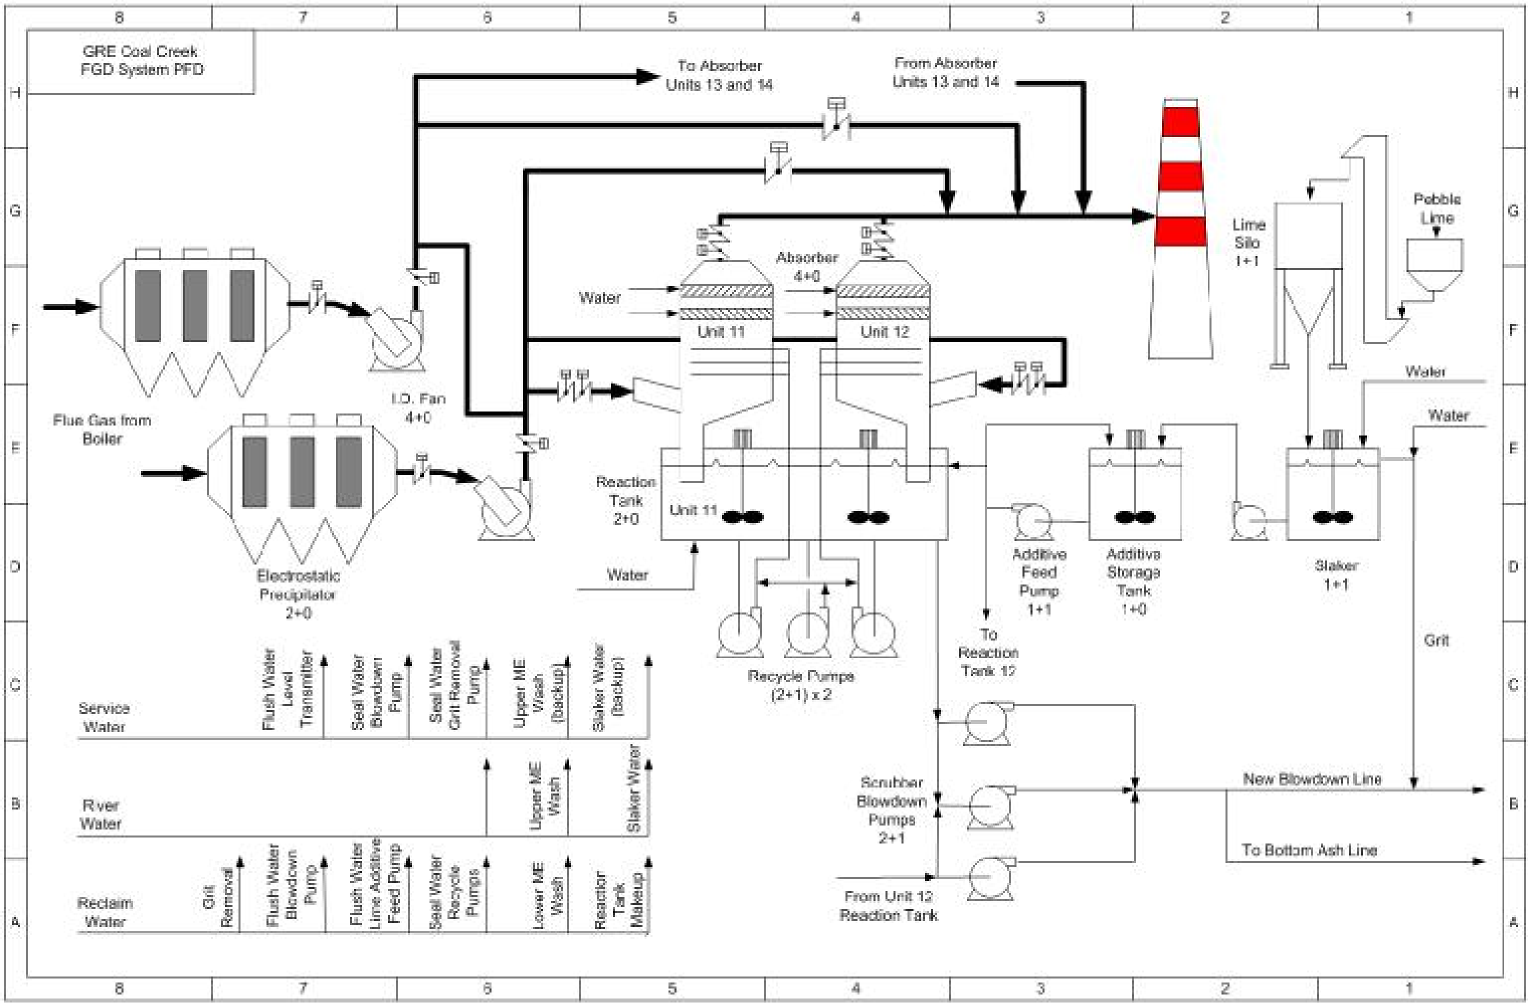
Review of Options to Reduce SO_2 Emissions

October 26, 2004





Process Flow Diagram



URS

Current Operating Conditions

- Operating data provided by GRE
  - Boiler
  - Fuel
  - Flue gas
- In most cases, the median value was used
  - Data from several months available
  - No significant trends detected in heat rate, flow or sulfur

Boiler & Fuel Characteristics	**Units**	**Current**
Unit Load	MW $_{gross}$	595
Plant Heat Rate	Btu/KWh)$_{gross}$	10,500
Heat Input	MM Btu/hr	6,248
Capacity Factor	percent	85
Coal HHV, Btu/lb	Btu/lb	6,200
Sulfur	percent	0.64
FGD Characteristics		
Absorber Removal	percent	95.0
Bypass	percent	27.0
Plant Removal	percent	69.4
Emissions	TPY	13,817
Allowances	TPY	23,111
Credits	TPY	9,294
Flue Gas Characteristics		
Excess Air, APH Leakage	percent	17.0
APH O_2 Concentration	percent	2.6
APH Flue Gas Flow Rate	scfm	1,485,334
APH SO_2 Concentration		795
ESP, Ductwork Leakage	percent	10.0
Stack O_2 Concentration		4.0
Stack Flue Gas Flow Rate	scfm	1,707,670
Stack SO_2 Concentration		262
Stack Temperature	deg F	191

Determination of Current Bypass

- Current bypass flow was determined using several different methods:
  - ü Historical Emissions
  - ü Stack Temperature

Method	Bypass	Accuracy	Comment
Historical Emissions	27.0	Poor	Annual average
Stack Temperature	28.0	Good	Heat losses hard to estimate
Mass Balance	27.0	Medium	Combo of all parameters
Median	27.0		

Mass Balance, 27% Bypass

Available Options - Design

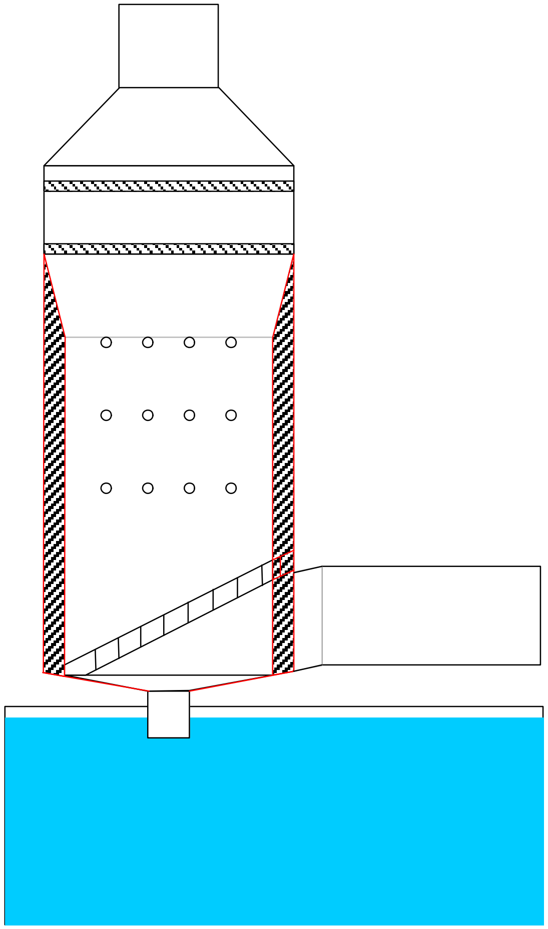
- Design, 10% Bypass
  1. Gas Velocity at 17 fps
  2. New mist eliminator
  3. Liquid Distribution Rings
  4. Duct and stack condensation traps
  5. Fan upgrade
     1. 2.4” increase in pressure drop
     2. Tip the fan
     3. New motor?
  6. Evaluate if DBA system is required to control scaling
     1. If scaling continues to be a problem – not expected

- Design, 0% Bypass
  1. Expand current towers or install a fifth module
     1. Reduce velocity from 18.9 fps to 15.4 modified
     2. Reduce pressure drop increase from 4.3” to 1.4”
  2. New mist eliminator
  3. Liquid Distribution Rings
  4. Fan upgrade
     1. 1.4” increase in pressure drop
     2. Within the capability of the existing fan?
  5. Duct and stack condensation traps
  6. **Stack upgrade or new stack**
  7. Evaluate if DBA system is required to control scaling
     1. If scaling continues to be a problem – not expected

URS

Expand Current Absorber Modules

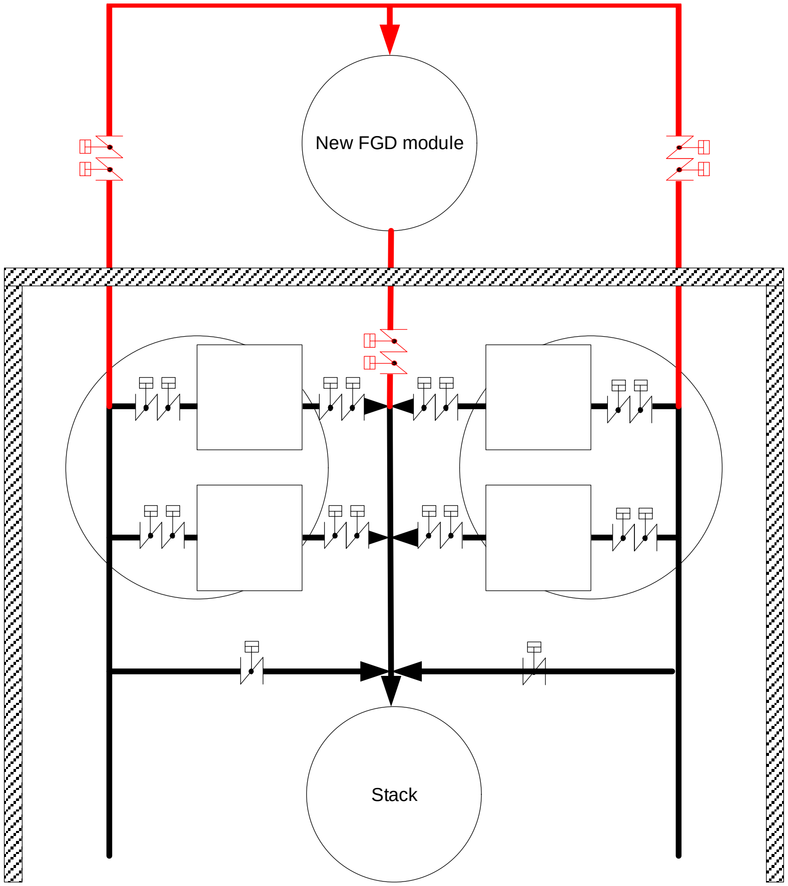
- Concept
  - Upgrade to straight sides
  - Pros
    - Complete utilization of ME area
    - 20 percent reduction in gas velocity
    - No changes in:
      - Foundation
      - Building
      - Electrical
      - Process etc
      - Equipment (pumps etc)
  - Cons
    - Module outages required
      - Can be completed over several regular scheduled outages
    - Substantial field work



URS

New Fifth Absorber Module

- Concept
  - Install a fifth absorber module
  - Pros
    - 20 percent reduction in gas velocity
    - Limited impact on operation
  - Cons
    - Considerable plant impact
      - Building expansion
      - Foundation
      - Electrical
      - Process (pumps, piping)
      - Ductwork
      - Dampers
      - Flow balancing



Lime Slaker Capacity

- Lime Consumption
  - Current: 4.7 tph
  - 10% bypass
    - 4.7 tph
    - One slaker required
  - 0% bypass:
    - 6.4 tph
    - Two slakers required
- Byproduct Blowdown
  - Current 234 gpm
  - Future 288 to 320 gpm
  - Sufficient capacity for all conditions

Bypass percent	Lime Consumption tph	Blowdown Rate gpm
0	6.4	325
10	5.8	292
20	5.2	260
27	4.7	237
30	4.5	227
6+4 tph slaker capacity		
2 x 300 gpm blowdown pump capacity		

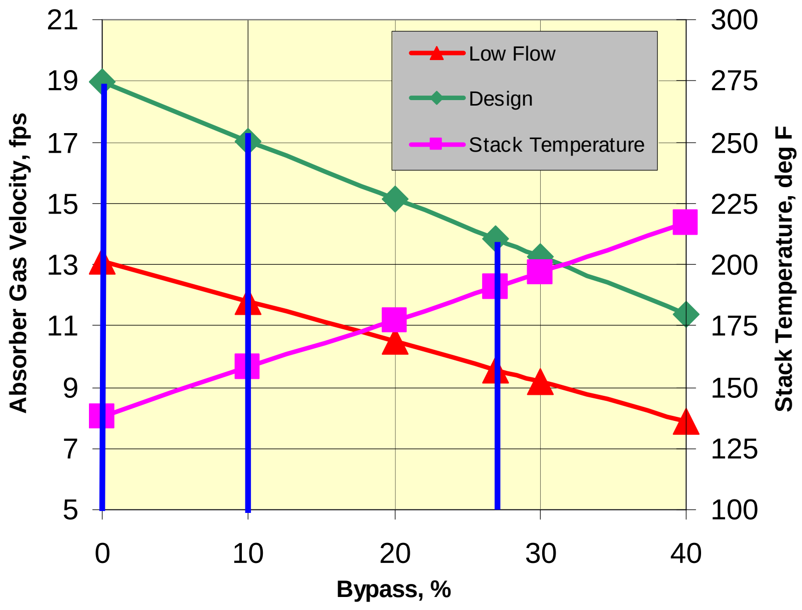
URS

Mist Eliminator and Stack

- Maximum gas velocity in the Spray Zone and ME

Bypass %	Design fps	Low Flow fps
0	18.9	15.9
10	17.0	14.3
20	15.2	12.8
27	13.8	11.6

- Issues from higher gas velocity
  - Higher liquid loading potentially leading to carryover
  - Increased alkalinity on the ME vanes potentially leading to scaling
  - Potentially higher wall sneakage leading to lower SO_2 removal
  - Reduced L/G leading to lower SO_2 removal

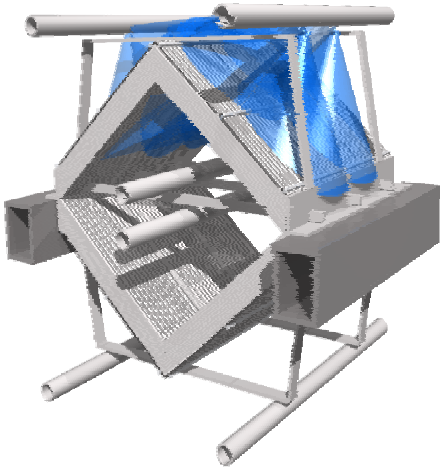


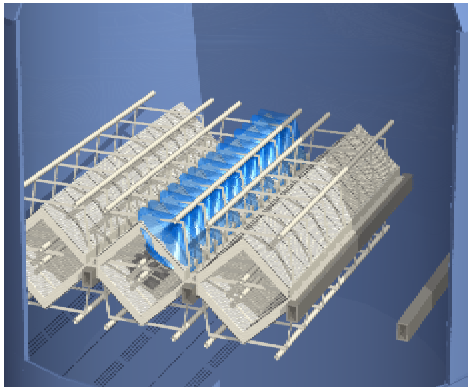
- Stack temperature
  - 158 ^{o}F at 10 percent bypass
    - May not be sufficient during winter
  - 138 ^{o}F at 0 percent bypass
    - Wet stack or reheat?

URS

Achieve Required ME Performance

- New High Velocity Mist Eliminator
  - Munters DV 210 Plus
    - Single layer, diamond shape ME
    - Increased disengagement zone
    - Ideal for rectangular tower designs
    - High velocity, up to 25 fps continuous flow
    - Can handle flue gas mal-distribution up to 29 fps
  - Change wash water to 50/50 mixture of ash/service water





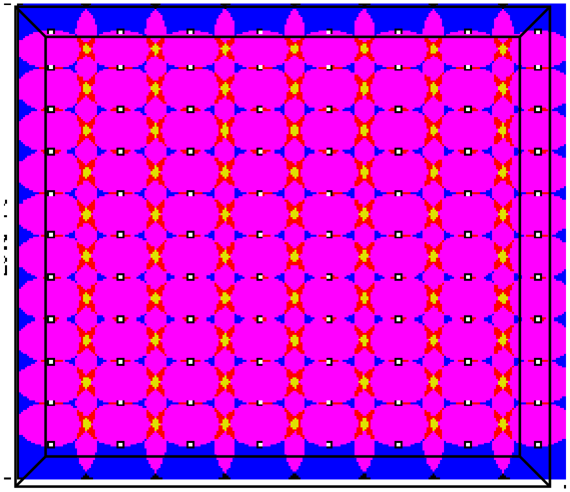
URS

ME Wash System Guidelines

- Wash intensity – 1.5 gpm/ft2
- Wash pressure - >40 psi
- Spray nozzle – 90 degree, full cone
- Wash coverage – 200% overlap
- Distance from tip of wash nozzle to ME surface – 18” to 36”
- Wash duration – 90 to 120 seconds
- Wash frequency – 1st stage and front side of 2nd stage every 2 to 3 hours
- Backside of 2nd stage every 4 to 8 hours
- Wash water - < 50% saturated

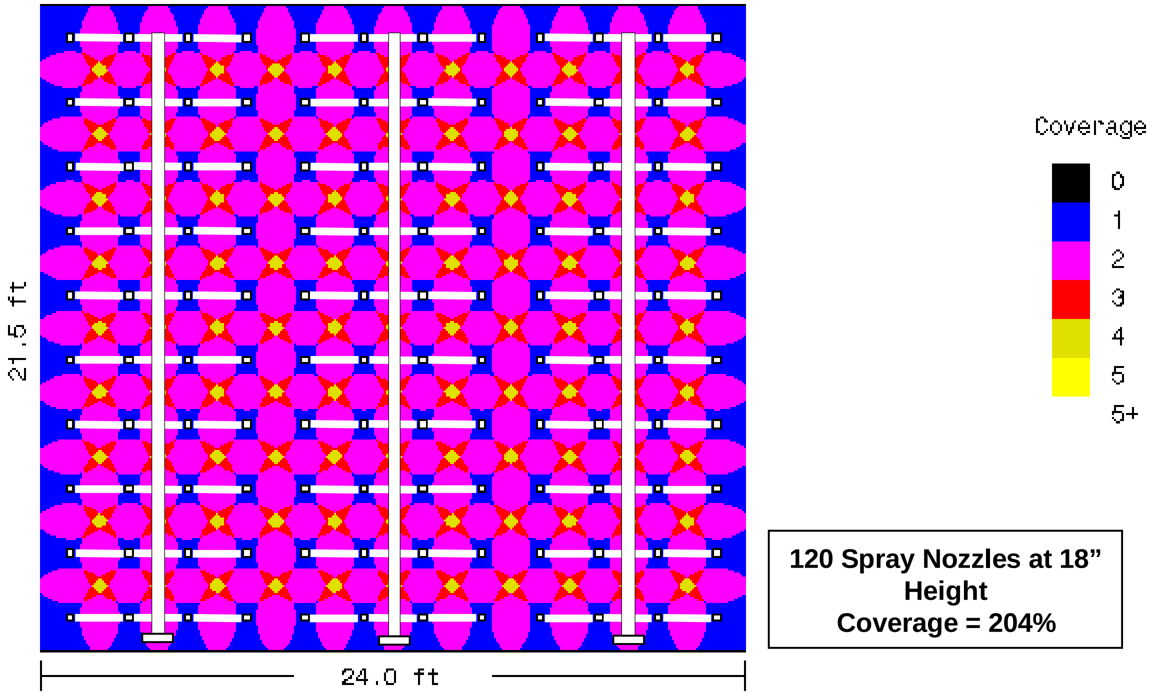
Eliminate Wall Sneakage

- Liquid Distribution Rings
  - improve gas distribution
  - eliminate wall sneakage
  - increase SO_2 removal



Conditions		Design		Low Flow	
		Absorber	Station	Absorber	Station
As is	0	89.9	89.9	90.1	90.1
	10	90.9	81.8	92.3	83.1
	27	93.7	68.4	96.0	70.1
with LDR	0	94.0	94.0	94.1	94.1
	10	94.6	84.6	95.4	85.4
	27	96.2	69.2	97.6	70.6

Proposed Nozzle Layout

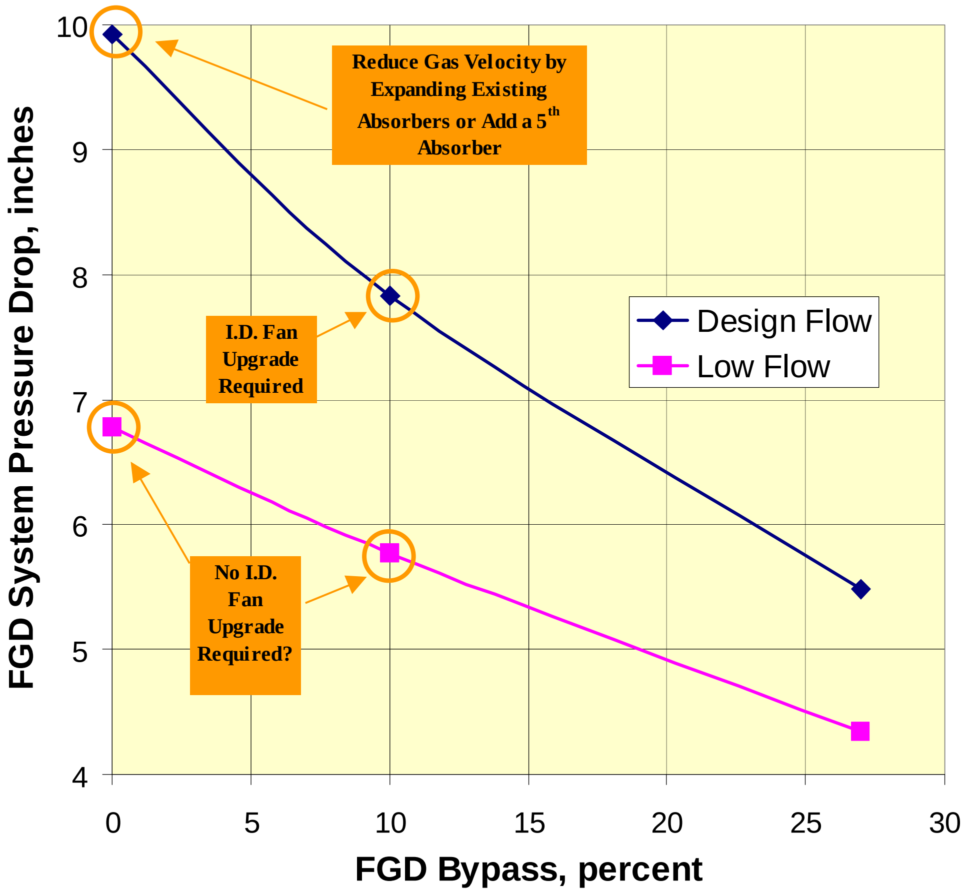


120 Spray Nozzles at 18" Height Coverage = 204%

Figure 3: Proposed Nozzle Layout and Wash Coverage for Intermediate Wash Levels

Fan Capacity – Pressure Drop

- No Absorber Mods Implemented
  - Design
    - 5.5” at 27% bypass
    - 7.8” at 10% bypass
    - 9.9” at 0% bypass
  - Low Flow
    - 4.2” at 27% bypass
    - 5.7” at 10% bypass
    - 6.8” at 0% bypass
- Fan upgrade required and/or
- Reduction in gas velocity



URS

Pressure Drop Prediction

	Design Flow				Low Flow			
	27%	10%	0%	O% Modified	27%	10%	0%	O% Modified
🟨 Outlet Ducts	0.70	0.70	0.70	0.70	0.70	0.70	0.70	0.70
🟪 Absorber	4.74	7.05	9.12	6.22	3.63	5.03	6.01	4.62
🟦 Inlet Ducts	0.10	0.13	0.16	0.16	0.07	0.10	0.12	0.12

URS

Remaining Issues – Path Forward

- Is partial bypass permissible
    - Costly stack modifications or a new stack can possibly be avoided
- Does zero bypass require a dry stack or is a wet stack feasible
    - Can the existing stack be upgraded to accommodate new conditions
- Can the existing fans be upgraded to provide the required head
    - Is the fan motor capacity sufficient
- Study gas distribution inside absorber modules and associated duct work using CFD to reduce overall pressure drop
- Select upgrade option/options, validate design assumptions and fine tune cost estimates

URS

Summary

- Stack uses other than condensation traps excluded from study
- If permissible, partial bypass (10%) is clearly the low cost option
- Reducing flue gas flow is very cost effective option
- If zero bypass is required, expanding the current absorber modules is the low cost and least intrusive approach
- URS has the experience and know-how to provide the required absorber modifications

Proposal No. 65-120220-00 rev01

October 6th, 2006

PROPIETARY AND CONFIDENTIAL INFORMATION

This proposal and the information, design and material contained and/or illustrated herein (hereinafter "proprietary and confidential" material), are the property of FOSTER WHEELER NORTH AMERICA CORPORATION, (FWNAC) and is submitted, lent and furnished to you in the strict confidence with the expressed understanding that you shall not use said proprietary material for any purpose other than for the evaluation of this proposal or reproduce, copy, lend, dispose of, or disclose said proprietary material to anyone outside receipt organization. By receiving said proprietary material you agree not to use the same in any way injurious to the interest of FOSTER WHEELER NORTH AMERICA CORPORATION, and agree to return to same upon request.

The Foster Wheeler North America Corporation Services Management Commitment

Foster Wheeler is committed to being the vendor of choice for our utility and industrial clients by continually supplying products and services that meet their need for improved profitability. We will accomplish this through open communication and measurable performance objectives and by being fiercely focused on cost.

Foster Wheeler is uniquely qualified to support the mission of Great River Energy with over a century of experience with design, fabrication, erection, commissioning, and rehabilitation of steam generating equipment. We have over 150,000 MW of installed equipment. Our mission is to provide our clients the best low NOx technology in the world. The experience we have gained through over 200 million hours of operation of our equipment and our sophisticated simulation models allow us to accurately predict how your unit will operate as a result of changes intended to increase performance, reliability, and operational flexibility, regardless of the OEM. As a subsidiary of Foster Wheeler Limited, we have the financial clout to stand behind our performance guarantees. We have the project managers, engineers, procurement and financial specialists and the manufacturing, erection, and commissioning capability to meet your needs regardless of complexity. Our list of repeat, satisfied customers is long and growing. We would like to continue our relationship with Great River Energy with this challenging project and look forward to the opportunity to work with you.

Sincerely,

Ed Dean

Executive Vice President, Services Division

1. EXECUTIVE SUMMARY

Foster Wheeler North America Corporation is pleased to submit to Great River Energy our proposal for the engineering and material supply of a TLN3 System for Coal Creek Units 1 & 2. Foster Wheeler has enjoyed the successful relationship we have and look forward to serving Great River Energy in this and future projects. Foster Wheeler believes this proposal is a high value solution with many unique features and capabilities that will benefit the long-term emission performance, operation and maintenance of these units.

The original TLN3 system supplied by Foster Wheeler in the late 1990s was designed to reduce NOx below 0.35 lb/MBtu. After installation and optimization, even lower NOx levels were achieved. Great River Energy is planning to install a coal drying system to reduce the coal moisture from current levels of 35 – 38%. After this system is on-line, the primary air will be greatly reduced from current levels of over 50%. This primary air reduction will result in more secondary air available for staging as well as introduction into the main windboxes.

The new TLN3 System is based on increasing the size of the SOFA windboxes and ducts to allow more overfire air and thereby lower NOx levels. In addition, the main windbox damper venturi system will be modified to accommodate the increased amount of secondary air.

Primary Scope of Supply

Our base scope of supply includes all the necessary components to achieve the requested 0.17 lb/MBtu NOx levels.

a) The proposed TLN system(s) will be based on a single level of separated overfire air (SOFA) including all necessary waterwall tube panel openings and secondary air ducting. The new, larger SOFA windboxes will be located in the same location as the current windboxes. The SOFA ductwork is larger to allow more flow, but is less tortuous to provide less pressure drop.

b) Larger damper venturis will be provided to allow operators with enhanced air-staging capability. It also improves windbox-to-furnace and secondary air damper control over a greater unit load range.

c) Foster Wheeler patented Double Shroud “Boundary” auxiliary air nozzles will be provided to direct air in “multiple directions” versus just “concentrically”, to reshape the fireball for control of slagging, emissions, as well as oxygen and temperature profiles.

Other typical features of the Foster Wheeler TLN Systems

a.) Our separated overfire air systems are designed to <u>reduce installation time and costs</u> including minimal, or no buckstay modifications, minimal tube cuts, etc.

b.) All nozzle tips, windbox components and upgrades are <u>100% compatible</u> and interchangeable with existing windbox equipment.

c.) We provide a <u>full line</u> of tilt, damper and other related tangential firing equipment upgrades to compliment your TLN retrofit.

Our vision is to provide our clients with the best low NOx coal fired technologies in the world. We believe we have achieved this goal. As part of this goal we provide user-friendly, low NOx systems that not only meet your long-term emission and boiler performance objectives, but also minimize retrofit and long-term operating costs. We look forward to continuing our relationship with Great River Energy with this project.

2. INTRODUCTION TO FOSTER WHEELER NORTH AMERICA CORPORATION

In 1927, Foster Wheeler Corporation was formed when Wheeler Condenser and Engineering Company of Carteret, New Jersey merged with Power Specialty Company of Dansville, New York. Innovators in the field of superheaters and condensers, the two companies, operating as Foster Wheeler Corporation, went on to form other subsidiary companies to specialize in different facets of the steam generation and process plants industries.

Foster Wheeler Corporation grew and subdivided into Foster Wheeler Ltd., Foster Wheeler International Corporation, and Foster Wheeler Equipment, Process Plants and Fired Heater Divisions. In 1973, Foster Wheeler Energy Corporation (FWEC) was established by joining the FWC Equipment, Process Plants and Fired Heater Divisions.

In 1985, Foster Wheeler Energy Corporation transferred the assets of the Process Plants and Fired heater Division to form Foster Wheeler USA Corporation. Foster Wheeler Constructors, Inc. was formed in 1987 to provide construction services for both FWEC and FWUSA. In 2001, Foster Wheeler Corporation organized and adopted the name Foster Wheeler Ltd. Today, Foster Wheeler Ltd. is an internationally operating company addressing the needs of clients through two operating groups. They are the Engineering & Construction and Energy Equipment Groups.

Foster Wheeler Power Corporation (FWNAC) is the wholly owned subsidiary of Foster Wheeler Power Group, Inc. (FWPGI) in the United States of America. FWPGI provides products and services in steam generation and process plant markets throughout the world.

With the acquisitions of Zack Power and Industrial and Alhstrom Pyropower in 1995, Foster Wheeler Power Group Inc. now offers greater capabilities within our range of products and services. Operations have expanded and include engineering and construction services, manufacturing, research and development, aftermarket customer service and project management. Our equipment includes pulverized coal, oil and gas boilers (both utility and industrial), fluidized bed boilers (bubbling and circulating), condensers, feedwater heaters, tubular air heaters, wall, tangential and arch fired burners, pulverizers and other related equipment.

The scope of FWNAC Services includes, but is not limited to, engineered unit retrofits, increase in unit efficiency and availability, test and performance engineering, inspection services, engineering and life extension studies, alternative fuel firing, options and analysis, and replacement parts. This full-service operation ranges from conceptual analysis through manufacturing and construction for all boiler types, regardless of size, fuel or original design.

3. TECHNICAL DISCUSSION

3.1 Unit Description

Coal Creek Units 1 & 2 are 560 MWG, controlled circulation, radiant, reheat, balanced draft, and divided furnace, Combustion Engineering (CE) generating units. Each unit was originally designed for a maximum continuous rating (MCR) for superheat and reheat steam flow of 3,730,000 lbs/hr and 3,325,000 lbs/hr, respectively. Steam conditions at the superheater outlet are 1,005°F and 2620 psig. Reheat outlet temperature of 1,005°F is controlled by fuel nozzle tilt and superheat outlet temperature is controlled by two desuperheating spray valves (one for each furnace half).

The unit is designed to fire North Dakota Lignite from the nearby Falkirk mine, through eight (8) 1043 RP mills with hydraulics into eight elevations of tilting tangential fuel nozzles. Each of the 1043 RP pulverizers were designed to pulverize 136,8000 lbs/hr coal flow with a Hardgrove Grindability Index (HGI) of 35, while producing coal fineness output of 65% through 200 Mesh and 2% on 50 mesh screens. The moisture of the coal was specified for design as 36.6%, but typically varies between 35 and 42%. The design airflow through these 1043 RP mills was 255,000 lbs/hr.

In the early 1990’s, the 1043 RP mills were retrofitted with ABB-CE vane wheels to increase airflow. Currently, these mills operate at 350,000 lbs/hr airflow in order to keep the mill outlet temperatures above 145 °F. At mill outlet temperatures below 145 °F, these pulverizers have the tendency to load up and/or plug up.

In the late 1990’s, Foster Wheeler designed and supplied the current TLN3 low NOx system. It was designed to achieve NOx emission levels of 0.35 lb/MBtu. Further reduction with the Foster Wheeler TLN3 System was achieved after tuning and optimization. Currently, NOx emissions range between 0.18 – 0.30 lb/MBtu.

3.2 Technical Evaluation of Current Unit Operation

We believe that it is very important, when designing a low NOx firing system retrofit, that the designers understand the current unit operation including fuel effects, equipment limitations and client requirements. Each boiler windbox arrangement is simulated with our proprietary Windbox Simulation Program to assure proper flow distribution for staging and air jet penetration for optimal fuel air mixing. We also look at the boiler design and arrangements, fuel ranges and constituents, pulverizer air, coal and fineness, burner zone heat release rates, etc. We also compare each proposed design to other similar units that we have retrofit, further assuring successful post-retrofit performance.

Foster Wheeler was last on site to perform some unit optimization in August 2005. Some highlights of this evaluation are presented below. FWNAC believes that such on-site evaluations and discussions with operations personnel allow the designer to provide a low NOx system custom tailored for the unit.

- Overall, this unit currently operates at average NOx levels compared to units of similar vintage and size firing similar coals. NOx emissions at full load range from 0.18 to 0.30 lb/MBtu. The EPA website data shows the NOx averaging 0.22 to 0.24 lb/MBtu at full load. The higher NOx values are attributed (most likely) to a function of main windbox burner tilt location, excess air levels and manual, non-adjusted control of main windbox air dampers. During the August optimization, NOx levels were maintained at 0.18 lb/MBtu for extended periods.
- Main burner tilts operate above horizontal position between 5 to 12 degrees
- CO levels are not measured on these units.
- UBC is reportedly below 0.5%
- Mill fineness is reported as 65% though 200 mesh and 98% through 50 mesh.
- Windbox-to-furnace differential pressure averages 4.0 – 4.5 In. H_2O at 100% MCR.
- Superheat and reheat temperatures were 1000 °F and 1003 °F respectively.
- Boiler O_2 averaged 2.5% during optimization with side to side values measuring ±0.2% from average.
- All pulverizers were evenly loaded during the testing.

3.3 Foster Wheeler’s Tangential Low NOx (TLN) Systems

3.3.1 Design Philosophy

Foster Wheeler North America Corp’s (FWNAC) Tangential Low NOx (TLN) Combustion Systems provide industrial and utility boiler owners with an alternative solution to their NOx compliance needs. Our philosophy is to provide our clients with the highest value low NOx system.

- Our systems are designed to maximize NOx reduction efficiency while minimizing the impact on combustion performance or unit operation. Our combined wall and tangential-fired combustion expertise gives FWNAC a unique perspective no other combustion equipment supplier can claim. An extensive support team of experienced technical and project specialists backs our commitment.

- We focus on designing systems that minimize changes to the furnace and/or the boiler house. This reduces installation time and costs for the owner.

- We believe each TLN application should compliment the unit's operational capabilities as well as the range of current and future fuels.

- We believe that each TLN system should provide years of reliable service. All tangential-fired windbox components are manufactured in either our own facilities or per our specifications by high quality suppliers.

- A team of experienced and qualified tangential firing engineers, project managers, service engineers and suppliers, supports each project. Our goal is to make each of your TLN retrofits your most favorable project.

Our system technology is supported by a continuous commitment to improve performance and reliability. For example, our on-line, real-time, ECT coal flow distribution, velocity and particle size monitoring technology combined with our CADM system allows fuel and air to be more balanced for lower CO and higher combustion efficiency.

3.3.2 FWNAC’s TLN Systems

Foster Wheeler’s Tangential Low NOx (TLN) firing systems are based on the application of secondary air staging technology commonly referred to as “overfire air”. Both in-windbox and separated secondary air-staging arrangements are applied depending on current windbox configurations and the desired level of NOx reduction. Staging of secondary combustion air has been well documented throughout the international boiler industry to be the single most effective technique for reducing NOx emissions from tangentially fired boilers. By redirecting a portion of the combustion air above the upper fuel elevation, fuel nitrogen conversion and thermal NOx production is reduced. Control of this staging process through proper nozzle and damper design is critical in order to maximize combustion efficiency and component longevity. Depending on the unit configuration and required NOx reductions, Foster Wheeler can offer several high value options. These include the TLN1, TLN2 and TLN3 arrangements, which are shown below in **Figure 1.**

FWNAC’s **TLN1** arrangement is an “in-windbox” secondary air staging system. It consists of reconfiguring the tangential windbox fuel and air nozzle arrangement to provide the required air staging effect. The TLN1 arrangement requires lowering existing upper coal elevations in the windboxes to make provision for “in- windbox secondary air staging, or overfire Air. Depending on the specific windbox arrangement, these systems can provide up to approximately 250 ppm (corrected to 3% O_2) of NOx reduction.

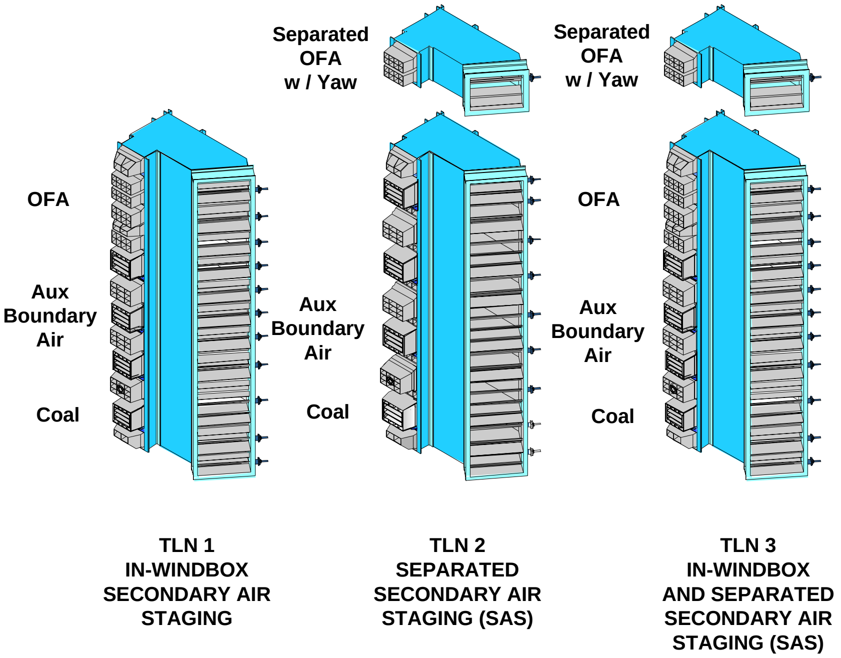

Figure 1 - FWNAC Tangential Low NOx (TLN) Configurations

Alternatively, for units that already have in-windbox/CCOFA compartments installed, the TLN1 installation would involve installing High Efficiency (HE) type CCOFA and top end air nozzle tips. These provide up to an additional 30% more flow area than the original tips. By utilizing the existing manual tilt capabilities in the CCOFA compartments, separation can be obtained between the CCOFA and the main combustion zone. In addition, the flow areas in the bottom end air, auxiliary air, and coal elevations would be optimized to bias air flow to the top end air / CCOFA elevations and nozzle tips would be re-sized to maintain design outlet velocities.

The TLN1-HE arrangement can also be upgraded to a TLN3 System in the future with minimal main windbox modifications

FWNAC also offers more aggressive NOx control arrangements using Separated Overfire Air (SOFA), including the TLN2 and the TLN3 systems. Increased separation between the upper most coal elevation and overfire Air level results in greater NOx reduction. Depending on the unit design and fuel, these arrangements are capable of NOx reductions exceeding 70%.

FWNAC's **TLN2** system consists of adding an additional level of overfire Air above the main firing zone to provide the required air staging effect. Because of increased spacing from the upper coal elevation, these arrangements generally provide higher NOx reduction efficiencies compared with in-windbox arrangements.

FWNAC's **TLN3** system consists of adding single level of separated overfire Air to units that already have an in-windbox OFA. This system is best suited for both post-NSPS or unit units previously retrofit with in-windbox overfire Air arrangements. Other applications of the TLN3 arrangements are units where interferences do not permit placement of an adequate single overfire Air windbox. According to our experience, the reduction efficiencies of the TLN3 systems are similar to TLN2 systems.

It should be noted that applying more levels of overfire air results in a limitation of furnace residence time for carbon particle burnout; therefore careful design consideration is required to minimize UBC losses.

3.4 Typical TLN Components and System Features

3.4.1 Separated Overfire Air Systems

The advantages of the FWNAC Separated Overfire Air (SOFA) system over other suppliers are its compact, yet performance efficient, design. This reduces the physical changes within the boiler house, thereby reducing installation time and cost. See **Figure 2** below for typical SOFA windbox and nozzle assembly**.**

Figure 2 - TLN Separated Overfire Air Windbox with Horizontal Yaw and Vertical Tilt Control

Introduction of staged secondary air, as “overfire air” is the single most important NOx performance component in any tangential low NOx system retrofit. Whether it is located in the main windbox or separated, it should provide the highest NOx reduction efficiency. The FWNAC SOFA systems provide the following specific features:

1. Compact separated windbox design that minimizes installation costs associated with tube panels, buckstay or other boiler house modifications.
2. Optimum vertical and horizontal placement assures highest NOx reduction efficiency and maximizes fuel/air mixing during this critical stage in the combustion process.
3. SOFA placement considers minimizing tube cuts and welds.
4. Adjustment capability is provided for maximizing fuel/air mixing through horizontal yaw, velocity, tilt and flow control.
5. Separated staging windboxes are fitted with turning vanes. The associated connecting duct designs are laid out to minimize system resistance, reducing auxiliary power requirements.
6. A minimal number of nozzle tips and linkages are applied to improve reliability and reduce long-term maintenance.
7. No refractory SOFA ports, only proven adjustable stainless nozzle tips with directional control are used.
8. Pressure taps in each compartment provide air distribution information and are used in the optimization process.
9. All components are designed and fabricated for long-term reliability.
10. For more aggressive NOx control, Foster Wheeler offers ours ECT and CADM systems, which allow for real-time quantified coal pipe distribution, velocity and particle size as well as air distribution.
11. Pressure taps in each compartment provide air distribution information and are used in the optimization process.
12. All components are designed and fabricated for long-term reliability.
13. For more aggressive NOx control, Foster Wheeler offers ours ECT and CADM systems, which allow for real-time quantified coal pipe distribution, velocity and particle size as well as air distribution.

Installed TLN SOFA System

Figure 3 - Foster Wheeler Separated Overfire Air Windbox

14. Pressure taps in each compartment provide air distribution information and are used in the optimization process.

15. All components are designed and fabricated for long-term reliability.

16. For more aggressive NOx control, Foster Wheeler offers ours ECT and CADM systems, which allow for real-time quantified coal pipe distribution, velocity and particle size as well as air distribution.

3.4.2 Coal Nozzle Tips and Nozzle Assemblies

All Foster Wheeler coal nozzle tips and coal nozzle assemblies are designed to match coal characteristics and pulverizer performance. This is key to preventing future pluggage or burn-back problems that reduce component life and inhibit unit long-term emission performance. All are designed to provide localized air staging, complimenting the overfire air based TLN system. Each Foster Wheeler coal nozzle assembly offers the following features:

1. All coal nozzle tips are designed to maintain high temperature structural integrity. This includes the mechanical design aspect as well as radiation protection for the internal sections. Foster Wheeler's new "Double Shroud" (DS) coal nozzle tips (US

Patent No. 6,260,491) are standard on most TLN retrofits. This design can offer even greater high temperature thermal resistance over conventional designs. See **Figure 4** below.

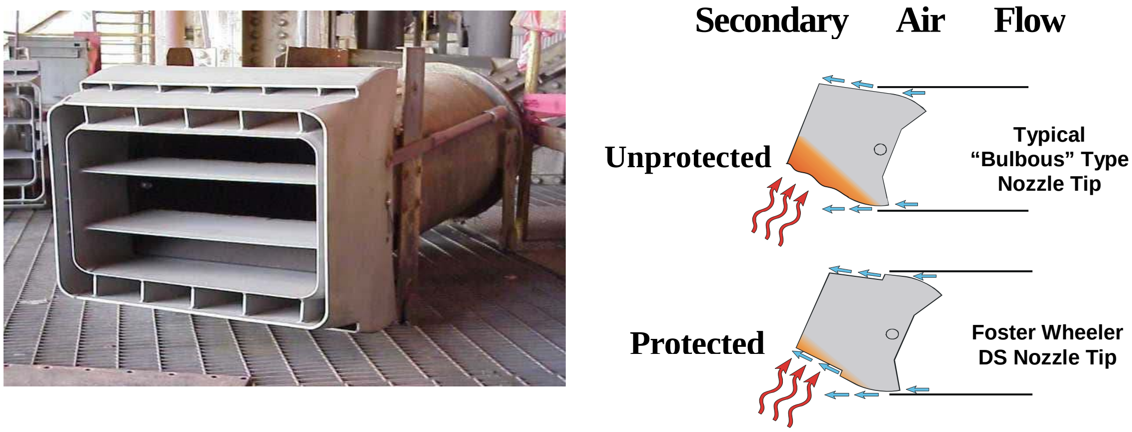

Figure 4 - Foster Wheeler’s Double Shroud Coal Nozzle Tip

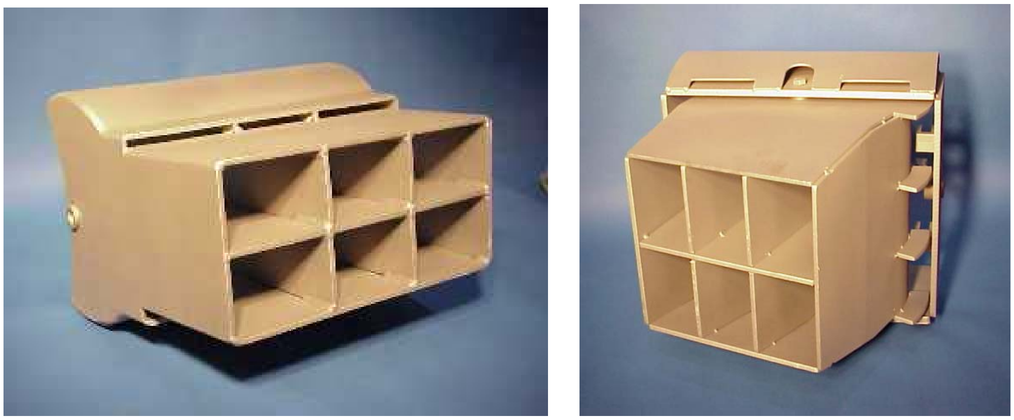
2. The new DS style coal nozzle tips are available in either single piece or two-piece stainless steel construction. Most Foster Wheeler DS style coal nozzle tips are capable of being replaced from the furnace side without removing the stationary coal nozzle assembly. This feature also allows coal nozzle tip side clearance adjustment without having to remove the complete stationary coal nozzle assembly. This feature saves 80 to 100 man-hours per coal nozzle.
3. Contoured outer radiation shrouds provide laminar air flow around the tips for added cooling and directional control of the air.
4. All nozzle tips are designed to maintain structural integrity due to thermal stresses.
5. All Foster Wheeler coal nozzle tip assemblies are 100% compatible and interchangeable with all existing windbox tilt linkages and other windbox internals.
6. The leading edges of splitter plates are hard surfaced for increased erosion resistance.
7. *Optional* coal nozzle tips are also available without seal plates.
8. *Optional* coal nozzle and tip assemblies are available with added wear resistant hard-surfacing and or materials.

3.4.3 Auxiliary, Boundary and Overfire Air Nozzle Tips

Typical windbox changes, associated with a TLN retrofit, consist of replacing many of the nozzle tips and associated hardware. Replacing particular nozzle tips is required primarily for performance reasons and secondly for reducing long-term maintenance costs. Foremost, it allows the system designer to redistribute the air properly in order to achieve the desired staging for NOx reduction. Secondly, it maximizes the air velocity leaving the air nozzle to ensure the highest degree of fuel/air mixing in the main firing zone. Thirdly, is assures adequate nozzle tip film cooling is maintained. Consequently, service life of individual nozzle tips is noticeably increased through proper nozzle sizing. Significant maintenance cost reductions can be realized in these cases.

All FWNAC air nozzle tips are designed for high temperature structural integrity. Each is available either as a single or two-piece design fabricated from a 309 stainless steel for high temperature oxidation resistance. Other specific materials are available upon request. Where applicable, the new “Double Shroud” (US Patent No. 6,260,491) design is provided for all air nozzle tips. See **Figure 5**.



(a) Tilting *(b) Boundary Air*

Figure 5 - FWNAC’s Double Shroud Air Nozzle Tips

The configuration of each newly provided nozzle tip consists of a contoured inlet for more laminar flow under tilted conditions as compared to the current equipment. An optional two-piece design allows replacement from the furnace side should it ever become necessary.

Foster Wheeler’s “Boundary Air” nozzles direct secondary air tangent to two or more imaginary circles within the furnace. The air tips in each corner are set independently to direct air from a given corner at a significantly different angle from the air coming from another corner or other corners. These range from one corner being aimed directly at the center of the furnace for instance, to another directing air along the furnace waterwall, etc. This variable positioning allows further control of the fireball shape to provide more even flue gas conditions exiting the combustion zone. These tips are provided only when required to reduce furnace waterwall slagging and/or any localized corrosion. This is usually a one-time adjustment that is set during post-retrofit system optimization. See **Figure 6** following.

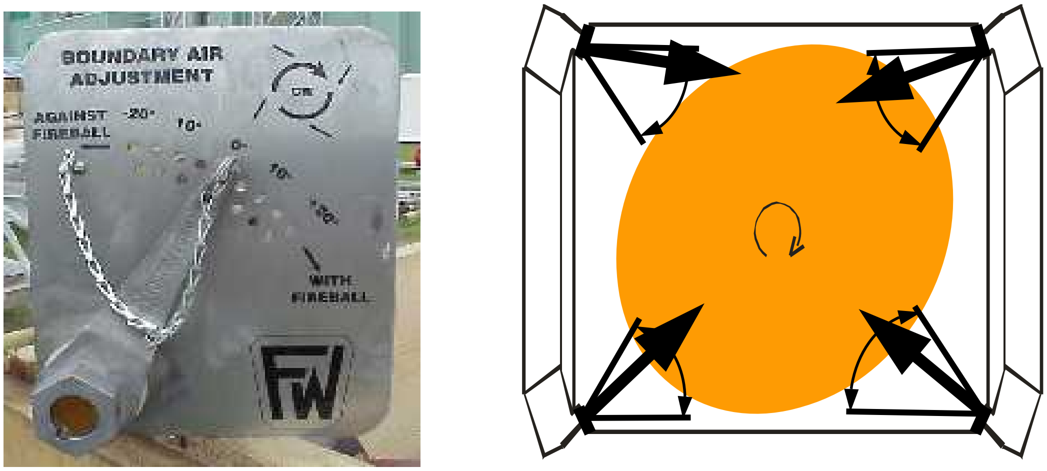


Figure 6 - Boundary Air Direction Control

The FWNAC SOFA nozzle tips include a similar feature that provides horizontal yaw adjustments. The nozzles from each individual SOFA windbox can be aimed, in unison, to direct the overfire air as required to maximize fuel/air-mixing momentum in this final phase of the combustion process. This adjustment is key for controlling exit CO emissions. This is a manual adjustment that usually requires only an initial adjustment during optimization. See **Figure 7** following.

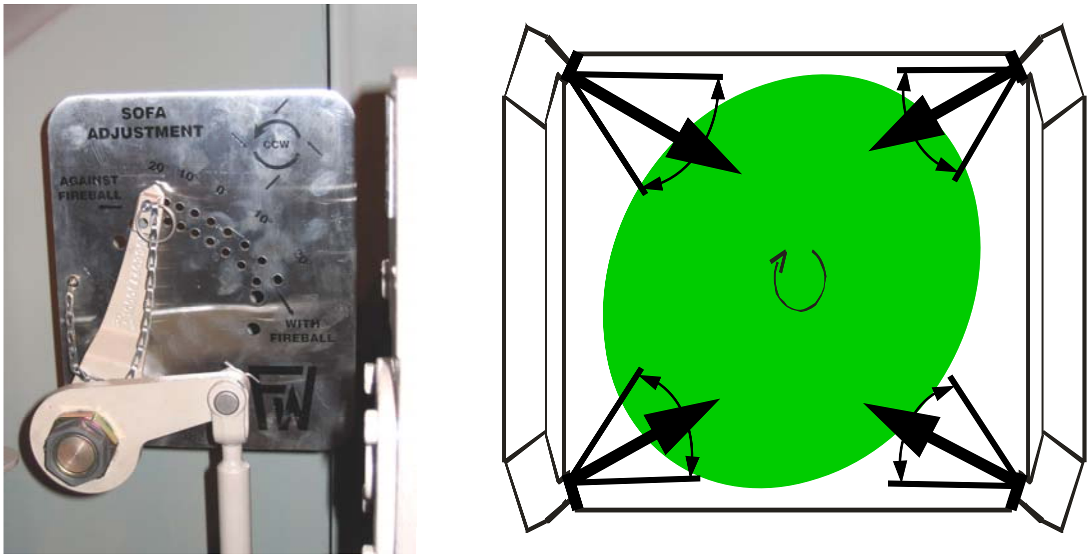

Figure 7 - SOFA Direction Control

3.4.4 Damper Venturi Inserts

FWNAC includes damper venturi inserts on most TLN retrofits. This upgrade, available for either existing or new damper systems, re-establishes windbox differential pressure control over the load range, lost due to the addition of overfire Air. It also insures that dampers operate in a controllable range. Another application is older tangential-fired units. These units tend to lose some windbox differential pressure control due to increasing furnace in leakage or other increased differential pressure requirements. Venturi damper inserts help re-establish this control.

The upgrade consists of installing venturi plates around existing damper blades or with new windbox dampers. It is an aerodynamic solution to increase the damper to nozzle tip flow ratio, providing improved air flow control and increased windbox to furnace differential control over a greater load range. A typical damper venturi installation is shown in **Figures 8 and 9.**

For information on the Optional Full Windbox Damper Upgrade, see “Design Update Bulletin No. 114.

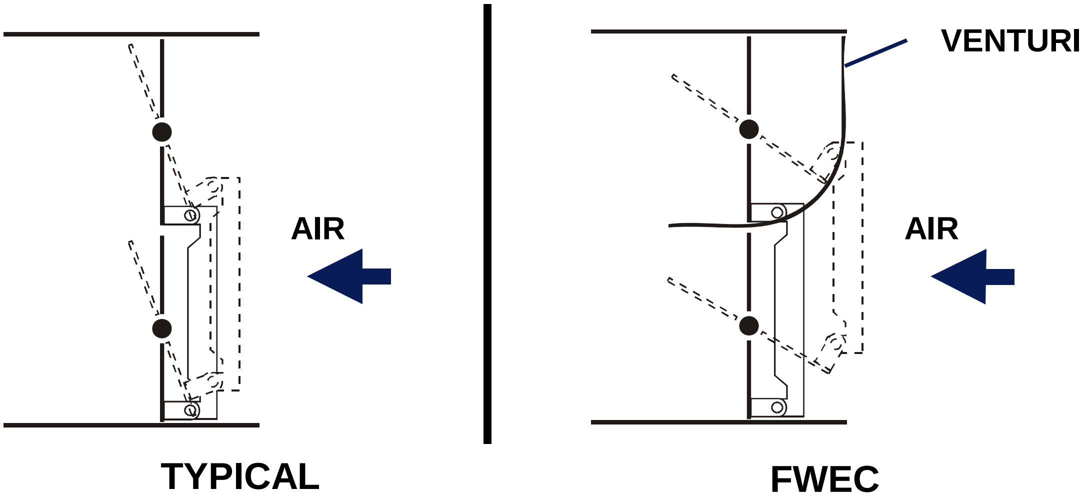

Figure 8 - FWNAC Damper Venturi Inserts

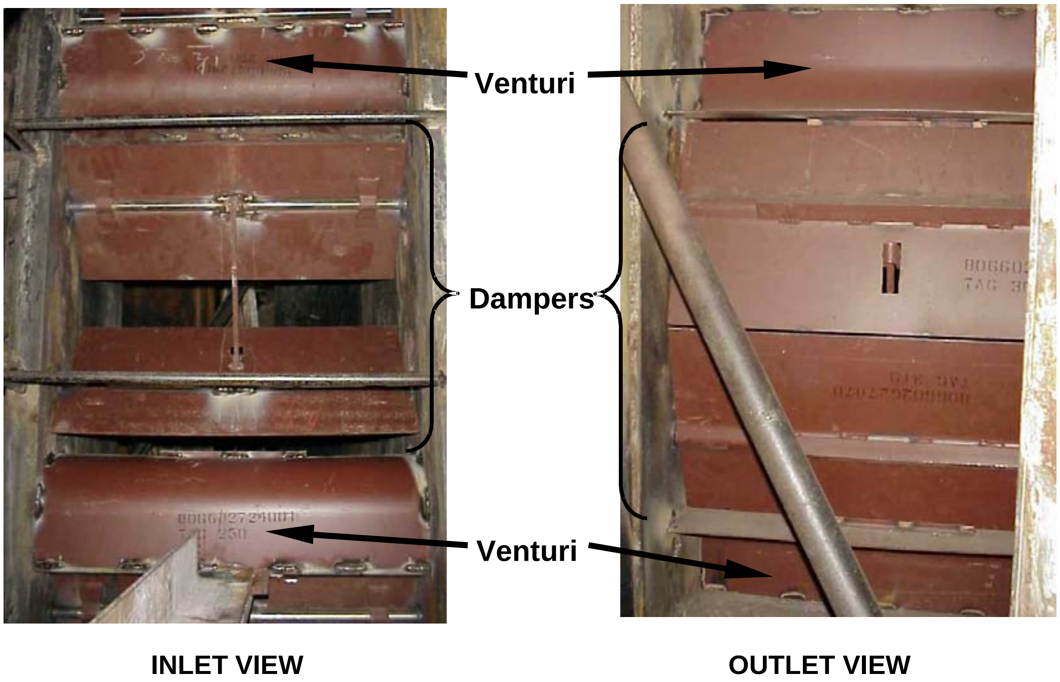

Figure 9 - Typical Damper Venturi Installation

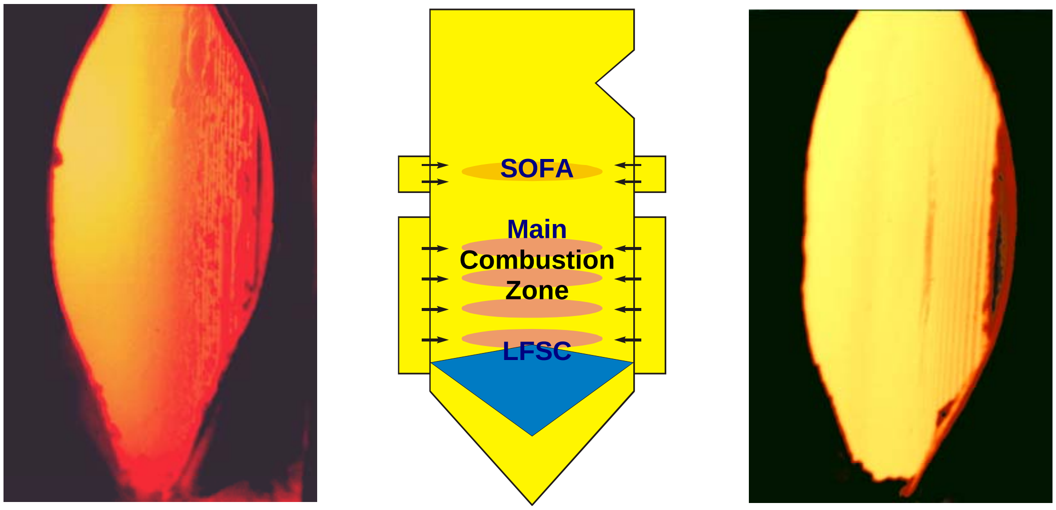
3.4.5 Lower Furnace Stoichiometry Control (LFSC)

FWNAC's Lower Furnace Stoichiometry Control was developed to help control the lower furnace hopper conditions created during deep staged low NOx combustion. Specifically, this FWNAC unique feature was developed to manage the fuel rich, smoky conditions as well as slag buildup in the lower furnace. Dark lower furnace /hopper conditions are common on many tangential-fired units equipped with competitor's tangential low NOx systems. LFSC includes nozzle tips (sometimes) and linkage modifications (always) to independently direct a percentage of secondary combustion air into the furnace hopper. Besides reducing the dark lower furnace conditions, FWNAC's experience with the LFSC system has also seen NOx benefits. The lower furnace concept is depicted as **Figure 10**.



Original Firing Arrangement

TLN System With LFSC

Figure 10 - Comparison of Lower Furnace Conditions Without & With FWNAC's TLN System

3.4.6 Windbox Secondary Air Biasing

In order to efficiently achieve the lowest NOx levels from tangential-fired units, some degree of secondary air flow biasing, is usually recommended as part of every TLN retrofit. Depending on what air biasing capability exists presently, FWNAC may recommend some or all of the following biasing controls:

- Corner-to-corner auxiliary air biasing.
- Hot and cold corner fuel and auxiliary air biasing (8 corner units).
- Front-to-rear and/or side-to-side secondary air biasing.

- Elevation air biasing.
- Furnace-to-furnace air biasing.
- Individual compartment air flow control.

Many tangential-fired units have oblong “fireballs” due to the aspect ratios associated with this type of firing system. These conditions, especially under deeply-staged low NOx firing conditions, if left uncontrolled, could lead to high CO emissions, increased corner slag buildup, furnace oxygen imbalance, etc. Such limitations could become barriers to achieving the lowest possible NOx emissions. FWNAC’s experience with air biasing shows that by selective air biasing, these conditions can be lessened and a rounder fireball shape can be achieved.

3.4.7 On-Line Conduit Coal Flow Measurement System (ECT)

Older vintage NOx reduction systems were capable of achieving moderate reductions in NOx at best. With the current emphasis on ultra low NOx emissions, these levels of reduction are no longer sufficient. Knowing and controlling the fuel and air distribution in a modern ultra low NOx combustion system is now key to achieving reliable long-term air staged operation without excessive CO or UBC formation. This fact has become evident, as more units are required to achieve very low emission levels. Without balance, high CO levels, unburned carbon, unequal oxygen profiles and temperature splits, etc. limit the reduction potential of low NOx systems. As a result, Foster Wheeler recommends the Electric Charge Transfer (ECT) system to provide operators with on-line, real time indication of coal flow conduit mass distribution, velocity and/or coal particle size.

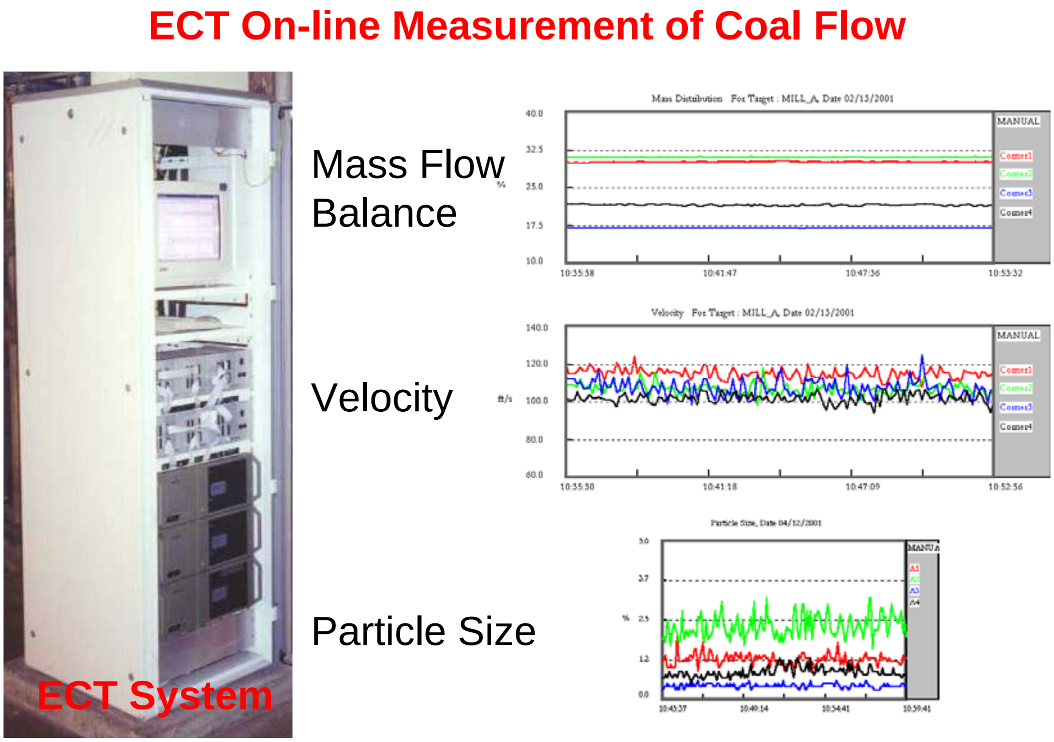


Figure 11 - ECT System and Features Measured

Due to aggressive CO requirements in typical specifications, Foster Wheeler commonly offers a system that monitors both the coal flow, velocity and/or particle size in each coal conduit as well as windbox air flow distribution in real time.

The ECT measurement, coupled with individual windbox compartment static air pressure measurements further enhances and accelerates the combustion optimization process. This type of information and control technology is well suited for application with Boiler Optimization Software. Additional information on the ECT System is presented in Attachments.

3.4.8 Compartment Air Distribution Monitoring (CADM) System

As mentioned previously, it is becoming more apparent in the low NOx power industry that in order to achieve ultra low NOx levels, air and coal flow distribution must be simultaneously monitored and controlled. This is analogous to the automobile industry changing from carburetors to fuel injection. Foster Wheeler is taking the lead in the industry with this Fuel Injection approach for pulverized coal-fired units.

Combined ECT/CADM are available as a fully automatic DCS controlled system. This is Foster Wheeler's Fuel Injection (FI) system. Coal flow through each coal nozzle is measured in real-time along with secondary air flow through each windbox compartment. Comparisons are made and the DCS is instructed to adjust secondary air balancing the air to match the coal floe distribution entering the furnace. Besides NOx and other gas profile benefits, results have shown extremely low CO levels under ultra low NOx operating conditions. **Figure 12** shows typical benefits data obtained from combined ECT/CADM System.

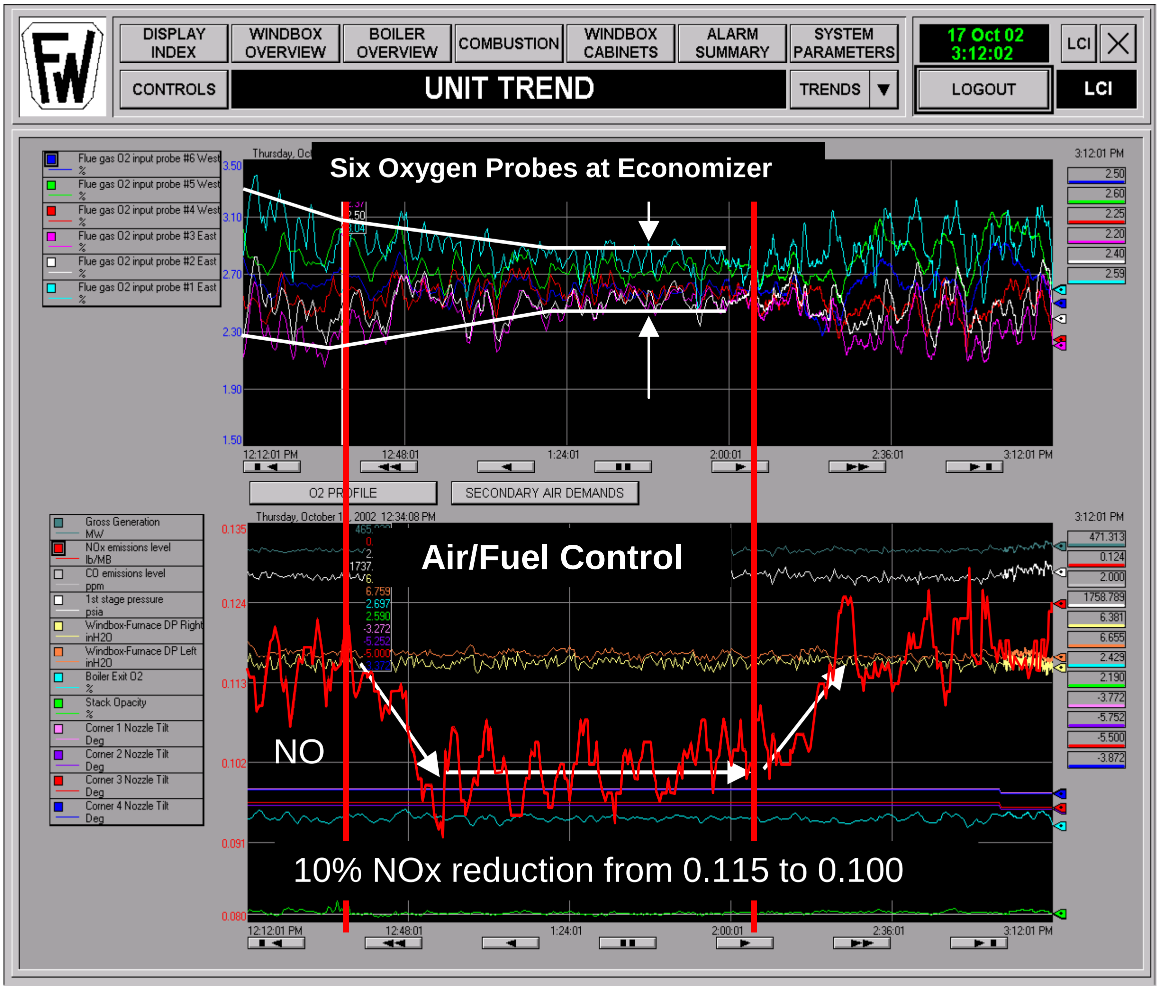

Figure 12 - NOx Reduction and O_2 Profile Improvement Results from 480 MW Unit Firing PRB Coal and Equipped with a TLN3 and both ECT and CADM operating under DCS Control

4. DESCRIPTION OF PROPOSED FWNAC TLN3 SYSTEM

4.1 Proposed TLN3 System for Coal Creek Units 1 & 2

Based on Great River Energy's requirements and FWNAC's evaluation of the current unit operation, FWNAC is proposing an "expanded" TLN3 System. Foster Wheeler's approach is to increase the amount of SOFA to each corner by installing larger SOFA windboxes and ducts, while staying between the existing buckstays, thereby reducing installation time and costs.

The descriptions of Foster Wheeler modifications are the same for both units. This will allow for design interchangeability.

The proposed FWNAC modifications to Coal Creek Units 1 & 2 are shown on FWNAC proposal drawings attached in the Appendices.

a) A SINGLE level of new separated SOFA windboxes will be provided as part of the FWNAC TLN3 system. This would consist of four (4) new, larger SOFA windboxes. To minimize physical changes to the boiler house, the new overfire air windboxes would be installed where the existing SOFA windboxes are. The new, larger SOFA windboxes are wider but maintain the same height so as to fit between the buckstays. The SOFA windboxes would be designed to supply an increased amount of combustion air as overfire air. Each new windbox will be provided along with new waterwall panels and the necessary larger, connecting ductwork, hangers, expansion joints and steel modifications to interface with the secondary air ducts. The new SOFA duct arrangement will eliminate the "S-shaped" bends to the inner corner windboxes, thereby providing less pressure drop. Each windbox will be fitted with nozzle tips, turning vanes, access doors, air control dampers and electric actuators and static pressure taps to provide total overfire air control. Manual "set and forget" horizontal yaw and vertical tilt capability would be provided in the SOFA to help control CO as well as back end gas temperature and oxygen profiles. The yaw linkage, manual tilt gearbox and damper drives will be accessible from the sides of each windbox.

b) On the rear waterwall, at the inside corners, there is an existing economizer valve that will need to be relocated. This is noted on the proposal drawing and will be detailed during the engineering and design phase. Currently, this relocation is anticipated as a simple matter of moving the valve down an elevation. (Note: there are several wall blowers one elevation above this valve).

c) Platform and structural steel modifications are not needed.

d) New Double Shroud "Boundary" auxiliary air nozzle tips for the (non-oil) 19 ¼" compartments. These nozzle tips are designed to provide the necessary velocity, air flow distribution and direction control to benefit NOx emissions, fireball shaping while maximizing combustion efficiency.

e) All CCOFA, coal and auxiliary air windbox compartments will be modified with FWNAC’s larger damper venturi plates to improve air flow distribution control over a larger load range.

5. PROPOSED SCOPE OF SUPPLY

The Scope of Supply for the Foster Wheeler TLN3 System is listed below. Due to the similarities between Coal Creek Units 1 & 2, components are interchangeable. Quantities listed are for one (1) unit only.

5.1 TLN3 Engineering Scope

Item	Quantity	Description
1	One (1) lot	Engineering and design analysis for new TLN3 System.
2	One (l) lot	Engineering arrangement drawings to incorporate TLN equipment and unit modifications, including Bill of Materials.
3	One (l) lot	SAMA control diagrams to describe the desired control SOFA dampers, (see Appendix for typical SAMA drawings).
4	One (l) set	Listing of all required I/O

5.2 TLN3 Equipment Scope

Item	Quantity	Description
1	Eight (8)	Separated SOFA windbox; 32” wide furnace channel by approx. 56” high, complete with an appropriate number of compartments, including turning vanes, yaw and tilt mechanisms and 48” wide opposed blade damper assemblies. Damper blades will be carbon steel with stainless steel damper shafts. Damper bearings will be stainless steel except for the outboard damper bearings that will be self-aligning graphite. Two (2) Hagan pneumatic drives, and all mounting brackets and hardware are provided with each SOFA windbox (16 total). Each compartment will be fitted with an individual static air pressure tap. A rear access door is also provided.
2	One (1) lot	Complete secondary air duct system for SOFA. Includes structural steel check for proposed hanger assemblies.

3	Four (4)	Waterwall tube panels to incorporate SOFA. Rifled/ribbed tubes of material similar to existing water wall.
4	Two (2)	Duct scoops to direct secondary air into the overfire air ducts.
5	Thirty-two (32)	“Boundary” air nozzles for each of the 19 ¼” auxiliary air (non-oil) compartments. Includes quadrants.
6	Sixty-four (64)	Air deflector plates (3” high) for installation in each of the 19 ¼” auxiliary air (non-oil) compartments. Replaces the current 2” high deflector plates. Material: 309 SS
7	One Hundred Twenty (120)	Flow controlling damper venturi plate sets for all coal and auxiliary air compartment dampers. Material: Corten.
8	Fourteen (14)	Fabric Expansion joints with welded flange joints.
9	One (1) lot	Hanger rod assemblies
10	One (1) lot	Spare pins and hardware for installation support as determined by FWNAC.
11	Ten (10)	Operating instruction manuals with parts lists.
12	One (1)	Three (3) day Operator Training Sessions and ten (10) Training Manuals (prior to startup).

5.3 Technical Field Support

1	Technical support of FWNAC service engineer time covering pre-outage, outage and post-outage time frame. Billed on a Per Diem rate presented in the Appendix.

5.4 Scope NOT Included

The following work will be performed or furnished and installed by others:

a) Installation.

b) Asbestos removal.

c) Instrumentation and control equipment or modifications, except as expressly specified by FWNAC. Great River Energy is required to incorporate FWNAC provided SAMA control logic into their DCS as part of the TLN retrofit.

d) Any new/additional neural network inputs.

e) Electrical wiring, cable trays/modifications and conduit.

f) Pneumatic and control system additions or modifications, including relocation of existing pneumatic piping.

g) Insulation and lagging. Insulation removed for fitting SOFA system or for other work proposed by FWNAC is not included.

h) Material for removal or relocating sootblower (other than the required pipe material), downcomers, economizer valves, refractory replacement, material to limit spray arc of sootblowers etc. Material for relocating cable trays, fire water, service air piping is not included.

i) Structural steel or modifications to the existing steel is by others except where specified by Foster Wheeler.

j) Temporary office space or trailer with telephone and electricity at the jobsite for use by FWNAC Service Engineer(s) should be provided by Great River Energy and is not included in FWNAC scope.

k) Repair or replacement of damaged components discovered during TLN outage.

l) Fuel, ash sampling and lab analysis is not included in FWNAC scope of supply.

m) If coal flow balancing is required during baseline testing and/or optimization, FWNAC scope does not include procuring and installing coal pipe sampling ports and any subsequent corrections.

n) Provision and installation of the necessary ports and sampling probes at the economizer outlet for system optimization is not included.

5.5 Terminal Points

The FWNAC terminal points for this scope will be as shown on the attached proposal drawings and are further identified by the material listed in Section 5 under “Scope of Supply”.

A) OFA System:

Ductwork termination points are at the connecting point to the existing air ducts and at the register. The ductwork includes expansion joints, hangers and support steel only as required to attach to existing steel. The termination point is the connection at the existing steel. The register includes the tube openings and seal boxes. Termination points are the tube ends of the panels.

B) Windbox Material:

Material to replace identified tilting nozzle tips is included. Termination points are at the windbox front channel and the windbox damper frame. Plate work and hardware as required to modify the windbox is included. Any additional material required to return the existing windbox shell or internal structural components to a structurally sound and dimensionally true condition is not included in FWNAC's scope.

C) Electrical and Controls:

All electrical, pneumatic and control interface points are the field device termination points of the identified field devices.

D) Control System:

Seller will provide SAMA drawings.

5.6 Post-Retrofit System Tuning/Optimization

The objective of this phase is to optimize the newly installed TLN system for the required emissions performance and unit operation. The unit's Continuous Emission Monitoring System (CEMS) will be used as the basis for assessing NOx. It will again be the client's responsibility to ensure the accuracy of the CEMS system through proper calibration and maintenance procedures. To evaluate and confirm long-term emission performance, FWNAC estimates approximately a one (1) to four (4) week period for optimization to establish and confirm long-term reliable operating set points.

To ensure a technically proper evaluation of the low NOx burner performance, it will be necessary to have steady state system operating conditions during evaluation of individual settings.

a) The unit's Continuous Emission Monitoring System (CEMS) will be used as the basis for assessing NOx. A multi-point gas sampling grid at the economizer outlet, which can be provided by FWNAC, to measure exit gas NOx, CO and O_2 on a per point basis can be utilized as well. This has been proven to reduce optimization time and costs. FWNAC will provide an Engineer to conduct the optimization program. Great River Energy should also provide an air-conditioned test facility for the test instrumentation during optimization. Supply utilities such as electric power and air at sampling locations are also required by client.

b) FWNAC will request that Great River Energy make preparations for supplying and firing a coal within the guarantee range.

c) If coal fineness is suspect, Great River Energy may be requested that coal fineness be taken on a mill basis.

d) Normal unit board data, furnace slag profiles and temperature measurements, etc. necessary for proper boiler performance evaluation, will be taken.

e) Great River Energy shall perform any required station instrumentation calibration, if necessary and assist if requested in making control room data available to FWNAC.

f) FWNAC will provide an optimization plan prior to commencement of the TLN3 system.

g) FWNAC will provide a Service Engineer for unit testing. The extension of field testing service time and/or schedules for reasons beyond the control of FWNAC, shall be considered extra work assignments and be billable at the standard FWNAC service rates (see Appendices for standard rates).

5.7 Post-Retrofit Performance Testing

a) Prior to guarantee testing, FWNAC will conduct preliminary "dry-runs" of guarantee testing.

b) Foster Wheeler will notify Great River Energy when the unit is ready to be tested. Individual testing will be conducted at MCR steam flow (3,730,000 lbs/hr) over a four (4) hour period. FWNAC will work with Great River Energy to establish the final post-retrofit test plan, following engineering submittal.

c) Guarantee testing will consist of a four (4) hour test period conducted under steady-state NORMAL OPERATING CONDITIONS as identified under guarantee requirements.

d) To ensure a technically proper evaluation of the TLN system performance it will be necessary to have a four (4) hour test period with normal, non-transient, boiler operation and consistent fuel supply with confirmation of fineness levels. Any periods of unit upsets or if unplanned transient conditions occur, additional time will be required.

e) Unit should be fuel seasoned for at least two (2) days of MCR operation. Great River Energy is requested to provide coal fineness from each mill.

f) FWNAC site representative may request changes in the sootblowing procedures as required for fuel changes and / or performance requirements.

Post-Retrofit Performance Testing will be conducted under FWNAC guidance. FWNAC will assign an engineer to participate in witnessing the test program. If the allotted Service time has been exceeded, additional service time above those listed in the Scope of Supply will be considered as extra work assignments.

FWNAC will accept post-retrofit testing using the plant CEMS equipment and standard fly ash sampling methods with the following provision.

Note: For optimization FWNAC may elect to install probes into existing economizer outlet gas duct taps. The probes will be provided by Great River Energy. It is assumed this unit is already equipped with economizer outlet taps that are in good shape.

5.8 FWNAC Outage Support

FWNAC can furnish one qualified service representative to assist in installation and commissioning activities for erection coverage. It is estimated that this individual would be required for four weeks of the scheduled outage. Pricing is based up an eight hour day for six days a week for four weeks. If activities extend beyond the anticipated time or allotted hours, service engineer’s time will be billed on a per diem basis at the agreed upon rates.

6. PREDICTED PERFORMANCE

The Tangential Low NOx Operating System offered in this proposal is designed for current operating conditions. The system is designed with enough flexibility for 7/8 mills in service (pre-drying system) and for 6/8 mills in service (post-drying system) to achieve 3,730,000 lbs/hr of main steam flow. Fuel analyses provided by Great River Energy were utilized in the design.

Note: The following projections are not to be construed as guarantees.

6.1 NOx Emissions

Foster Wheeler predicts the following NOx emissions at the customer defined MCR load point for the TLN3 proposed within this document:

- The TLN3 system is designed with the potential to produce 0.15 lb/MBtu NOx emissions at full load MCR.

Figure 13 shows the current NOx performance been achieved on the Coal Creek boilers (2^{nd} quarter 2006 EPA data) and the predicted NOx levels that will be achieved post-retrofit on these boilers.

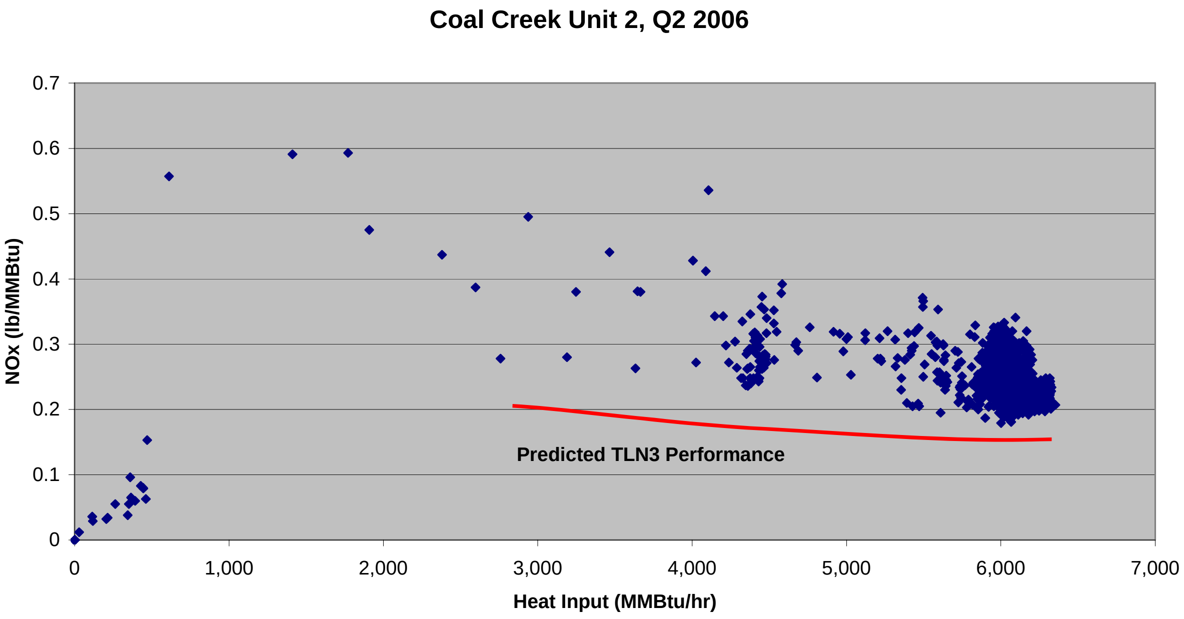

Figure 13 - Predicted NOx Performance on Coal Creek Boilers

Notes

1.) All full load predictions are based on ideal boiler operating conditions and 7/8 mills in service (pre-drying system) or 6/8 mills in service (post-drying system). They are also based on the assumption that burner tilts are no higher than the horizontal position.

Low load NOx performance is very unit specific. Since the reduction of heat input into the furnace inhibits the NOx formation, NOx emissions should decrease with reduced loads unless excess air increases. However, the actual amount of reduction also depends on other boiler operating parameters such boiler excess O_2 and actual levels of boiler in-leakage. In addition, nozzle tilts are often brought above horizontal to maintain steam temperature at lower loads, thereby decreasing furnace residence time. Therefore, the appropriate SOFA flows at various points in the load range will be determined during post-retrofit tuning to maintain Low NOx operation.

Current data gathered from the EPA website for Coal Creek No. 2 indicates that as unit load is decreased, NOx emissions is reduced.

See **Figure 13** for low load NOx predictions.

Note:

NOx emissions are not directly affected by variances in mill fineness levels. Values lower than 65% through 200 mesh will most likely result in higher percentages on the 50 mesh and this will indirectly cause NOx emissions to increase by virtue of reducing staging to control UBC levels. Fineness on it’s own has no direct impact on NOx formation.

6.2 Unburned Carbon (UBC) in Flyash

As with the NOx emissions, Foster Wheeler's predictions for the Coal Creek boilers are based on past experience with these types of fuel and unburned carbon levels.

Foster Wheeler predicts that the UBC levels for the proposed TLN3 system will be as follows:

- Less than 0.5% when firing the design coal at MCR.

Improved fineness levels and coal/air distribution can help reduce the UBC in fly ash levels. Current predictions are based on a minimum fineness of 65% through 200 mesh and 1.5% on the 50 mesh.

Fuel related impacts on unburned carbon are much higher than on NOx. Therefore, any future changes in actual fuel characteristics might necessitate revision of the above predictions.

UBC does not significantly increase when firing lignite fuels under staged conditions, again due to its relatively high reactivity. However, as with all other performance parameters, the unburned carbon is negatively impacted by up-tilt on the burners. High tilt positions on tangential-fired units result in poor fuel/air interaction leading to higher UBC and CO. Thus, it will be important to maintain the tilts at or below horizontal to ensure high levels of burnout.

6.3 Steam Temperature Performance

Foster Wheeler predicts that steam temperatures will remain near current levels following the TLN3 retrofit. Our experience with at Coal Creek and with tangential-fired units firing similar fuels to that being fired on the Coal Creek boilers is that a more balanced or uniform temperature profile will result following the TLN3 retrofit. After the first Foster Wheeler TLN retrofits, the Coal Creek units experienced cleaner waterwalls in the firing zone. Foster Wheeler predicts no change in steam temperatures from current values.

6.4 Effects of Excess Air (Boiler O_2 levels)

Excess air is an important parameter that affects NOx, steam temperatures, boiler efficiency, etc. Maintaining proper boiler O_2 levels is key to low NOx combustion. Too much O_2 at the burner can create high NOx as well as contribute to lower boiler efficiencies due to stack losses. However, too little O_2 can lead to unacceptable UBC and CO values as well as lowered steam temperatures. FWNAC evaluates each of these parameters to determine the optimum post-retrofit excess air level. The TLN3 will be designed to operate at or near current O_2 levels. However, the effects of excess air levels will be investigated during the optimization/tuning phase.

6.5 Effects of Nozzle Tilt Angle

In order to maintain steam temperatures, main burner nozzle tilt angle is typically modulated. Through the tilt range, various combustion effects are reflected through fluctuating NOx, CO, and UBC levels. A downward tilt angle will provide increased residence time for greater carbon burnout, hence lower UBC levels. Increased residence time also helps NOx emissions. CO effects are typically unit and fuel specific. It is predicted that the burner tilt positions at MCR conditions will remain unchanged (or possibly lower with more SOFA flow) following the TLN3 retrofit.

6.6 Effects of Coal

Coal properties play a very important role in operation of any low NOx combustion system. For both NOx and UBC, fuel reactivity plays the key role. FC/VM, HHV(daf), as well as fuel nitrogen loading are the primary parameters. Ash constituents also are important as they effect the furnace thermal environment that affects NOx and UBC.

7. PERFORMANCE GUARANTEES

7.1 Performance Guarantees

The following Performance Guarantees contained in sections 7.2 through 7.5 are the **exclusive performance guarantees** offered by FWNAC relating to the equipment supplied by FWNAC. Any graphs, stated performance values, predictions or discussions in other sections of the proposal shall not be construed as performance guarantees.

- The guarantee will be considered met, if the average of the guarantee value, over the test period meets the guarantee values offered below by FWNAC.

- All performance conditions, test methods, and referenced fuels/ranges of fuels as defined in Section 7.2 of this proposal are considered a prerequisite for the guarantees. All sampling must ensure that a representative average of the flue gas emissions and fly ash sample is taken.

7.1.1 NOx Guarantee

- **NOx will average less than or equal to 0.170 lb NOx/MBtu** at 100% MCR (3,730,000 lbs/hr steam)

7.2 Performance Condition Requirements

To ensure a technically proper evaluation of the low NOx system performance, it is necessary to have normal, non-transient unit operating conditions. The following requirements are the basis for the post-retrofit performance period (cold/hot commissioning, optimization and performance guarantee test):

a) Unit Operation - Operation of the unit should be in accordance with the manufacturer's instructions and the direction of Foster Wheeler’s site representative. Adjustable parameters include O_2, mill sequencing, mill biasing, windbox-to-furnace differential pressure, damper and yaw settings, load ramping rates, sootblowing and others. Boiler and steam cycle equipment must be operated in a manner similar to baseline conditions including normal design temperatures, flow, pressures, etc. tests. Boiler should be seasoned to the fuels being fired. Any modifications to boiler heat transfer equipment (i.e., SH, economizer, air preheaters) or changes in system operation (such as feedwater heaters out of service) prior to the retrofit outage will require alterations of guarantees.

NOTE: All emission and steam temperatures guarantees are subject to maintaining the same baseline main steam flow and pressure, reheat flow and pressure, feedwater temperature and cold reheat inlet temperature following retrofit. This will assure a fair evaluation basis for both Great River Energy and Foster Wheeler to evaluate the TLN3 system performance.

b) The NOx guarantees are based on the post-retrofit coal being within the shaded qualifying region shown on **Figures 14** and within the ranges from **Table 1.** Should the coal fall outside that region the appropriate NOx emission corrections shall apply.

c) For the performance guarantee test, coal fineness levels on a per mill basis will be no coarser than 1.5% on Mesh 50, 88% passing Mesh 100, and 65% passing Mesh 200.

d) All pulverizers are to be operated in accordance with the manufacturer's instruction and the Buyer is responsible for ensuring that coal pipe riffle elements and orifices are in good condition prior to optimization. Primary air flow must be in accordance with the associated pulverizer airflow curves. Foster Wheeler has designed the system to accommodate the current 350 klb/hr primary air flow and the expected future (post-drying system) 255 klb/hr primary air flow. Coal flow imbalance between coal conduits should not exceed the normal industry standard of ± 20% from average on an elevation basis. It is assumed that the pulverizers are operating in accordance with the OEM's air flow and temperature criteria. Primary air flow between coal conduits should be within the normal industry standard of ± 10% from average on an elevation basis.

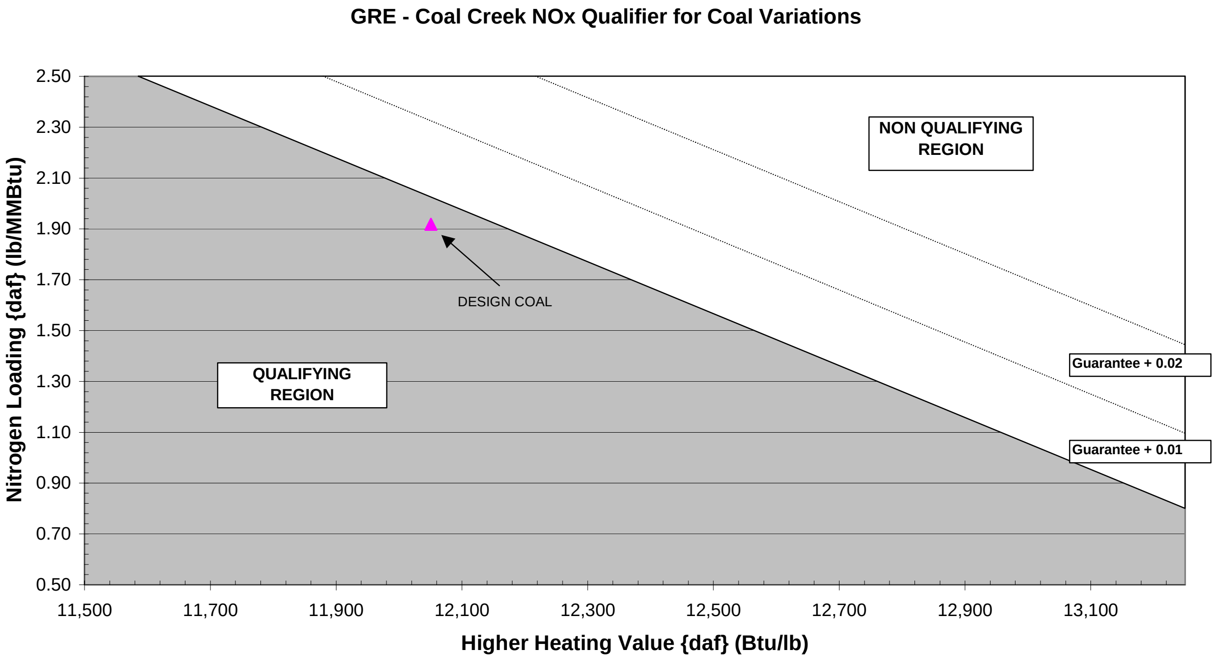

Figure 14 - NOx Fuel Qualifier Curve for HHV (daf) and Nitrogen Loading (daf)

e) A qualified Foster Wheeler Technical Services representative will recommend the final O_2 operating level during the start-up and optimization of the low NOx firing system. The actual level of excess oxygen will be adjusted to simultaneously optimize NOx, CO, and UBC. The low NOx firing system will be designed for a target average excess oxygen level of 2.5 %.

f) All performance guarantee testing shall be conducted under standard plant operating conditions at steady-state loads of 3,730,000 lbs/hr (100% MCR) steam flow with no feedwater heaters out of service, no hindrances due to incapacitated FD or ID fans, flue gas cleaning equipment, coal feeders, pulverizers, ash handling system, sootblowers, wall blowers and burner controls.

g) It is assumed that all other existing related windbox structure, linkage, hardware and nozzle tips not supplied under this proposal are in good operating condition.

h) All guarantee parameters measured during the performance test will be an average over the four (4) hour test period.

i) The CEMS shall be used to determine the NOx emission levels during all performance tests. If the guarantee testing fails to demonstrate the guaranteed emissions, EPA methods 3A, 7E, and 10 and isokinetic testing shall be used at a grid in the economizer outlet to determine excess O_2, NOx and CO during a second performance guarantee test. This data is the determining data.

j) Economizer O_2 must be maintained within a ± 0.20% range from set-point.

Fuel - Coal characteristics play a major role in determining achievable emission as well as combustion efficiency. For both NOx and UBC, fuel reactivity plays the key role. FC/VM, HHV (daf), as well as fuel nitrogen loading are the primary parameters. Ash constituents also are important as they effect the furnace thermal environment that affects NOx and UBC. These are listed below. Foster Wheeler has taken all these parameters into consideration in offering our guarantees. Consequently, all guarantees are based on firing the following fuel consistent with fuel parameters identified below. Coals outside the qualification ranges in **Figure 14** and **Table 1** below do not qualify as fuels that meet the performance conditions. During optimization and testing, coal loaded in various bunkers must be kept consistent, i.e. same coal in same bunkers. Prior to commencing any testing, the boiler must be properly seasoned with the design fuel that will be burned during the test.

LOW NOX SYSTEM DESIGN COAL AND ALLOWABLE RANGE		
Fuel Parameter	**Design**	**Allowable Range**
Volatile Matter, as rec. (VM), %	25.2	See FC/VM

Table 1.Design Coal

Furnace In-Leakage - The furnace in leakage shall be less than 8%. Should the furnace fail to meet the in-leakage requirement, emissions and combustion efficiencies will be affected and thus the related performance guarantees will have to be adjusted accordingly.

Slagging - Furnace slagging should be controlled in accordance with normal industry practice.

8. COMMERCIAL OFFERING

8.1 Project Schedule

The project schedule is very aggressive. Based upon current shop loadings and space availability, equipment delivery to support the March 15, 2007 outage start date can be achieved. FWNAC will monitor shop space during the engineering phase of the project and alert GRE to any changes to shop space availability. A preliminary schedule can be found in the Appendices.

8.2 Pricing & Payment Terms

8.2.1 Engineering and Material Supply:

FWNAC offers to perform the scope of work contained in Sections 5.1 and 5.2 FOB jobsite, exclusive of taxes, subject to availability of shop space:

One Million Six Hundred and Fifty Thousand Dollars
US $ 1,650,000

8.2.2 Outage Support

FWNAC offers to provide technical outage support in accordance with Section 5.3

Forty Thousand Dollars

US $40,000

8.2.3 Commissioning and Optimization

FWNAC offers to provide technical support for the Commissioning and Optimization of the equipment on a per diem rate of $1200 for each eight hour day Monday through Friday plus Travel and Living expenses. Travel and Living expense will be invoiced at cost. Additional hours per day, weekends and Holidays would be billed at a rate of $225/ hour. The estimated **budget** cost for two Service Engineers for approximately four weeks for sixty hours per week plus Travel and Living expenses is $96,000.

8.2.4 Terms and Conditions

FWNAC offers to perform the above scope of work in accordance with the attached Standard FWNAC Terms and Conditions of Sale Material Only.

If the equipment fails to achieve the Guaranteed NOx level in Section 7, FWNAC will perform additional tuning and optimization of the equipment with a maximum cost of $30,000. Performing the additional tuning and optimization and expenditure of this money shall be in full settlement of all liabilities of FWNAC for failure to meet the Performance Guarantee.

A written notification of award setting forth the basis of the award including the agreed upon Terms and Conditions is required by FWNAC prior to starting work. In the event Great River Energy would like work to proceed prior to agreement on Terms and Conditions, FWNAC would do so in accordance with and upon receipt of the executed “Authorization to Begin Work” form included with this proposal.

8.2.5 Validity of Proposal

The prices tendered with this proposal are subject to acceptance by Great River Energy within a period of thirty (30) days from the date hereof, except Foster Wheeler North America Corp. shall have the right to withdraw its proposal at any time before formal acceptance by Great River Energy and receipt of written approval by an officer of Foster Wheeler North America Corp.

The proposed schedule is contingent upon receipt of an acceptable purchase order and full release to proceed by an award date of October 16, 2006. It is also contingent upon availability of vendor shop space at the time of material/equipment procurement.

8.2.6 Progress Payment Terms

The payment to Foster Wheeler North America Corp. shall proceed by the following schedule:

5% of Contract Value upon Award/Release

10% of Contract Value upon Drawing Submittal

30% of Contract Value upon Purchase of Major Material and Equipment

45% of Contract Value upon Delivery of Material and Equipment

10% of Contract Value upon Successful Achievement of Performance Guarantee or Six Months after delivery whichever is sooner.

AUTHORIZATION TO BEGIN WORK

Great River Energy hereby authorizes Foster Wheeler North America Corporation to perform the work described in its Proposal No. 65-120220-00 rev01 dated October 6, 2006 the rates and/or prices stated therein. Foster Wheeler North America Corporation is to commence the work in accordance with the Terms and Conditions of the proposal. It is understood that Great River Energy reserves the right to request changes in the Terms and Conditions and in the event that mutual agreement cannot be reached regarding the requested changes, we shall have the right to direct Foster Wheeler North America Corporation to stop work, in which case Foster Wheeler North America Corporation shall be paid for all materials as well as all work performed and Foster Wheeler North America Corporation shall have no further obligation to Great River Energy.

It is understood that a formal contract or purchase order will be prepared confirming this Authorization and or agreements regarding the work.

ACKNOWLEDGEMENT

The authors wish to acknowledge the contributions and support provided by various project managers: Dr. Sai Gollakota (DOE), Matt Coughlin (Barr), Dave Rian (Barr), John Wheeldon (EPRI), Tony Armor (EPRI), Dr. Ed Levy (Lehigh), Dr. Nedad Sarunac (Lehigh), and Mark Ness (GRE).

ABSTRACT

U.S. lignites have moisture contents ranging from 25 to 40 percent. This results in lower heating value, higher fuel flow rate, higher stack flue gas flow rate and stack loss, higher station service power, lower plant efficiency, and higher mill, coal pipe and burner maintenance requirements compared to that of the Eastern bituminous coals. Despite problems associated with their high-moisture content, lignite and sub-bituminous coals from the Western U.S. are attractive due to their low cost and emissions, and high reactivity.

A process that uses low-grade heat rejected from the steam condenser and waste heat from the flue gas leaving the boiler to evaporate a portion of the fuel moisture from the lignite feedstock in a fluidized bed dryer ("FBD") was developed in the U.S. by a team led by Great River Energy ("GRE"). The research is being conducted with Department of Energy ("DOE") funding under DOE Award Number: DE-CF26-04NT41763.

The objective of GRE's Lignite Fuel Enhancement project is to demonstrate a 5 to 15 percentage point reduction in lignite moisture content (about ¼ of the total moisture content) by using heat rejected from the power plant. This will significantly enhance the value of lignite as a fuel in electrical power generation power plants. Although current lignite power plants are designed to burn wet lignite, the reduction in moisture content will increase efficiency, reduce pollution, and improve plant economics.

The benefits of reduced-moisture-content lignite are being demonstrated at GRE's Coal Creek Station (CCS). A phased approach is used. In Phase 1 of the project, a full-scale prototype coal drying system, including a fluidized bed coal dryer, was designed, constructed, and integrated into Unit 2 at Coal Creek.

The prototype coal drying system at CCS has been in almost continuous, fully automatic operation since February 2006. Performance of the prototype dryer and the effect of partially dried coal on unit performance and emissions were determined from a series of paired performance tests that were conducted at carefully controlled test conditions. In addition, dryer performance during regular operation was determined.

According to the test results, at the baseline feed rate of 75 tons per hour, the prototype coal dryer easily meets the performance goals and specifications established for the project. The maximum continuous feed rate to the dryer is 101 t/hr. Further increases in feed rate are prevented by limitations on the coal conveying system throughput and dust collector fan power limits.

A commercial coal drying system, consisting of four fluidized bed dryers will be designed, built, installed, and tested at CCS during Phase 2 of the project. With four dryers in service it will be possible to reduce moisture content of the total coal feed to Unit 2 at Coal Creek to a target level of 29.5 percent. This will allow determination of boiler and unit efficiency improvements and emissions reductions, and evaluation of the effects of partially dried coal on unit operation and maintenance requirements.

1. INTRODUCTION

U.S. low-rank coals have moisture contents ranging from 15 to 30 percent for sub-bituminous coals and from 25 to 40 percent for lignites. When high-moisture coals are burned in utility boilers, about seven percent of the fuel heat input is used to evaporate fuel moisture. The use of high-moisture coals results in higher fuel flow rate, higher stack flue gas flow rate, higher station service power, lower plant efficiency, and higher mill, coal pipe and burner maintenance requirements compared to that of the Eastern bituminous coals. Despite problems associated with their high-moisture content, lignite and sub-bituminous coals from the Western U.S. are attractive due to their low cost and emissions.

Countries with large resources of high-moisture low-quality coals are developing coal dewatering and drying processes. However, thermal processes developed thus far are complex and require high-grade heat to remove moisture from the coal. This significantly increases process cost, which represents a main barrier to industry acceptance of the new technology. A review of thermal drying technology is presented in [1].

A process that uses low-grade heat rejected from the steam condenser and waste heat from the flue gas leaving the boiler to evaporate a portion of fuel moisture from the lignite feedstock in a fluidized bed dryer (FBD) was developed in the U.S. by a team led by Great River Energy (GRE). The research was conducted with Department of Energy (DOE) funding under DOE Award Number: DE-CF26-04NT41763.

The objective of GRE's Lignite Fuel Enhancement project is to demonstrate a 5 to 15 percentage point reduction in lignite moisture content (about ¼ of the total moisture content) by incremental drying using heat rejected from the power plant. This will significantly enhance the value of lignite as a fuel in electrical power generation power plants. Although current lignite power plants are designed to burn wet lignite, the reduction in moisture content will increase efficiency, reduce pollution, and improve economics.

The benefits of reduced-moisture-content lignite are being demonstrated at GRE's Coal Creek Station. A phased approach is being used. In Phase 1, a full-scale prototype coal dryer was designed, constructed, and integrated into Unit 2 at Coal Creek. Dryer performance was tested at the baseline coal feed rate of 75 tons per hour. Field experience, dryer performance, and the effects of burning a lower moisture coal on unit performance, emissions, and operations are described in this report.

An additional four full-scale coal dryers will be designed, built, installed, and tested during Phase 2 of the project. With four dryers in service it will be possible to reduce the moisture of the total coal feed to Unit 2 at Coal Creek. This will allow determination of the efficiency improvement and emissions reduction for a unit operating on partially dried coal. Also, the effects of burning coal with reduced moisture content on unit operation will be evaluated.

A fluidized bed coal dryer ("FBD") was selected for this project due to its good heat and mass transfer characteristics which result in a much smaller dryer, compared to a fixed bed design. The FBD size, flow rate of fluidizing air and the power required to drive the fluidizing air fan are strongly influenced by the FBD operating conditions, such as coal size, bed depth, fluidizing air temperature, maximum allowed bed temperature, heat transferred to the fluidized bed by the in-bed heat exchanger, desired moisture level in the dried coal leaving the dryer, and amount of waste/rejected heat that could be used for drying. Higher dryer temperatures result in a smaller dryer size but require a more expensive heat exchanger system, working at higher temperature levels.

EXECUTIVE SUMMARY

A process which uses low-grade heat rejected from the steam condenser and waste heat from the flue gas leaving the boiler to evaporate a portion of fuel moisture from the lignite feedstock in a FBDwas developed in the U.S. by a team led by Great River Energy (GRE). The research was conducted with Department of Energy (DOE) funding under DOE Award Number: DE-CF26-04NT41763. The objective of GRE's Lignite Fuel Enhancement project is to demonstrate a 5 to 15 percentage point reduction in lignite moisture content by incremental drying using heat rejected from the power plant.

The benefits of reduced-moisture-content lignite are being demonstrated at GRE's Coal Creek Station (CCS). A phased approach is used. In Phase 1 of the project, a full-scale prototype coal drying system, including a fluidized bed coal dryer, was designed, constructed, and integrated into Unit 2 at Coal Creek.

The prototype coal drying system at CCS has been in almost continuous fully automatic operation since February 2006. Performance of the prototype dryer, and the effect of partially dried coal on unit performance and emissions, was determined in a series of paired performance tests that were conducted at carefully controlled test conditions. In addition, dryer performance during regular operation was determined as well.

According to the test results, the prototype coal dryer easily meets the performance goals and specifications established for the project, while operating at the baseline feed rate of 75 tons per hour. The maximum continuous feed rate to the dryer is 101 t/hr. Further increases in feed rate were prevented by limitations on the coal conveying system throughput and dust collector fan power limits. With a coal feed rate of 101 t/hr, a moisture reduction in the 7 to 9 percentage point range (20 to 26 percent on a relative basis) was achieved in the prototype coal dryer. The corresponding improvement in higher heating value (HHV) was in the 875 to 1,280 Btu/lb range, or 14 to 21 percent.

The plant performance parameters are summarized in Table E-1. For the total coal feed moisture reduction of 1.14 percent that was achieved with one coal dryer in service, boiler efficiency was improved by 0.37 percentage points. The improvement in net unit heat rate was 40 Btu/kWh, or 0.37 percent.

Table E-1

Effect of Partially Dried Coal on
Plant Performance Parameters Determined From Parametric Tests

Paired Performance Tests					
Parameter	**Units**	**Wet Coal**	**Partially Dried Coal**	**Absolute Change WRT Wet Coal**	**Relative Change WRT Wet Coal [%]**
Dried Coal	**% of total**	**0.00**	**14.12**	**14.1**

ID Fan Power with VSD	kW	11,782	11,430	**-351**	**-3.0**
PA Fan Power with VSD	kW	6,618	6,923	**305**	**4.6**
Total Fan and Mill Power with VSD	kW	24,624	24,427	**-197**	**-0.8**
Net Unit Heat Rate	**BTU/kWh**	**10,693**	**10,639**	**-54**	**-0.50**

With four driers in service, it would be possible to partially dry 100 percent of coal feed to the boiler. Performance predictions for a target moisture removal level of 8.5 percent are summarized in Table E-2. The results show that reducing the coal moisture content from 38.5 to 30 percent, would improve boiler efficiency by 1.70 percentage points. The improvement in net unit heat rate would be 219 Btu/KWh, or 2.05 percent.

Table E-2

Predicted Performance Improvement for Target Coal Moisture Removal of 8.5 Percent

Predicted Performance					
Parameter	**Units**	**Wet Coal**	**Partially Dried Coal**	**Change WRT Wet Coal**	**Percent Change WRT Wet Coal**
Dried Coal	% of total	0.00	100	100

Coal HHV	BTU/lb	6,299	7,150	851	**13.5**
Mill Power	kW	4,176	3,100	-1,076	**-25.8**
FD Fan Power with VSD	kW	2,049	1,928	-120	**-5.9**
ID Fan Power with VSD	kW	11,782	10,551	-1,231	**-10.5**
PA Fan Power with VSD	kW	6,618	8,305	1,687	**25.5**
Total Fan and Mill Power with VSD	kW	24,624	23,884	-740	**-3.0**
Flue Gas Flow Rate at Scrubber Inlet	klbs/hr	7,140	6,864	-276	**-3.9**
Boiler Efficiency	**%**	**78.07**	**79.77**	1.70	**2.18**
Net Unit Heat Rate	**BTU/kWh**	**10,688**	**10,469**	-219	**-2.05**

The effect of the prototype coal drying system on plant emissions is summarized in Table E-3. As the test results show, firing of partially dried coal has resulted in reduced NO_x, SO_x, CO_2, and mercury emissions.

Table E-3

Effect of Partially Dried Coal on Plant Emissions Determined From Parametric Tests

Paired Performance Tests		Segregated Stream Mixed with Product Stream				Segregated Stream not Mixed with Product Stream		
Parameter	**Units**	**Wet Coal**	**Partially Dried Coal**	**Absolute Change WRT Wet Coal**	**Percent Change WRT Wet Coal**	**Partially Dried Coal**	**Absolute Change WRT Wet Coal**	**Percent Change WRT Wet Coal**
NOx Emissions	lbs/hr	1,469	1,359	-111	**-7.5**			**-7.5**
CO_2 Emissions (due to HR Improvement)	klbs/hr	848	844.5	-3.2	**-0.37**			**-0.37**
SO_x Emissions (all 16 paired tests)	lbs/hr	3,670	3,641	-30	**-0.81**			**-1.8 to -2.5**
SO_x Emissions (first 12 paired tests)	lbs/hr	3,692	3,621	-71	**-1.93**			**-2.0 to -2.7**
Mercury Emissions					**-0.37**			**-2.2 to -3.9**

With the current design of the prototype coal drying system at CCS, the segregated and product streams are mixed. The segregated stream is mostly comprised of the non-fluidizable material discharged from the first dryer stage, and contains 3 to 3.5 times more sulfur and mercury compared to the product and feed streams. If the segregated stream were not mixed with the product stream, the mass flow rates of sulfur and mercury to the boiler would be reduced, resulting in lower emissions of these pollutants.

The predicted reduction in emissions for a target value of moisture reduction of 8.5 percent, is summarized in Table E-4 for the cases where the segregated stream and product streams are mixed, and for the case where the segregated stream is further processed and not mixed with the product stream. The results show the potential for significant reductions in SO_x and mercury emissions.

Table E-4

Predicted Emission Reduction for Target Coal Moisture Removal of 8.5 Percent

Predicted - Fanroom Coil in Service		**Segregation Stream Mixed with Product Stream**				**Segregation Stream not Mixed with Product Stream**		
Parameter	**Units**	**Wet Coal**	**Partially Dried Coal**	**Absolute Change WRT Wet Coal**	**Percent Change WRT Wet Coal**	**Partially Dried Coal**	**Absolute Change WRT Wet Coal**	**Percent Change WRT Wet Coal**
NOx Emissions					**> -7.5**			**> -7.5**
CO_2 Emissions (due to HR Improvement)					**-2.4**			**-2.4**
SO_x Emissions					**> -2**			**-12 to -17**
Mercury Emissions					**-15**			**-25 to -35**

The predicted reductions in SO_x and Hg emissions due to the sulfur and Hg removal from the feed stream in the first dryer stage are affected by the accuracy of the measured sulfur and Hg concentration levels in the feed, segregated, and product streams, and the segregated stream flow rate. The actual reductions in SO_x and Hg emissions will be determined when the commercial coal drying system at CCS is operating at 100 percent capacity.

A commercial coal drying system, consisting of four fluidized bed dryers will be designed, built, installed, and tested at CCS during Phase 2 of the project. With four dryers in service it will be possible to reduce the moisture content of the total coal feed to Unit 2 at Coal Creek to a target level of 29.5 percent. This will allow determination of the resulting efficiency improvement and emissions reduction and evaluation of the effects of partially dried coal on unit operation and maintenance requirements.

2. DESCRIPTION OF COAL CREEK STATION

Coal Creek Station (CCS) is a 1,200 MW lignite-fired power plant located in Underwood, North Dakota. The plant supplies electricity to 38 member cooperatives in

Minnesota. Two tangentially fired CE boilers supply steam to two single reheat GE G-2 turbines rated at 560 MW each. The units are designed for 1,005°F main steam and reheat steam temperature at a 2,520 psi throttle pressure. Three mechanical draft cooling towers are used to reject heat to environment. The boiler fires lignite coal from the nearby Falkirk mine. The coal that has a HHV of 6,200 Btu/lb and total moisture content of approximately 38 percent. An aerial photograph of Coal Creek Station is presented in Figure 1-1.

Figure 1-1: Aerial Photograph of Coal Creek Station

A schematic representation of heat flows for the CCS is given in Figure 1-2. For full unit load (gross power output of 576.7 MW (546 MW nameplate)) and fuel containing 40 percent moisture, the heat input with the fuel (Q_{fuel}) is approximately 5,670 MBtu/h. The boiler loss (Q_{loss}), including dry stack loss (Q_{stack}) and fuel moisture evaporation loss (Q_{evap}) is approximately 1,090 MBtu/h, or 19.2% of the fuel heat input. This gives a boiler efficiency of 80.78%. The dry stack loss is 436 MBtu/h, which represents 7.7 percent of the fuel heat input. The loss due to evaporation of fuel moisture is 370 MBtu/h (approximately 6.6 percent of fuel heat input). Thermal energy

(Q_T) transferred to the working fluid in the boiler is about 4,580 MBtu/h. The thermal efficiency of the steam turbine cycle is approximately 43 percent, which gives rejected heat of approximately 2,600 MBtu/h (46 percent of the fuel heat input). The gross unit efficiency is approximately 34.7 percent, with a gross unit heat rate of 9,825 Btu/kWh.

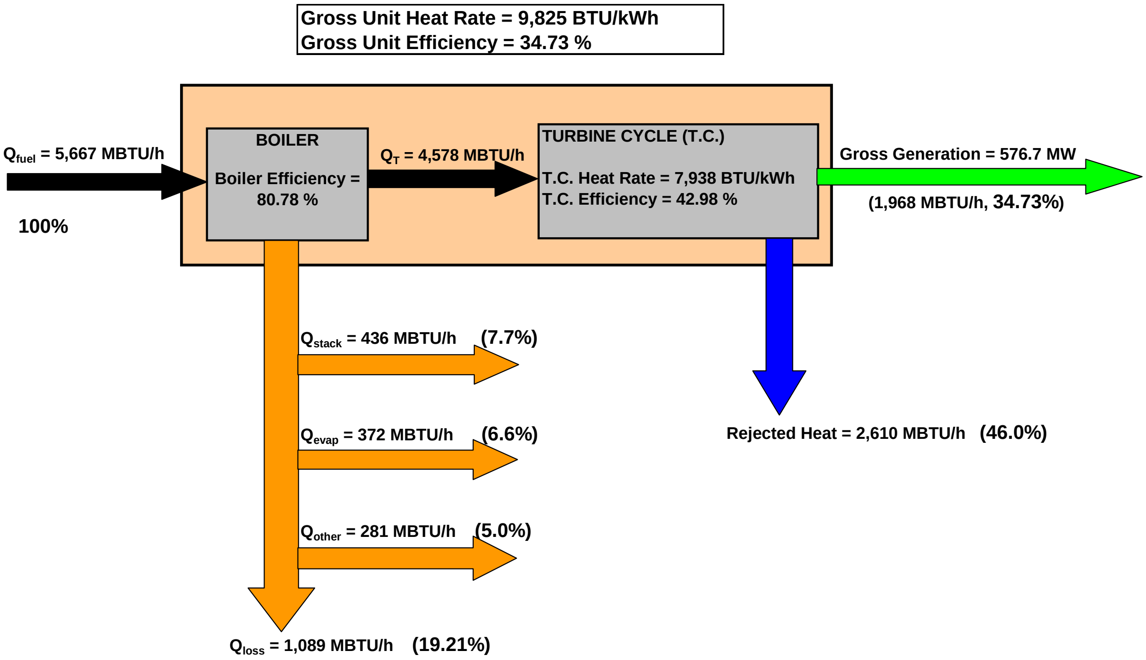

Figure 1-2: Coal Creek Unit Heat Flow Schematic – One Unit

2.1: Sources and Magnitudes of Waste Heat

Thermal energy in the flue gas leaving the plant represents waste heat. For one unit of the Coal Creek Station with a lignite feed containing 40 percent moisture, the waste heat in the flue gas is approximately 440 MBtu/hr. Engineering analyses show that using waste heat in flue gas to remove 5 percent of coal moisture would decrease the stack temperature by approximately 30°F.

Heat rejected in the main steam condenser represents another large source of waste heat. For one unit of the Coal Creek Station, heat rejection in the condenser is approximately 2,600 MBtu/hr (about 46 percent of the fuel heat input). The cooling water leaving the Coal Creek condenser has a temperature of approximately 120°F. This warm cooling water is then cooled in the cooling towers to approximately 90°F and is circulated back to the condenser. Engineering analyses show that, at full unit load, approximately 2 percent of the heat rejected in the condenser/cooling tower would be needed to decrease the coal moisture content by 5 percent. The cooling water circuit is constructed of pipes, which makes the access to this waste heat source relatively easy.

3. PREVIOUS WORK

During the 1990's the engineering staff at CCS began investigating alternative approaches to dealing with future emission regulations. Conventional approaches included changing fuels and/or adding environmental control equipment. This approach often results in lowering emissions at the expense of increases in unit heat rate and operating and maintenance costs. Higher heat rate results in higher required fuel heat input, higher CO_2 emissions, higher flow rate of flue gas leaving the boiler and lower plant capacity. Lower capacity is due to higher station service power requirements or limited equipment capacity. Also, increased flue gas flow rate requires a larger size of environmental control equipment, higher equipment cost and station service power.

A theoretical analysis was performed by the Lehigh University's Energy Research Center (ERC) in 1997-98 to estimate the magnitude of performance improvement that could be achieved by firing coal having lower moisture content [2]. The results showed that a decrease in fuel moisture would have a large positive effect on unit performance, Figure 1-3.

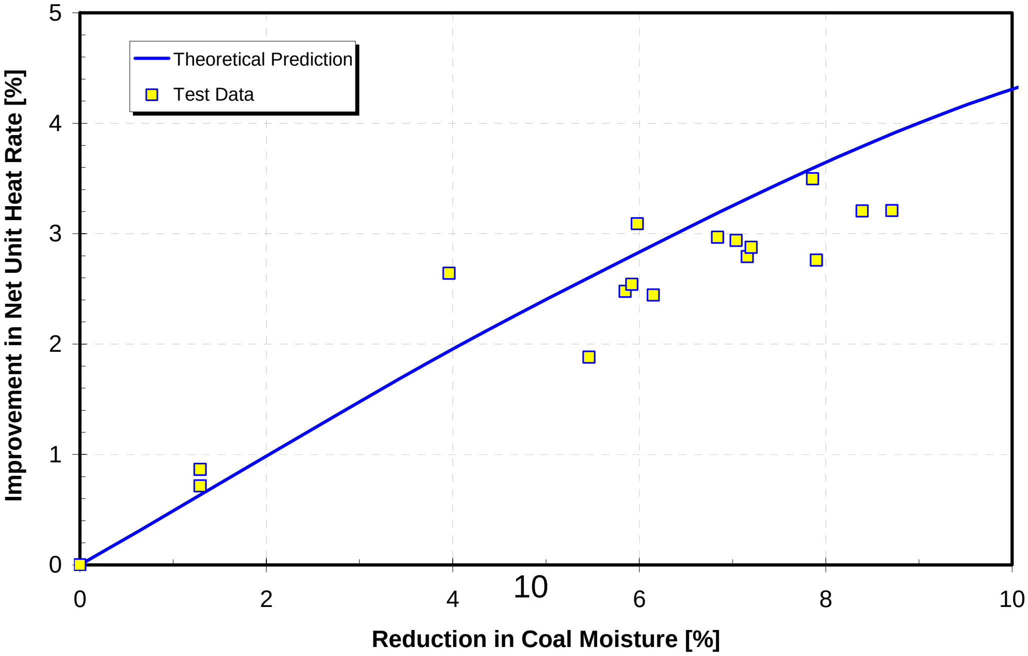

Figure 1-3: Effect of Fuel Moisture on Unit Performance

Based on these theoretical results, CCS personnel performed test burns with partially dried lignite in 2001 to confirm whether the boiler and coal handling system could handle the partially dried lignite. Except for dust in the transfer hoppers, no other fuel handling problems were encountered. Also, test results confirmed the theoretical performance improvement predictions [3].

After demonstrating the benefits of firing dried fuel, a technology for coal drying needed to be selected. Based on laboratory testing conducted at the ERC in 2002, a FBD was selected as the best technology due to its high heat and mass transfer coefficients and compact size.

GRE submitted an application to DOE in 2002 under the Clean Coal Power Initiative (CCPI) to develop a prototype fluidized bed coal dryer and develop and install a commercial coal drying system on one unit at CCS. GRE, ERC, EPRI, Barr Engineering and Falkirk Mining Company participated in the proposal development. The project was negotiated with DOE for funding under the CCPI in July 2004. Previous work and project activities are summarized in Table 1-1.

Table 1-1

Previous Work

Time Period	Activity
1997-1998	Preliminary studies and concept development.
1999	Lignite-drying tests using low-temperature fixed-bed dryer.
2000	CCS Boiler modeling. Laboratory lignite drying tests. Full-scale test burns using 20,000 tons of lignite dried using low-temperature air.
2001	Fixed bed dryer designed. Fluidized bed dryer selected for coal drying due to higher efficiency, smaller size, and lower cost. Application for funding under the PPI initiative was filed but turned down. Laboratory-scale FB drying tests at ERC.
2002	Application filed with DOE under the Clean Coal Power Initiative (CCPI)
2003	Application selected for negotiation with DOE. Pilot FBD built at CCS. Pilot FBD testing.
2004	Contract signed with DOE. Design of the prototype coal dryer and associate equipment.

2005	Construction of prototype coal dryer begins.
2006	Prototype dryer checkout and start-up. Prototype dryer performance testing. Unit performance testing. Maximum capacity testing. Data analysis and project report. August: Phase 1 milestone.

The project is divided into two phases. The first phase involved design, construction, installation and testing of a prototype coal drying system at CCS consisting of one FBD. The prototype coal drying system was designed in 2004. The construction began in 2004 and was finished in February 2006. The system checkout tests were conducted in February and March 2006. Performance testing was performed in March and April. Maximum capacity tests were performed in June 2006.

The second phase of the project involves installation of a commercial drying system at CCS capable of drying 500 tons/hr of wet lignite fuel.

3.1: Pilot Coal Dryer

Prior to DOE Project selection, and with funding from the North Dakota Industrial Commission (NDIC), GRE designed and constructed a 2 ton/hr pilot dryer at CCS in 2003 to provide operating experience and design scalability data for the DOE project. The pilot dryer is depicted in Figure 1-4. Field testing was conducted over a range of FBD operating conditions. A methodology for analyzing test data and determining FBD performance was developed [4].

The pilot coal dryer was operated for a 12-week period beginning in September 2003. The pilot dryer dried 150 tons of coal in 38 tests reducing the moisture content of the lignite by 24 to 60 percent, Figure 1-5. Moisture-free heating values for the feed and product streams indicated that no appreciable carbon oxidation took place during the drying process.

A buildup of the non-fluidizable material on the distributor plate, close to the coal feed point, was observed during testing. This was especially evident in the final days of testing when non-fluidizable material was cleaned out between tests, and its mass was measured. It was realized that accumulation of non-fluidizable material on a distributor plate could be used to segregate out ash, pyrites, and other impurities from the coal.

Analysis of collected samples confirmed that the non-fluidizable material on the bed bottom exhibited very high concentrations of ash, sulfur, and mercury. Depending on the feed material, it is likely that removal of this material from the feed stream would create a relatively minor energy loss, while causing a significant reduction in ash sulfur and mercury. It is possible that removal of the concentrated bed bottom material could result in SO_2 and mercury reductions of greater than 20 percent as was seen in several tests.

The pilot dryer field results were also compared to the predictions obtained by a FBD Simulation Code, developed under DOE Award Number DE-FC26-03NT41729 by ERC researchers [5] and [6]. Comparison between measured and predicted values is given in Table 1-2. A very good agreement between measurements and predictions was achieved.

Figure 1-4: Pilot Fluidized Bed Dryer at CCS

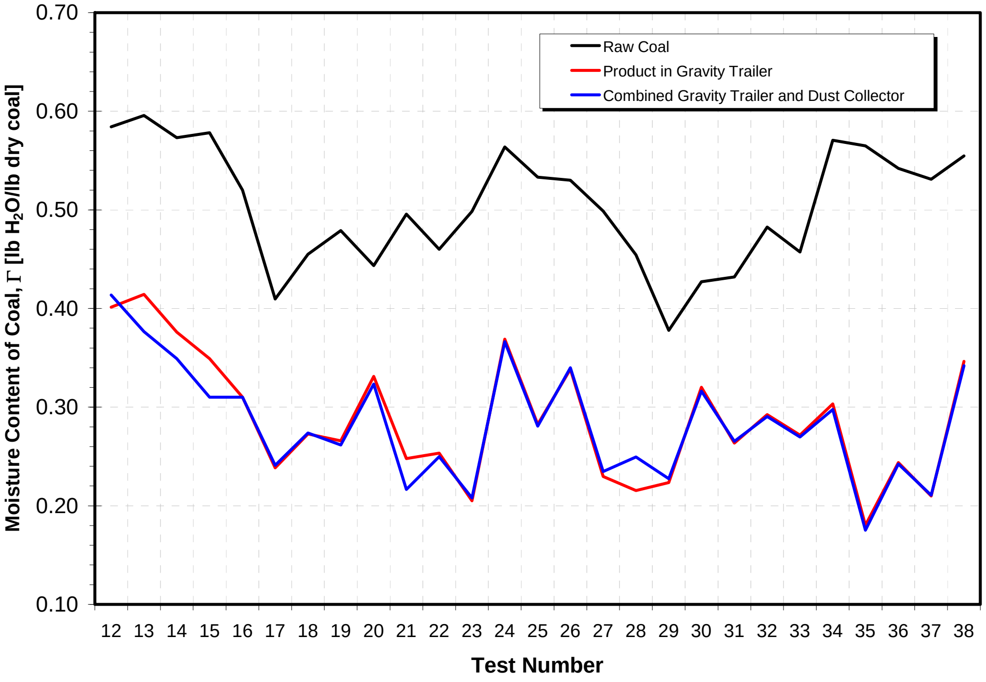

Figure 1-5: Pilot Test Results

Table 1-2

Comparison Between Pilot Test Results and FBD Simulation Code Predictions

Test Number	ΔΓ [lb/lb dry coal]		Outlet Air Temp. [°C]		RH of Outlet Air [%]	
	Measured	Predicted	Measured	Predicted	Measured	Predicted
4	0.175	0.151	25.5	26	72.5	69
20	0.134	0.217	33.5	36.7	86.9	70
23	0.300	0.335	36.9	37.8	66.7	67
30	0.107	0.150	30.2	33.3	86.1	72

The FBD simulation code was used to design a prototype coal dryer and, later on, the commercial coal dryers at CCS. The technical approach and results are described in [7] and [8].

PART 1: PROTOTYPE COAL DRYER AND ITS PERFORMANCE

4. COAL CREEK PROTOTYPE COAL DRYING SYSTEM

The prototype coal drying system employed at Coal Creek is based on using waste heat from the steam condenser and the hot flue gas to heat the fluidizing air used for coal drying. These two waste heat sources are also used to provide heat within the freeboard region of the FBD to provide an additional drying of the coal. The prototype coal drying system and FBD were designed by a design team assembled by GRE.

Coal feed for the dryer is supplied from existing coal bunker No. 28 (Figure 1-6). The wet coal (feed stream) is fed by a vibrating coal feeder (Figure 1-9) to a coal crusher and crushed and sieved to -1/4”. The crushed coal is screened by a vibrating screen (Figure 1-7) and conveyed to the dryer inlet hopper. Two rotary coal feeders (air locks) feed coal to the first stage of the FBD. The screen bypass flow (i.e., the larger particles separated out by the screen that were not therefore dried in the dryer) is mixed with a product stream leaving the dryer employing a bypass conveyer. Mixing of the two streams takes place downstream of the coal sampling location.

Figure 1-6: Coal Feeder

Figure 1-7: Vibrating Screen

The dried coal (product stream) leaving the dryer is stored in coal bunker No. 26, feeding coal mill 26. A coal conveyor and bucket elevator are used to transport dried coal to the No. 26 bunker. As product stream is transported from the dryer to the bunker, it cools down, and its temperature drops by approximately 10°F.

The coal-drying system was designed in modular fashion to allow incremental drying of the coal. Each coal-drying module will dry a portion of the total coal flow and will also include environmental controls (baghouse for dust control). With all four coal-drying modules in service it will be possible to dry 100% of the coal feed.

The commercial coal drying system design will provide redundancy whereby coal dryers will be able to supply dried product to any coal mill. This will provide backup in the event of the equipment problem. This redundancy will also extend from Unit 1 to Unit 2 and vice versa.

Also, in the commercial coal drying system, the segregated stream will not be combined with the product stream. This will have a significantly positive effect on SO_x and mercury emissions.

4.1: Fluidized Bed Coal Dryer

A fluidized bed dryer is a good choice for drying coal to be burned at the same site where it is dried. The coal dryer can be of single-stage or multiple-stage design, with the stages contained in one or more vessels. The multi-stage design allows maximum utilization of fluidized bed mixing, segregation and drying characteristics.

A two-stage fluidized bed dryer design, where the bed volume is divided into two parts, is employed at Coal Creek. The dryer was manufactured by Heyl & Patterson, Inc. and is comprised of two stages, packaged into a single vessel. The first stage occupies approximately 20 percent of the dryer volume.

In the first stage, the coal is preheated and partially dried (a portion of surface moisture is removed). Non-fluidizable particles segregate out, thereby forming the segregated stream. The first dryer stage accomplishes the following functions: separates the fluidizable and non-fluidizable material, pre-dries and preheats the coal, and provides uniform flow of coal to the second stage.

The fluidizable material flows over the weir to the second stage of the dryer, where the coal is heated and dried to a desired outlet moisture level. The product stream from the second stage is discharged over the discharge weir into the discharge hopper. From the discharge hopper, the product stream is fed to the product stream conveyor through three rotary coal feeders (air locks) (Figure 1-8). Although the second stage can also be used to further separate ash and other impurities from the coal, this option was not employed at CCS.

Figure 1-8: Dried Coal is Discharged through Three Rotating Coal Feeders

Fluidization and heating of coal and removal of coal moisture is accomplished within the fluidized bed by hot fluidization air. The air stream is cooled and humidified as it flows upwards through the coal bed. The quantity of moisture, which can be removed from the bed of fluidized coal, is limited by the drying capacity of the fluidization air stream. The drying capacity of the fluidization air stream can be increased by supplying additional heat to the bed by the in-bed heat exchanger. The in-bed heat exchanger not only increases drying capacity of the fluidizing air stream but it also reduces the quantity of drying air required to accomplish a desired degree of coal drying.

Five in-bed heat exchangers (bed coils), employing finned tubes, are used to supply additional heat to the coal: one in the first dryer stage, with the other four in the second stage. Different designs and materials were used for each bed coil tested in the prototype dryer. The best performing design will be used in the additional four dryers that will be built in Phase 2 of the project.

The prototype dryer design data are summarized in Table 1-3. As the data in Table 1-3 show, the heat transfer area for individual bed coils, depending on their design, varies from 1,144 to 1,982 ft^2. The average heat transfer coefficient for finned tubes of 18 Btu/hr-ft^2-°F was determined experimentally by GRE and Barr engineers.

Table 1-3

Prototype Dryer Design Data

Prototype Coal Dryer Parameter	Units	Prototype Value
Distributor Area	ft^2	**308**
First Stage Fluidizing Air Flow	klbs/hr	**55**
Second Stage Fluidizing Air Flow	klbs/hr	**250**
Expanded Bed Depth	"	**38 to 40**
In-Bed Heat Exchanger No. 1 HT Area	ft^2	**1,982**
In-Bed Heat Exchanger No. 2 HT Area	ft^2	**1,696**
In-Bed Heat Exchanger No. 3 HT Area	ft^2	**1,982**
In-Bed Heat Exchanger No. 4 HT Area	ft^2	**1,832**
In-Bed Heat Exchanger No. 5 HT Area	ft^2	**1,144**
Total In-Bed Heat Exchnager Area	**ft^2**	**8,636**
Total Exchanged Heat, In-Bed HXE	MBTU/hr	**16.53**
Average Heat Transfer Coefficient	BTU/hr-ft^2-^{o}F	**18.08**
Total Water Flow Through the In-Bed Heat Exchangers, Actual	gpm	**1,588**
Total Water Flow Through the In-Bed Heat Exchangers, Indicated	gpm	**1,363**

In order to achieve maximum drying, the drying air stream would need to leave the fluidized bed at saturation conditions (i.e., with 100 percent relative humidity). This is, however, undesirable since condensation would occur in the freeboard region of the dryer. To prevent this, the CCS prototype coal dryer was designed for an outlet air relative humidity less than 100 percent.

Alternatively, reheat surfaces in the freeboard region of the bed or duct skin heating can be used to increase the temperature and lower the relative humidity of the air leaving the dryer and prevent downstream condensation. This option was not implemented at CCS.

The particle control equipment, consisting of a dust collector (baghouse) and discharge fan, is used to remove elutriated fines from the moist air stream leaving the dryer. Collected particulate matter is mixed with the coal product stream, and clean particle-free moist air is discharged through a stack to the atmosphere, as presented in Figure 1-9.

Figure 1-9: Clean Moist Air Stream Leaving Dust Collector is Discharged into the Atmosphere

4.2: Instrumentation

The prototype coal drying system tested at CCS was instrumented to allow determination of dryer performance. Plant instrumentation was used to determine boiler efficiency and plant heat rate.

Measured variables include: coal feed rate, crusher power, inlet and outlet air lock (rotary feeder) loading, temperature of feed stream, temperature of coal in the No. 26 bunker, CO level at the dryer outlet and in the bunker, dust collector fan power, moisture in product stream, moisture in fluidizing air stream leaving the dryer and dust collector, temperature of fluidizing air stream at the dryer inlet, cold and hot PA temperatures, flow rate of fluidizing air into the first and second dryer stage, circulating water flow and inlet and outlet temperature, pressure of fluidizing air in the plenum, above the bed and other state points including dust collector inlet and outlet, and flow rate of the bypass and scrubbing air. An array of thermocouples is used to measure the coal and freeboard temperature in the dryer. Thermocouple arrangement in the dryer is presented in Figure 1-10. Process values, measured during dryer testing will be presented later.

It has to be noted that the on-line instrument for coal moisture measurement is not providing representative information since it measures surface moisture. A very poor correlation was found between coal moisture values measured by the on-line instrument and determined from the laboratory analysis of coal samples. Therefore, the on-line measurement of coal moisture content was not used in the data analysis.

The relative humidity of fluidizing air stream leaving the dust collector (baghouse) was usually in the 99 to 100 percent range. Its value was not affected by changes in dryer operating conditions. It is believed that this measurement, although correct, is not representative of the dryer outlet conditions. In addition, as elutriated coal particles are collected on a bag wall, they form a layer (cake) of wet coal. This layer is dried by the air flowing through the bags. Engineering analyses suggest that the air leaving the cake is saturated.

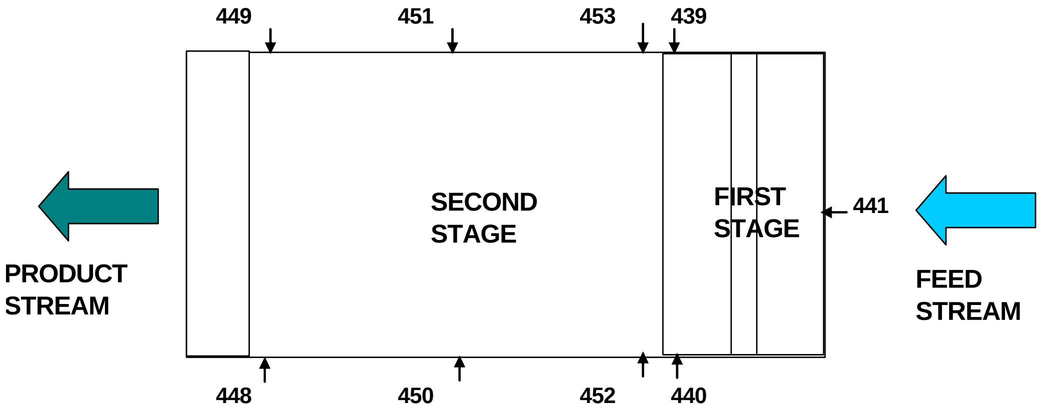

Figure 1-10a: Thermocouple Locations and Numbers in First and Second Stages of a Prototype Coal Dryer at CCS

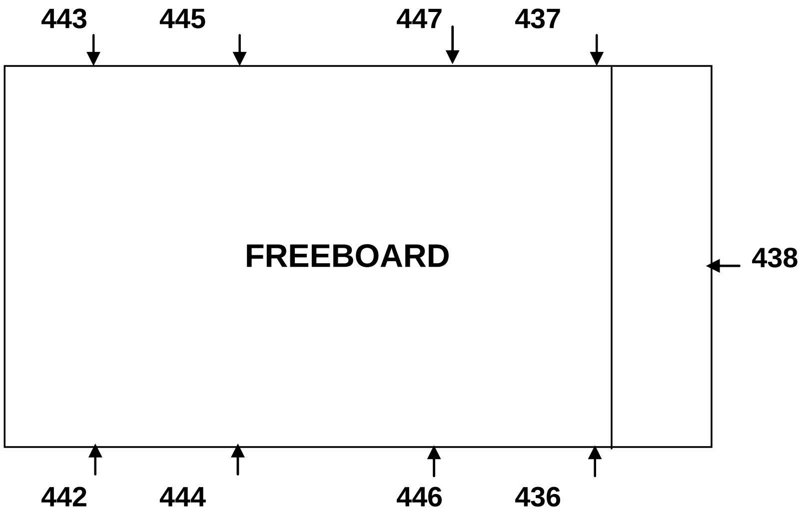

Figure 1-10b: Thermocouple Locations and Numbers in the Freeboard Region of a Prototype Coal Dryer at CCS

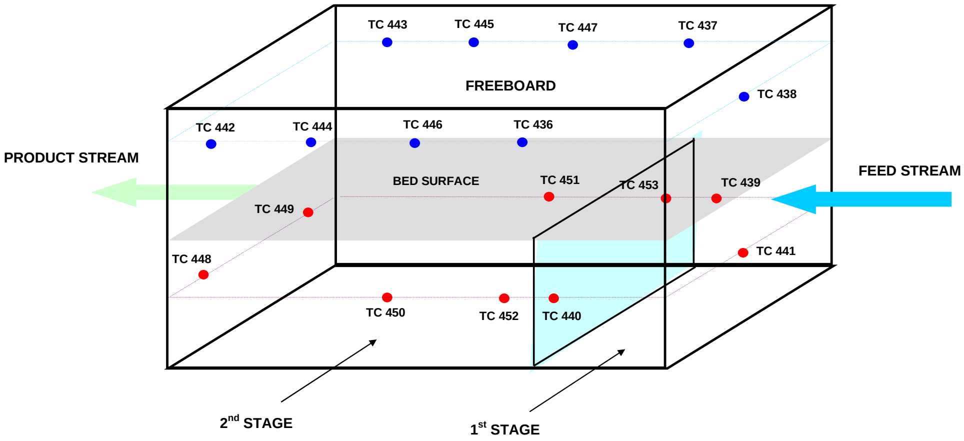

Figure 1-10c: Thermocouple Locations in First and Second Stagesand in a Freeboard Region of a Prototype Coal Dryer at CCS Isometric View

The second instrument for air moisture measurement, located at the dryer outlet, upstream of the dust collector was, unfortunately, not working properly. Therefore, no measured values of dryer outlet air moisture are available for analysis and comparison with theoretical predictions.

Two automatic coal samplers were used to collect samples of the feed and product streams. The feed coal sampler, located on the feed conveyer, is presented in Figure 1-11.

Figure 1-11: Automatic Coal Analyzer: Feed Conveyer

The automatic coal sampler for the product stream is located on the product conveyer after the product stream leaving the dryer is mixed with the segregated stream and elutriated coal particles collected by the dust collector. This introduces an uncertainty in product moisture and dryer performance. Manual coal samples were also taken from the segregated stream conveyer to determine composition of the segregated stream.

4.3: <u>Process Control</u>

Operation of the prototype coal drying system at CCS is completely automated, including the startup, shutdown, and emergency shut down procedures. Heat input to the dryer is controlled by adjusting the input flow rates of the waste heat sources to match the heat input required to accomplish the desired degree of drying.

Heat input to the dryer, Q_1, is defined as:

$$Q_1 = Q_{air} + Q_{Circulating\ water} \qquad \text{Eqn. 1-1}$$

where:

Q_{air}	Heat input with the air stream
$Q_{Circulating\ Water}$	Heat supplied to the in-bed heat exchanger

The required heat input to the dryer, Q_2, is defined as:

$$Q_2 = M_{coal}\ \Delta TM\ h_{fg} + \Delta Q_{Coal\ Sensitive} \qquad \text{Eqn. 1-2}$$

where:

M_{coal}	Coal feed flow rate
ΔTM	Required (desired) absolute reduction in total coal moisture content
h_{fg}	Latent heat of evaporation of coal moisture
$\Delta Q_{Coal\ Sensitive}$	Change in sensitive heat of coal

As long as $Q_1 < Q_2$, during the dryer startup or transient operation when coal feed rate to the dryer is increased, the control algorithm increases the hot air flow rate until the heat input supplied to the dryer matches the required heat input.

When the coal feed flow rate is reduced, or a lower reduction of coal moisture content is required, $Q_2 > Q_1$, the control algorithm reduces the flow rate of hot air flow until $Q_1 = Q_2$. This simple control algorithm works very well in practice.

5. DRYER PERFORMANCE

5.1: Factors Affecting Dryer Performance

Performance of a fluidized bed dryer is affected by many operating and design parameters. The most important include: flow rate and inlet moisture content of coal, flow rate, temperature and humidity of drying/fluidizing air, bed depth, coal residence time, and heat input by the in-bed heat exchanger. The latter is directly proportional to the heat transfer surface area and the average difference in temperature between the heat exchanger tube surface area and fluidized coal particles.

5.2: First and Second-Stage Dryer Performance

As discussed earlier, a two-stage dryer design offers several advantages, compared to a single-stage design. The most important advantage is segregation of coarse and non-fluidizable material which is collected at the bottom of the first stage and discharged from the dryer and scrubbing boxes. The fluidizable material flows over the weir separating the first and second dryer stages and enters the second stage. After passing through the second stage, dried coal is discharged into the outlet hopper over the discharge weir. The function of the discharge weir is to maintain the bed height.

The calculated variations of the bed temperature and coal moisture content along the length of the prototype dryer are presented in Figures 1-12 and 1-13 for a feed rate of 75 t/hr of wet Falkirk mine lignite, a fluidization air temperature at 170°F and an average bed coil temperature of 210°F are required. Calculations were performed with an inlet coal moisture content of 37.08 percent on a wet coal basis, corresponding to $\Gamma = 0.589$ lb moisture/lb dry coal.

The results presented in Figures 1-12 and 1-13 show that the main functions of the first and second dryer stages are very different. The incoming coal is preheated in the first dryer stage from the inlet temperature to a temperature corresponding to approximately 90 percent of the maximum coal temperature leaving the dryer. The reduction in coal moisture content in the first stage is small -- less than 10 percent of the total coal moisture is removed in the first stage. By contrast, the increase in bed temperature in the second dryer stage is very small -- only about 10 percent of the total temperature increase in coal dryer. However, the second dryer stage removes more than 90 percent of the total moisture removed from the feed stream.

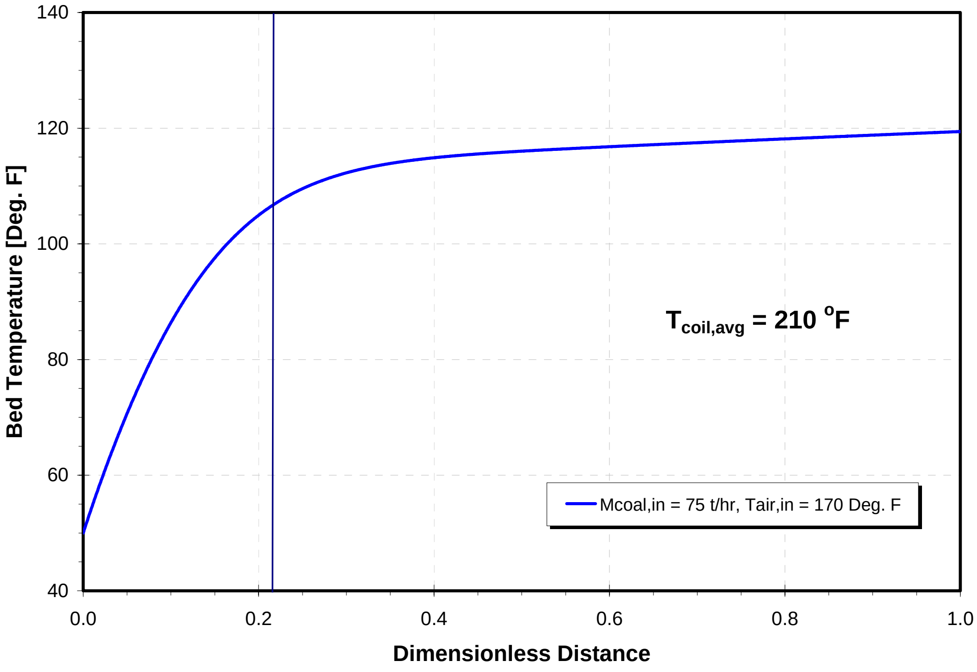

Figure 1-12: Variation of Bed Temperature Along the Dryer Length

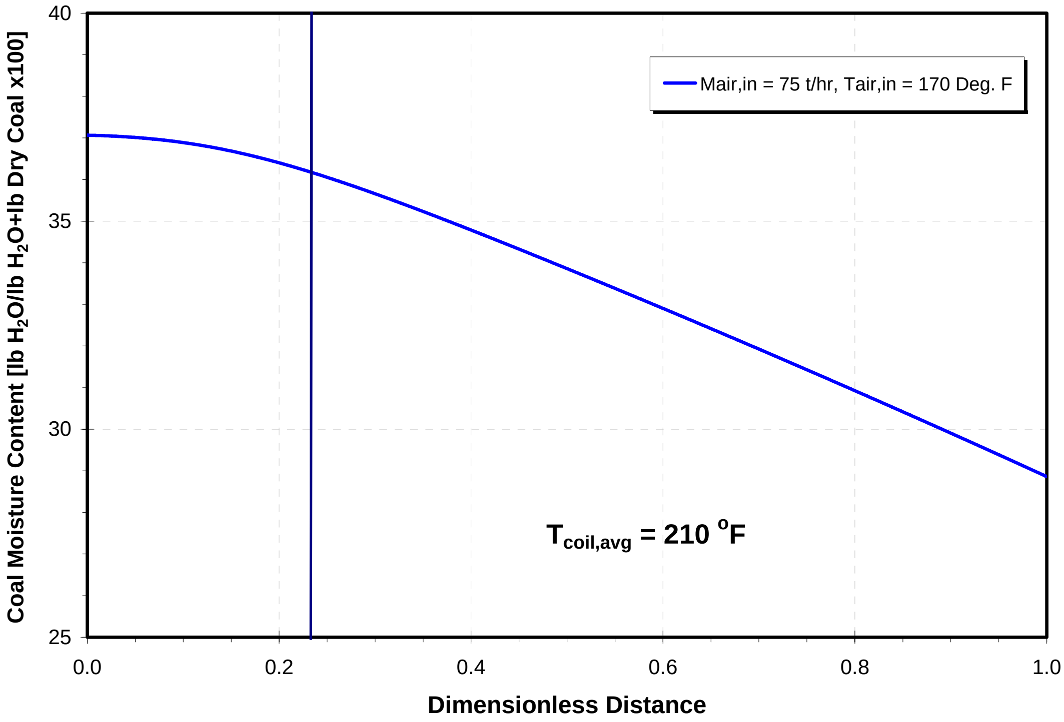

Figure 1-13: Variation of Coal Moisture Content Along the Dryer Length

6. TEST RESULTS

6.1: Operation Under Controlled Conditions

Performance tests were conducted under controlled conditions to determine dryer performance and the effect of firing dried coal on boiler efficiency and unit performance. As suggested by Dr. Moen, a paired-test approach was used where two consecutive performance tests were run per day: one with the prototype dryer in operation, the other with the prototype dryer off. The order of tests, i.e., dry and wet, or wet and dry, was determined randomly. Such an approach minimizes or eliminates the effects of bias errors, i.e., day-to-day differences/variations in plant operating conditions, and other uncontrollable variables.

Statistics was used to determine the number of required tests. The test uncertainty, i.e., random error vs. number of tests relationship presented in Figure 1-14, shows that the benefit of running more than 12 tests is very small. This is because test uncertainty is inversely related to the square root of the number of tests. The random error in Figure 1-14 was normalized with respect to the best estimate of standard deviation S. The absolute value of random error can be determined by multiplying values from Figure 1-14 by the numerical value of S.

Test uncertainty (random error) is defined as:

$$RE = \frac{tS}{\sqrt{N}} \qquad \text{Eqn. 1-3}$$

where:

RE	Random error (test uncertainty)
t	Student (W. Gosset) variable, where t = f(N, Confidence Level)
S	Best estimate of standard deviation σ

$$S = \sigma\sqrt{\frac{N}{N-1}} \qquad \text{Eqn. 1-4}$$

Standard deviation is calculated from the test data. Based on the statistical analysis, it was decided to conduct 16 paired performance tests.

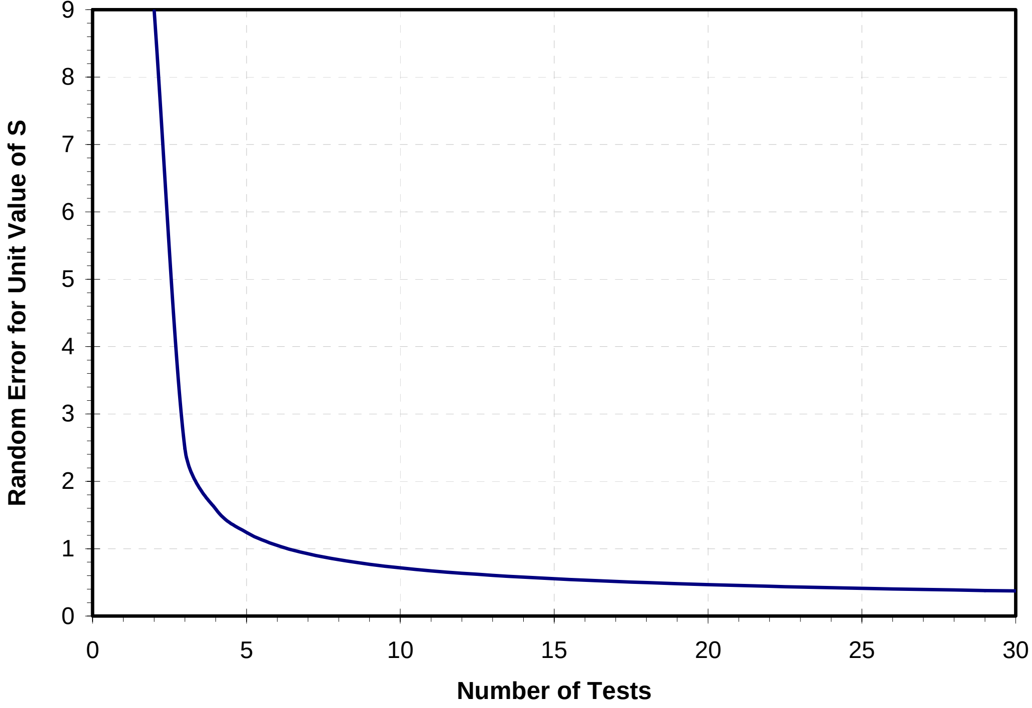

Figure 1-14: Normalized Random Error vs. Number of Tests Relationship

Statistics also provides information regarding the minimum detectable difference. The minimum detectable difference is the smallest statistically significant difference between two sets of measurements -- in this case between two sets of performance tests conducted with dried and wet coals. For sixteen performance tests, the minimum statistically significant difference in boiler efficiency that can be measured is in the 0.025 to 0.125 range, depending on the precision of the measurement. Assuming an S of 0.10 gives the minimum statistically significant difference in boiler efficiency of 0.096 (Figure 1-15). Since the theoretical difference in boiler efficiency, for the expected reduction in coal moisture content of feed coal is in the 0.35 percentage point range, the test results will be statistically significant.

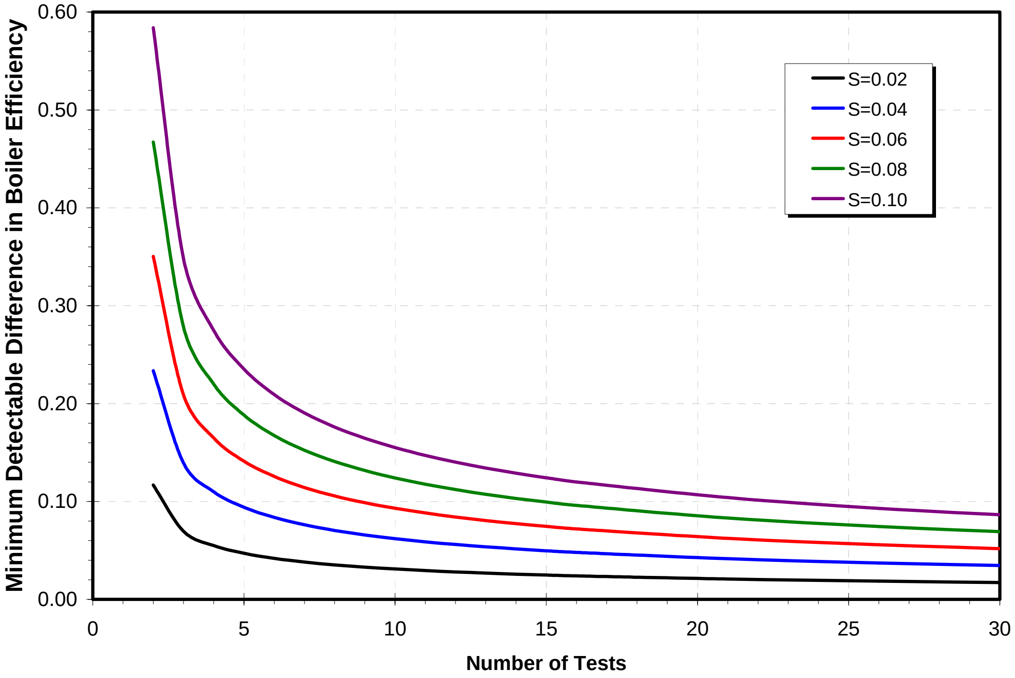

Figure 1-15: Minimum Statistically Significant Difference in Boiler Efficiency vs. Number of Performed Tests

Sixteen dryer performance tests were performed during time period from March 22nd to May 12th 2006, under controlled conditions with a baseline coal feed rate of 75 t/hr, fluidization air temperature in the 165 to 190°F range, and average bed coil temperature of 210°F. Under these operating conditions, in-bed heat input to the dryer was in the 15 to 16 MBtu/hr range.

A comparison of measured and predicted (simulated) dryer performance is presented in Figures 1-16 and 1-17. The total moisture content measured in the product stream is presented in Figure 1-16 as a function of fluidization air temperature. Dryer simulation results are represented by a solid line. As Figure 1-16 shows, there is a very good agreement between the measured and predicted product moisture contents. The results also show that the prototype dryer was operated with a relatively low fluidization air temperature. Increasing the fluidization temperature will have a positive effect on dryer performance.

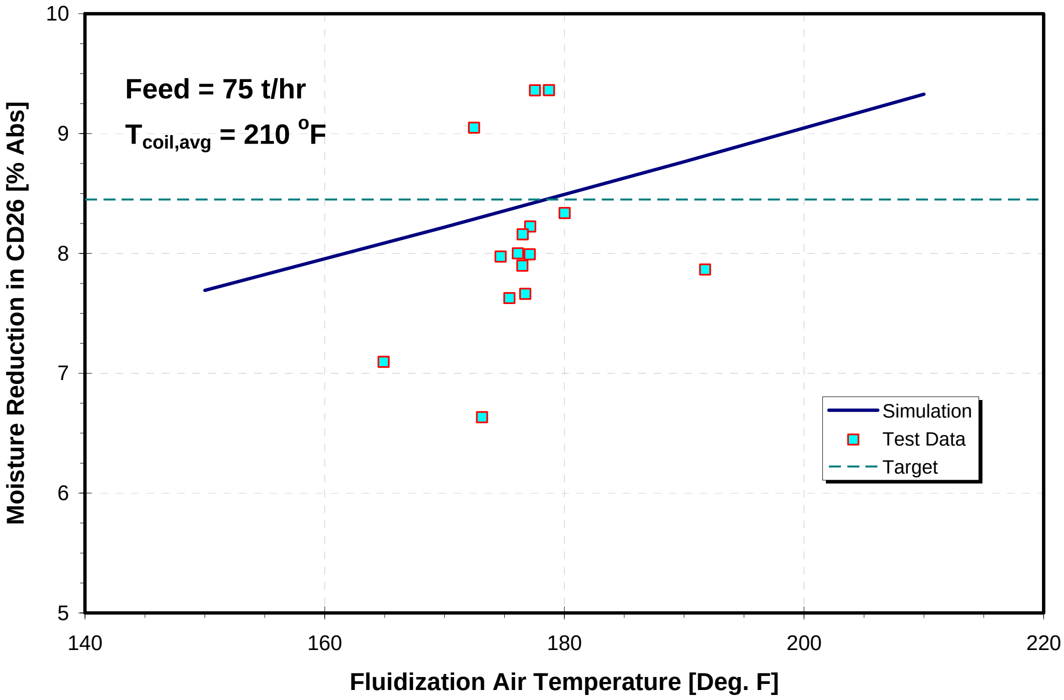

Figure 1-16: Measured and Predicted Dryer Performance: Total Moisture

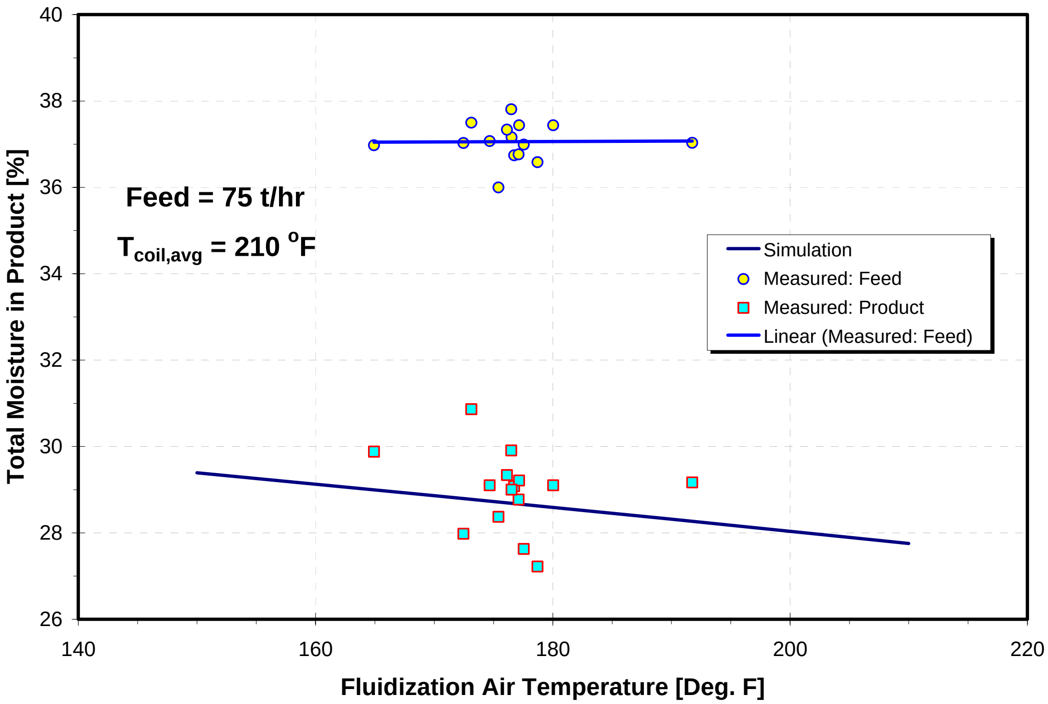

Figure 1-17: Measured and Predicted Dryer Performance: Moisture Reduction

Figure 1-17 compares the measured and predicted coal moisture reduction in the prototype dryer. Except for a few test points, there is very good agreement between the measurements and simulation. The target moisture removal level of 8.45 percent was easily reached by operating the prototype dryer with fluidization temperature at or above 180°F.

The total coal moisture (TM) and higher heating value (HHV) measured in the feed and product streams during the controlled dryer tests are summarized in Table 1-4 and presented in Figures 1-18 and 1-19. The Test 16 results show a much lower TM content and higher HHV value compared to the other tests and were, therefore, not included in the statistical analysis of data. The results show that average moisture reduction was 8.08 ± 0.42 percent. The HHV was on average improved by 727 ± 62 Btu/lb. The random error in Table 1-4 represents the 95 percent confidence interval. The variation in TM and HHV during the controlled tests is presented in Figures 1-41 and 1-19. The improvement in HHV and reduction in total coal moisture content are presented in Figure 1-20.

6.2: Regular Dryer Operation

Coal quality data were collected during regular dryer operation for the time period from March to April, 2006. Results are presented in Table 1-5 and Figures 1-21 and 1-22.

Table 1-5

Regular Dryer Performance: Coal Moisture and HHV

Parameter	Feed TM %	Product TM %	Change TM % Abs	Change TM % Rel
Average Total Moisture, TM	**36.78**	**28.55**	**8.23**	**22.4**

Parameter	Feed HHV [BTU/lb]	Product HHV [BTU/lb]	Change HHV [BTU/lb]	Change HHV [%]
Average HHV	**6,290**	**7,043**	**752**	**12.0**
Std. Deviation	**159**	**121**	**131**	
Std.Deviation of the Mean	**43**	**33**	**37**	

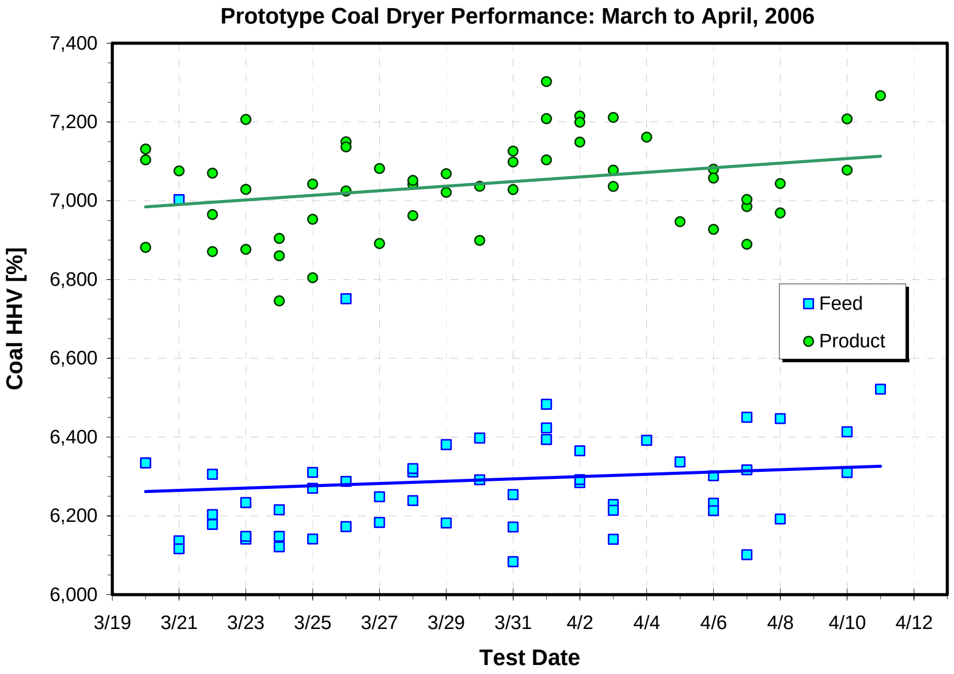

Figure 1-21: Coal Moisture in Feed and Product Streams Measured During Regular Dryer Operation

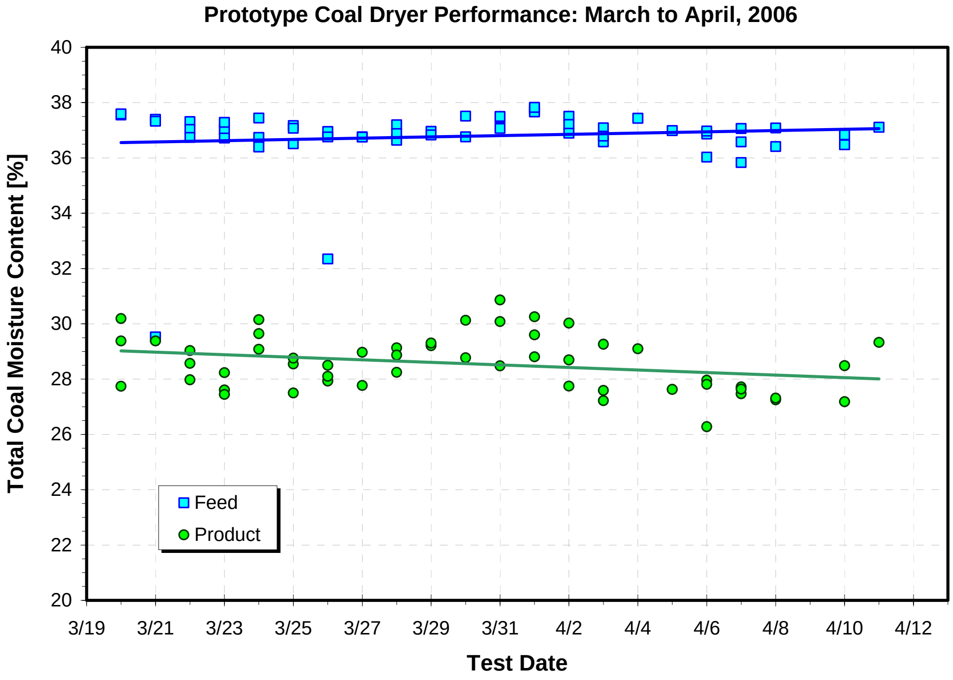

Figure 1-22: Higher Heating Value for Feed and Product Streams Measured During Regular Dryer Operation

The average moisture reduction, achieved during regular dryer operation, was 8.23 ± 0.6 percent. This is almost identical to the total moisture reduction achieved during the controlled performance tests. The improvement in HHV during regular dryer operation was 752 ± 74 Btu/lb. Within the accuracy of the data, this is the same improvement in HHV achieved during the controlled dryer performance tests. In conclusion, this means that dryer performance, measured during the controlled tests, is sustainable over the long-term [9].

6.3: Dryer Performance at Maximum Coal Feed Rate

6.3.1: Maximum Capacity Tests

The maximum design coal feed rate for the prototype dryer is 112.5 tons per hour. With four dryers in service, each operating at the maximum feed rate, it would be possible to dry the total full-load coal feed for Unit 2 at Coal Creek (450 t/hr).

Three maximum capacity tests (CT1, CT2, and CT3) were performed from June 21 to 23, 2006, wherein coal feed rate was increased from the baseline value of 75 t/hr first to 90 t/hr, and finally to the maximum value of 101 t/hr. The coal conveying system and dust collector fan power imposed a limit on the maximum coal feed rate, which fell short of the design value by 10 percent.

The maximum capacity test data are summarized in Tables 1-6 to 1-8. Operating conditions of the dryer, presented in Table 1-6, show that inlet temperatures of fluidizing air and circulating water were increased above the baseline values to accommodate higher coal feed to the dryer. With the maximum coal feed rate at 101 t/hr, fluidization air temperature was 40°F higher compared to baseline operation, while the circulating water temperature was 20°F higher. With the feed rate at 101 t/hr, the dried coal represented 21 percent of the total coal feed to the boiler.

Table 1-8

Maximum Capacity Tests: Improvement in HHV

Test	**Coal Feed**	**Feed HHV**	**Coal Dryer**			**Coal Feed to the Boiler**		
			Product HHV	**HHV Increase**	**HHV Increase**	**Average Coal HHV**	**HHV Improvement**	**HHV Improvement**
	t/hr	**BTU/lb**	**BTU/lb**	**BTU/lb**	**%**	**BTU/lb**	**BTU/lb**	**%**
1	90	5,895	6,886	991	16.8	6,076	181	3.1
2	90	6,198	7,074	876	14.1	6,361	163	2.6
3	101	6,116	7,393	1,277	20.9	6,384	268	4.4

The reduction in coal moisture, achieved in the maximum capacity tests, is summarized in Table 1-7. The results show that the coal moisture reduction in the 7 to 9 percentage point range (20 to 26 percent relative) was achieved. The average coal moisture in the coal feed to the boiler (blend of dried and wet coal), was in the 1.3 to 1.7 percent range.

The coal HHV improved as moisture was removed from the coal in the prototype coal dryer (Table 1-8). The achieved HHV improvement was in the 875 to 1,280 Btu/lb range, or 14 to 21 percent. The improvement in the HHV of the boiler coal feed was in the 160 to 270 Btu/lb range, or from 2.6 to 4.4 percent.

Computer simulations were performed using operating conditions corresponding to the dryer capacity tests. Measured and predicted values are presented in Figures 1-23and 1-24. The comparison between measured and predicted moisture reduction values are presented in Figure 1-46.

An excellent agreement was achieved between measurements and predictions for capacity tests 1 and 3 (CT 1 and CT3). The measured value of moisture reduction for CT2 was approximately one percentage point higher compared to the predictions. This disagreement could be due to an error in coal analysis or a mislabeling of coal samples that were sent to the plant coal analysis laboratory.

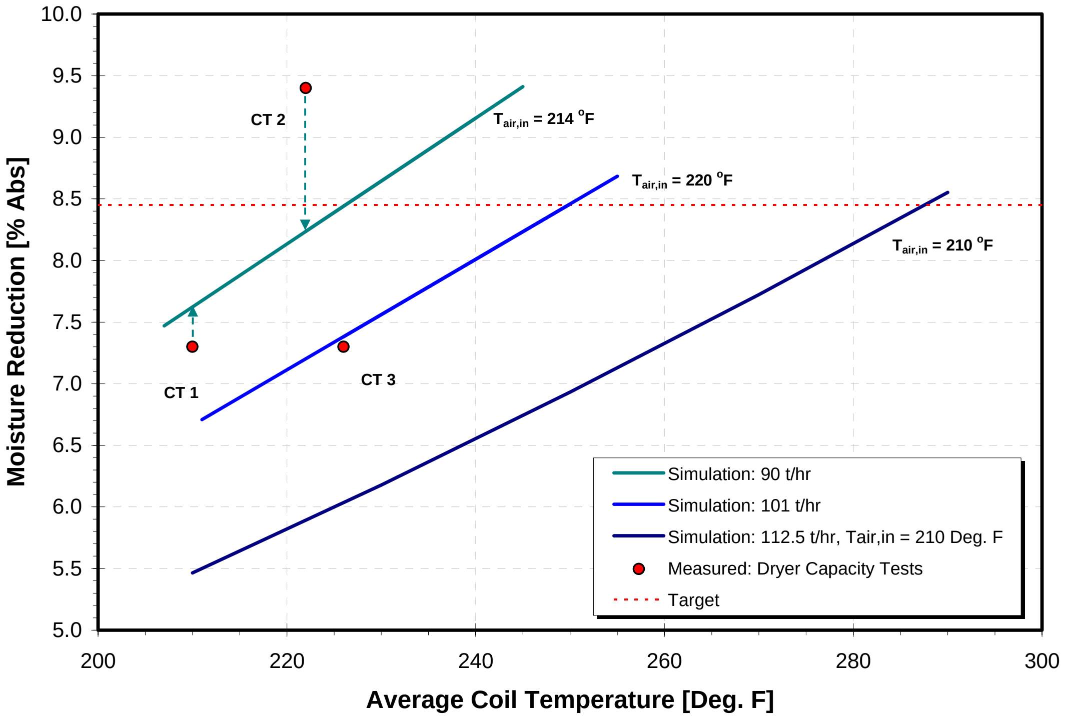

Figure 1-23: Maximum Capacity Tests - Measured vs. Predicted Values of Moisture Reduction

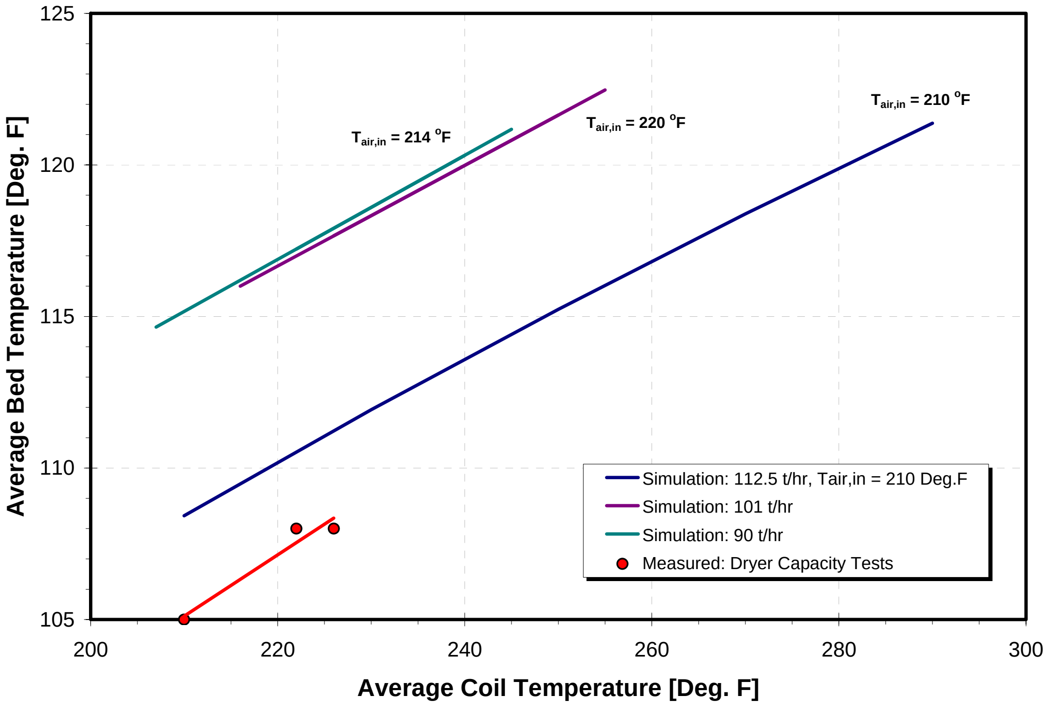

Figure 1-24: Maximum Capacity Tests - Measured vs. Predicted Values of Average Bed Temperature

The results also show that with a feed rate at 90 t/hr and an inlet air temperature at 214°F, the target moisture reduction can be achieved by increasing the average coil temperature to 227°F. With a feed rate at 101 t/hr and a fluidization air temperature at 220°F, the average coil temperature needs to be increased to 250°F. Predictions are also given for the maximum design coal feed at 112.5 t/hr and fluidizing air temperature at 210°F. It has to be noted that the average coil temperature is, for practical purposes, equal to the average of the circulating water inlet and outlet temperatures.

Predicted and measured values of the average bed temperature are presented in Figure 1-24. The results show that the predicted values followed the same trend as measurements, with measured values being, on average, 9°F lower. Considering locations of the in-bed thermocouples and uncertainties in bed temperature measurement, this represents a very good agreement.

6.4: First-Stage Segregation

The non-fluidizable material is removed from the dryer as the segregated stream by a patent pending system. Samples were taken from the segregated stream and analyzed to determine its composition. Results are presented in Tables 1-9 and 1-10 and in Figures 1-25 to 1-28 for baseline coal feed flow rate.

The total moisture, sulfur, and mercury content, and HHV of the feed, product, and segregated streams, determined from samples that were collected during the May-June time period, are summarized in Table 1-9. While the total moisture content of the product stream is significantly lower and its HHV higher compared to the feed stream, the moisture content and HHV of the segregated stream are similar to the feed stream. These experimental findings are in agreement with the dryer simulation results that show that only 10 percent of the total moisture removed in the dryer is removed in the first stage.

Table 1-10 presents the sulfur, mercury, and HHV of the segregated stream as percentages of the feed stream. The results show that approximately 30 percent of sulfur and mercury in the feed stream entering the dryer are removed in the first stage and discharged as the segregated stream. The segregated stream also contains approximately 10 percent of the inlet HHV. Additional processing of the segregated stream is needed to further concentrate sulfur and mercury and reduce the HHV content. Segregated stream processing will be incorporated into the commercial coal drying system.

The segregated stream samples were also collected during the maximum dryer capacity tests.

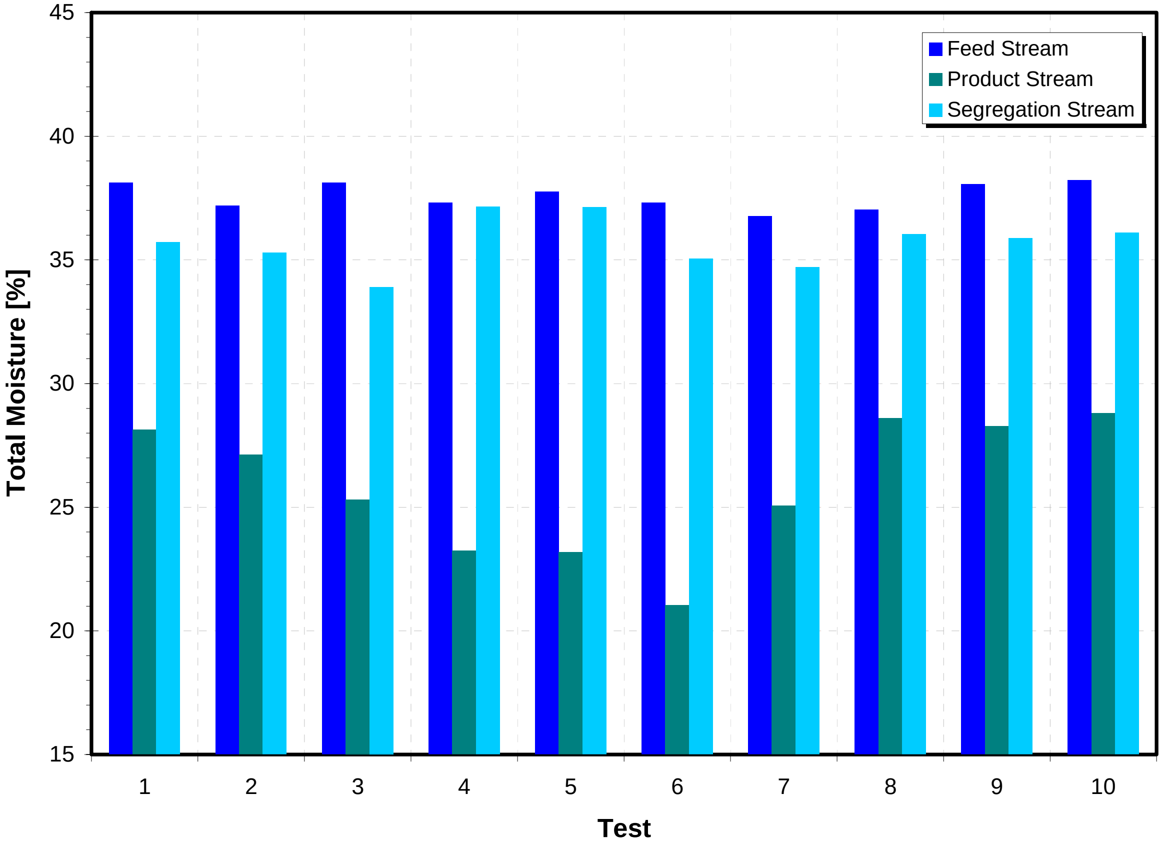

Figure 1-26: Total Moisture in the Feed, Product and Segregated Streams

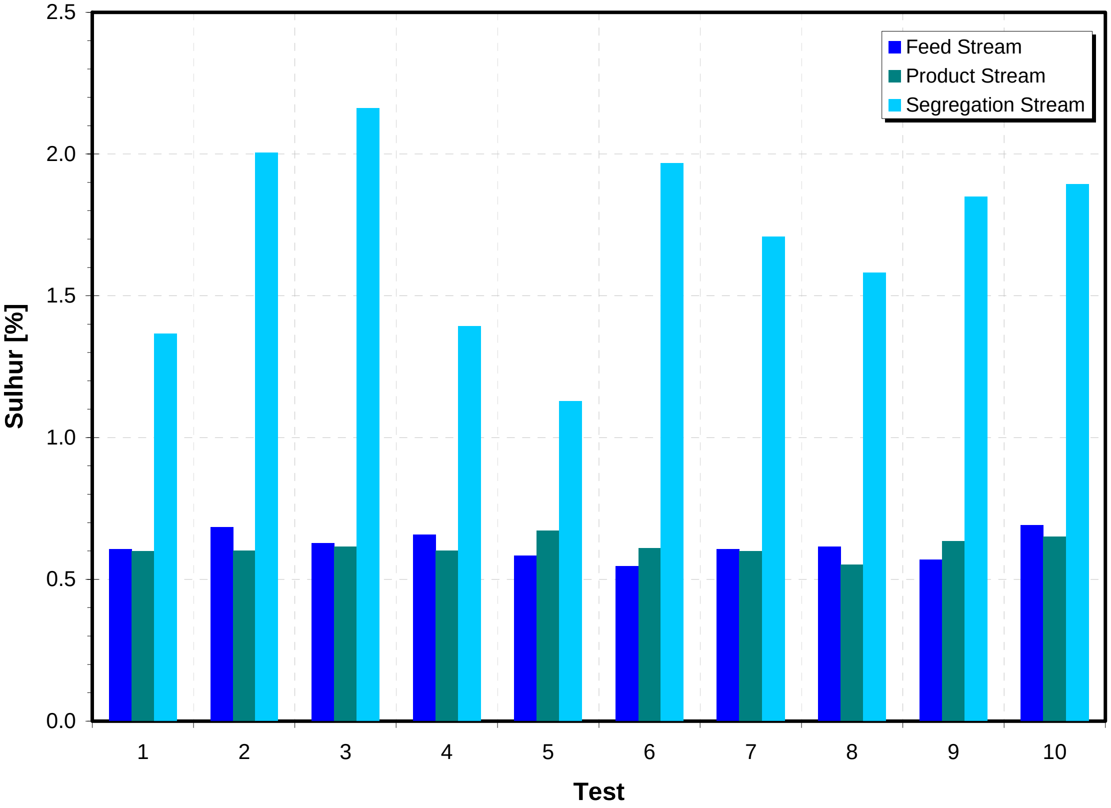

Figure 1-27: Sulfur in the Feed, Product, and Segregated Streams

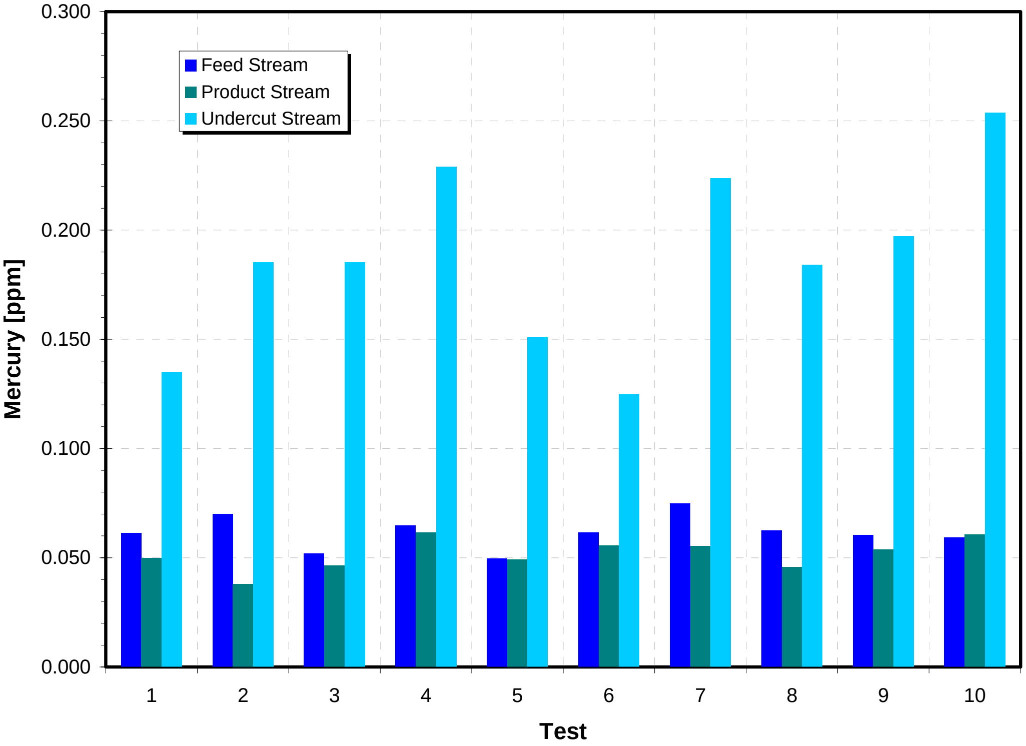

Figure 1-28: Mercury in the Feed, Product, and Segregated Streams

The S, Hg and HHV content of the segregated stream, expressed as percentage of feed, are summarized in Table 1-13 and Figure 1-29 as functions of feed rate. The results show that mercury content of the segregated stream increased as feed rate increased, while sulfur and HHV contents remained approximately constant.

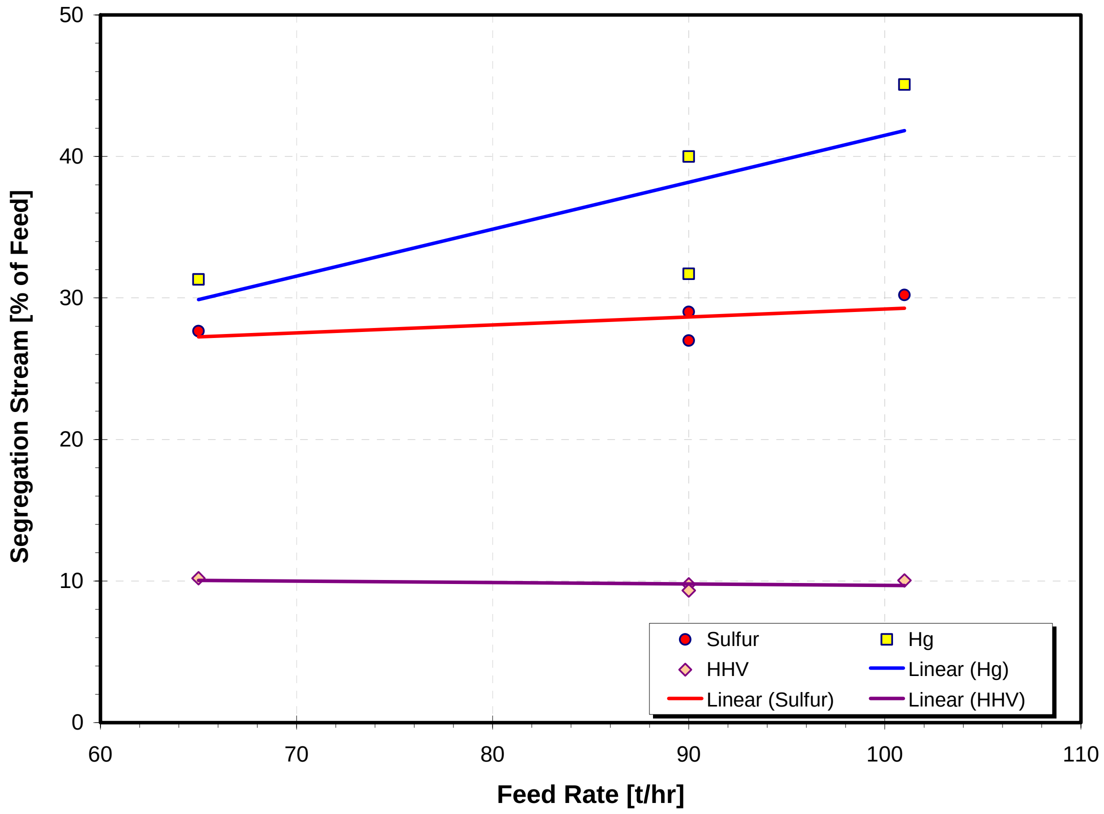

Figure 1-29: Sulfur, Mercury, and HHV Content of Segregated Stream vs. Feed Rate

PART 2: UNIT PERFORMANCE AND EMISSIONS

7. UNIT PERFORMANCE

As discussed in Section 6.1 (Operation Under Controlled Conditions), performance tests were conducted under carefully controlled conditions to determine the effect of firing dried coal on boiler efficiency and unit performance. A paired-test approach was used where two performance tests were run per day: one with the prototype dryer in operation, the other with the prototype dryer out of service. Such an approach minimizes or eliminates the effects of bias errors, i.e., day to day differences in plant operating conditions, variation in uncontrollable variables, and calibration drift of coal feeders.

Plant operating parameters such as main and reheat steam temperature, main steam and desuperheating spray flow rates, coal feeder flow rate, mill and fan power, flow rates of primary air to the mills, temperature of air and flue gas at a number of state points, and plant emissions were measured and recorded by the plant data acquisition system. Coal composition and HHV were determined from coal samples that were collected manually and by automatic coal samplers.

As predicted by theoretical calculations and confirmed in test burns, firing of partially dried coal in the boiler has a positive effect on boiler and unit efficiency, and stack emissions. The improvement in performance and reduction in emissions were determined for a series of 16 paired dryer tests.

In the current arrangement of a prototype coal drying system at CCS, the prototype coal dryer supplies dried coal to coal mill No. 26. With the prototype coal dryer in service and operating at a nominal coal feed of 75 t/hr, dried coal represents approximately 14 percent of the total coal flow rate supplied to the boiler (Figure 2-1).

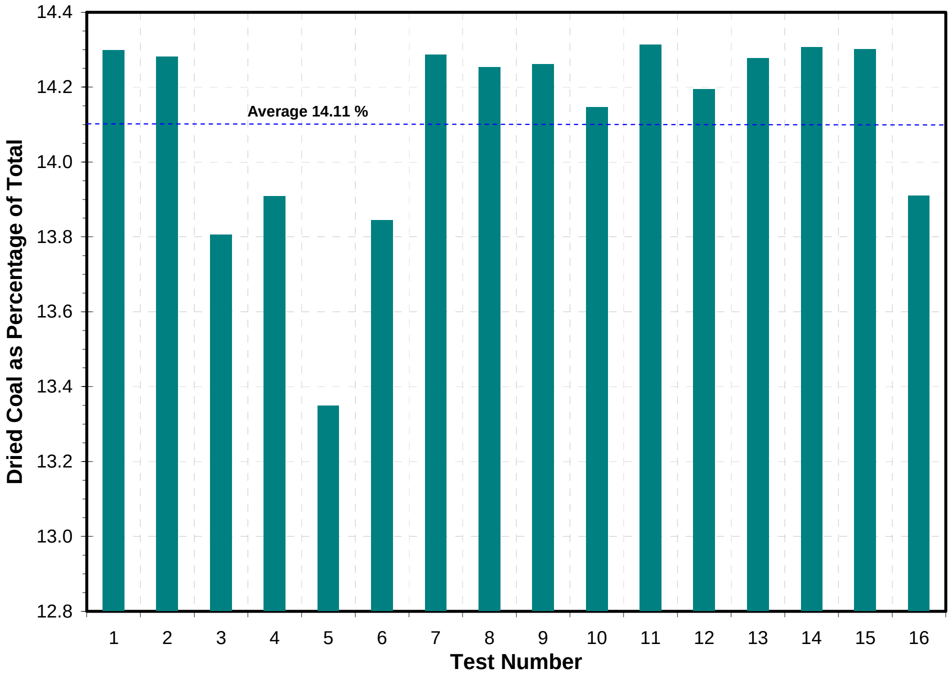

Figure 2-1: Dried Coal as Percentage of Total Coal Feed

Coal composition, HHV, and fuel heat input, determined for 16 pairs of coal dryer performance tests, are summarized in Table 2-1. With the prototype coal dryer (CD26) in service, the properties of the dried and wet coal streams were mass-averaged to determine properties of the coal blend fired in the boiler. The composition and HHV of the coal blend were determined from the following expression:

$$X_{\text{Mass-Average}} = X_{\text{Blend}} = X_{\text{Dry}}\ M_{\text{Dry}}/M_{\text{Total}} + X_{\text{Wet}}\ M_{\text{Wet}}/M_{\text{Total}} \qquad \text{Eqn. 2-1}$$

where:

X_{Blend} Composition or HHV of blended coal
X_{Dry} Composition or HHV of dried coal out of the CD26
X_{Wet} Composition or HHV of wet coal
M_{Dry} Flow rate of dried coal out of the CD26
M_{Wet} Flow rate of wet coal to the boiler
M_{Total} Total coal flow rate, where:

$$M_{\text{Total}} = M_{\text{Dry}} + M_{\text{Wet}} \qquad \text{Eqn. 2-2}$$

Table 2-1

Properties of Blended and Wet Coals

Description	**Units**	**Mass-Average Dry**	**Average Wet**	**% Change WRT Wet**	**Absolute Change WRT Wet**
C	% by weight	39.55	39.00	1.4	0.6
S	% by weight	0.68	0.66	1.6	0.0
H	% by weight	3.34	3.35	-0.1	0.0
N	% by weight	0.54	0.53	1.4	0.0
O	% by weight	8.55	8.26	3.5	0.3
Moisture	**% by weight**	**35.92**	**37.06**	**-3.1**	**-1.14**
Ash	% by weight	11.42	11.14	2.5	0.3
Total	**% by weight**	100.00	100.00		
HHV	**BTU/lb**	**6,402**	**6,299**	**1.63**	**103**
TOTAL FEEDER COAL FLOW RATE	**klbs/hr**	**953**	**971**	**-1.83**	
Total heat input	**MBTU/hr**	**6,102**	**6,117**	**-0.24**	
MAF-Basis HHV	**BTU/lb**	**12,157**	**12,160**	**-0.03**	**-4**

The results show that, with CD26 in service, the total moisture of the coal blend was reduced by 1.14 percentage points, or 3.1 percent on a relative basis, Figures 2-2 and 2-3. The improvement in HHV was 103 Btu/lb, or 1.63 percent, Figures 2-4 and 2-5. As expected, the coal HHV, expressed on a moisture-and-ash-free (MAF) basis, remained constant.

With the prototype coal dryer in service, the total coal flow rate, measured by the mill feeders, was reduced by 1.83 percent, Figures 2-6 and 2-7. The measured and theoretically predicted reductions in total coal flow rate are compared in Figure 2-8. The results show an excellent agreement between the calculated and measured values. For a target value of coal moisture reduction of 8.5 percent, the predicted decrease in coal flow rate is approximately 14 percent. This decrease is due to the higher HHV of the partially dried coal and improved boiler and unit performance.

The reduction in unit heat rate, due to the improvement in HHV and reduction in total coal flow rate, resulted in a 0.24 percent lower fuel heat input to the boiler, Table 2-2.

7.1: Boiler and Plant Operating Parameters

The average process parameters, determined in a series of 16 paired tests with the prototype CD26 in and out of service, are summarized in Table 2-2.

The gross unit load, main (throttle) and reheat steam temperatures, and fanroom temperature (temperature of the PA and SA at the inlet to the PA and FD fans) were constant throughout the test. The boiler feedwater flow was 0.3 percent higher with partially dried coal, compared to the wet coal. The superheater ("SHT") desuperheating spray flow rate was approximately 10 percent lower compared to the operation with wet coal.

The average coal feed to the prototype dryer during the test was 73 t/hr. This corresponds to 14.12 percent of the total coal input to Unit 2 boiler, or 15.5 percent of fuel heat input to the boiler.

Table 2-2

Average Process Parameters Determined in a Series of 16 Paired Performance Tests

Description	Units	Mass-Average Dry	Average Wet	% Change WRT Wet	Absolute Change WRT Wet

7.2: Mill Operation and Performance

With drier coal, mill power is 3.34 percent (140 kW) lower compared to the operation with wet coal (Figure 2-9). This decrease in mill power is due to a decrease in coal flow rate, and also due to the mill power required to grind a given coal flow rate, which is reduced with drier coal. With drier coal, the specific mill work is reduced by approximately 4.2 percent (Figure 2-10). The comparison of the measured and theoretically predicted reductions in mill power, presented in Figure 2-11, shows an excellent agreement between the calculated and measured values.

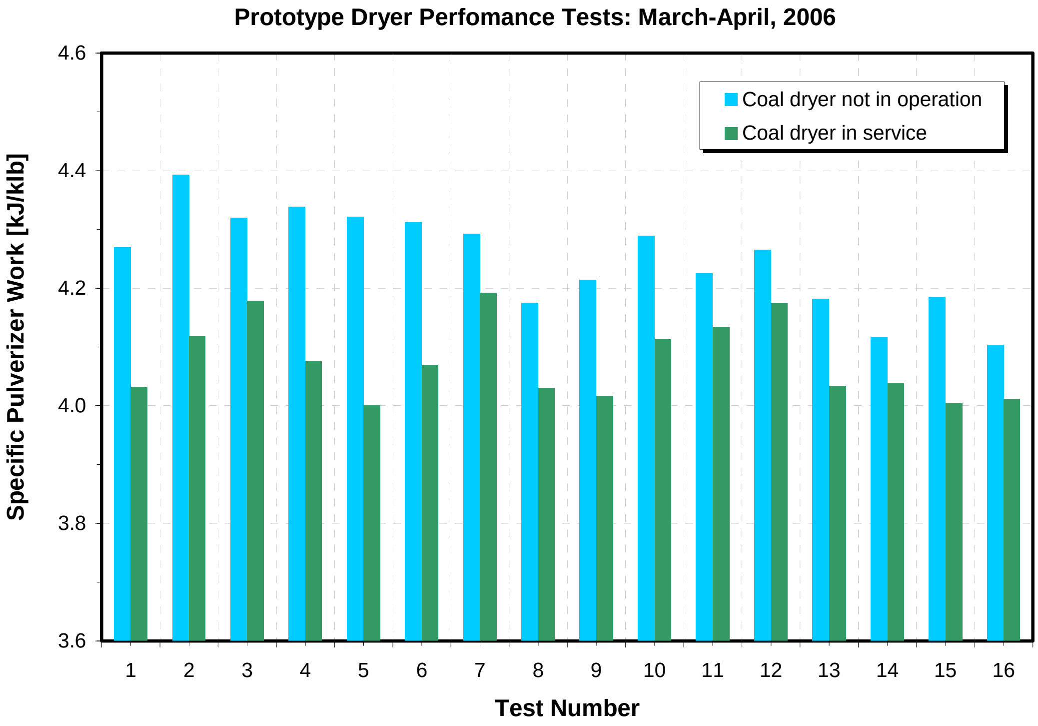

Figure 2-9: Total Mill (pulverizer) Power

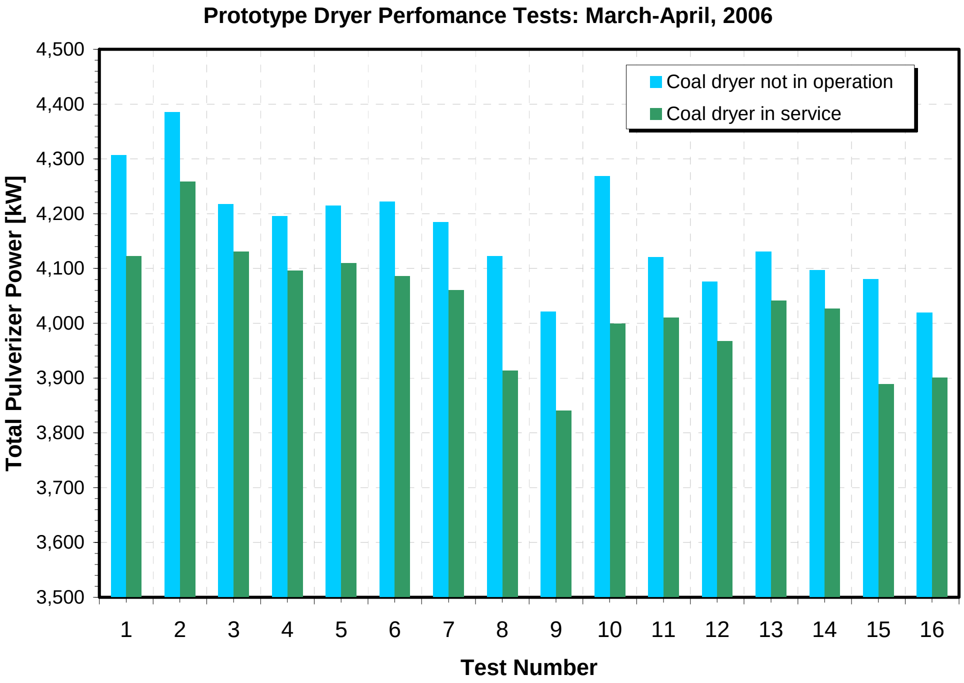

Figure 2-10: Specific Mill (pulverizer) Work

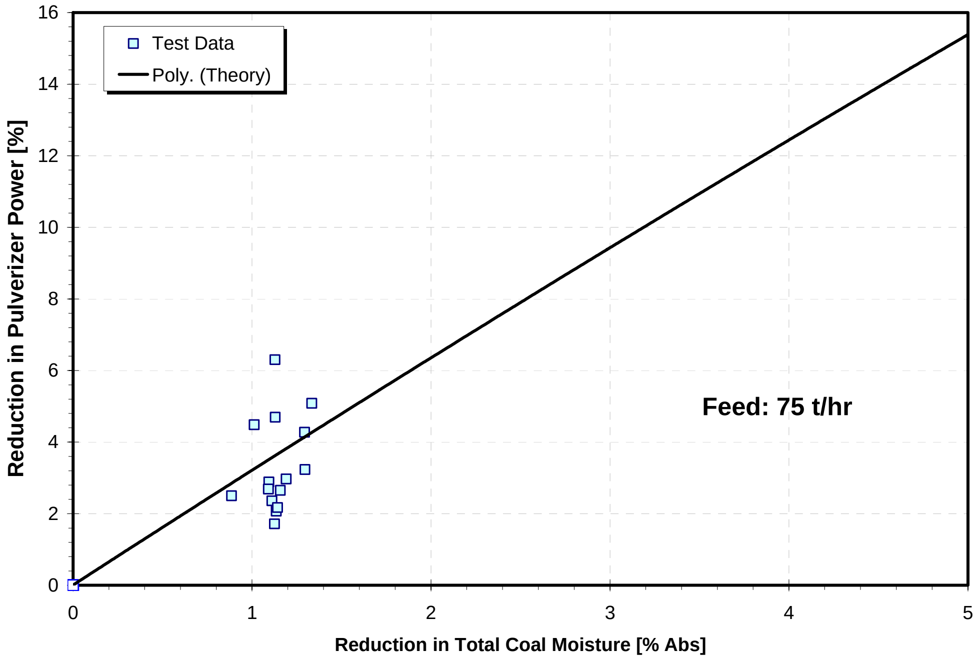

Figure 2-11: Comparison of Predicted and Measured Reduction in Mill Power

The temperature of the air-coal mixture leaving the No. 26 mill, processing partially dried coal, is 10°F higher compared to the mills processing wet coal (Figure 2-

12). This increase is due to the lower moisture content and higher temperature of partially dried coal entering the No. 26 mill.

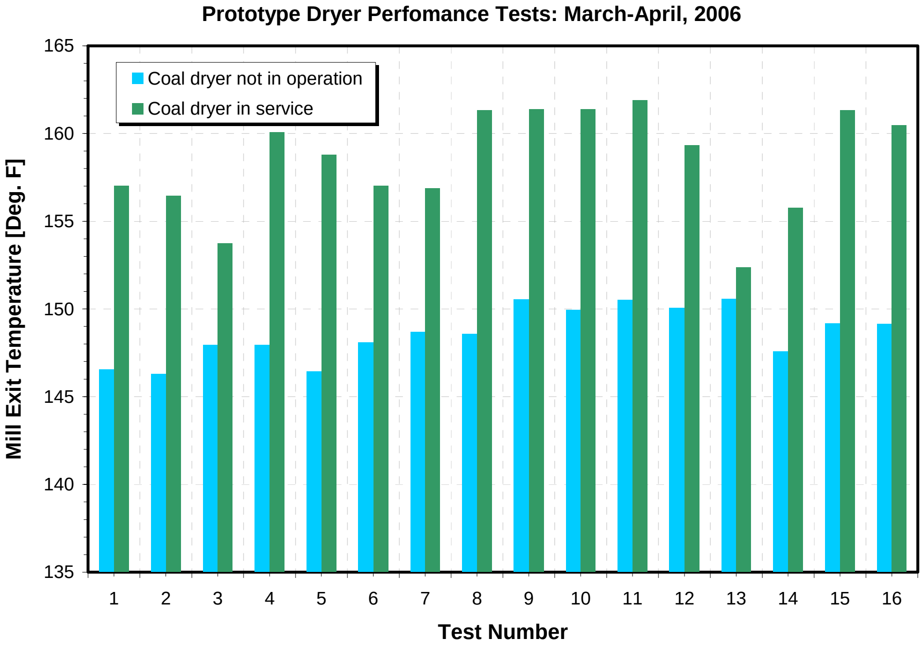

Figure 2-12: Mill Exit Temperature

Also, with CD26 in service, mill feeder No. 26 trips were eliminated. This is because the oversize material, typically responsible for feeder trips, was either screened out or discharged from the first dryer stage with the rest of the non-fluidizable material.

A coal crusher is used at Coal Creek to reduce coal top particle size to ¼-inch. The crusher power requirement for a baseline coal feed rate of 75 tons per hour is approximately 100 kW.

7.3: <u>Flue Gas Flow</u>

The flow rates of combustion air and flue gas decrease as coal moisture content is reduced. A decrease in combustion air flow rate is due to the improvement in boiler and unit performance, which result in a reduction in coal flow rate and heat input. The decrease in flue gas flow rate is due to the improvement in boiler and unit performance and decreased coal moisture content. A lower coal moisture results in lower water vapor content of flue gas. With blended coal fired during the paired tests, the flue gas moisture content was reduced from 15.5 to 15.1 percent on a volume basis. For a target value of total coal moisture removal of 8.5 percent, the flue gas moisture content will be reduced by more than 2.5 percentage points. As a result, the decrease in flue gas flow rate is larger than the decrease in combustion air flow rate.

The flue gas volumetric flow rates, measured by the plant CEM during the paired tests, are presented in Figure 2-13. A comparison between measured and predicted decrease in flue gas flow rate, presented in Figure 2-14, shows a very good agreement between the measured and predicted values.

For a target value of total moisture reduction of 8.5 percent, the predicted decrease in flue gas flow rate is approximately 3.9 percent. The average values of flue gas flow rate corresponding to the partially dried and wet coals are summarized in Table 2-3.

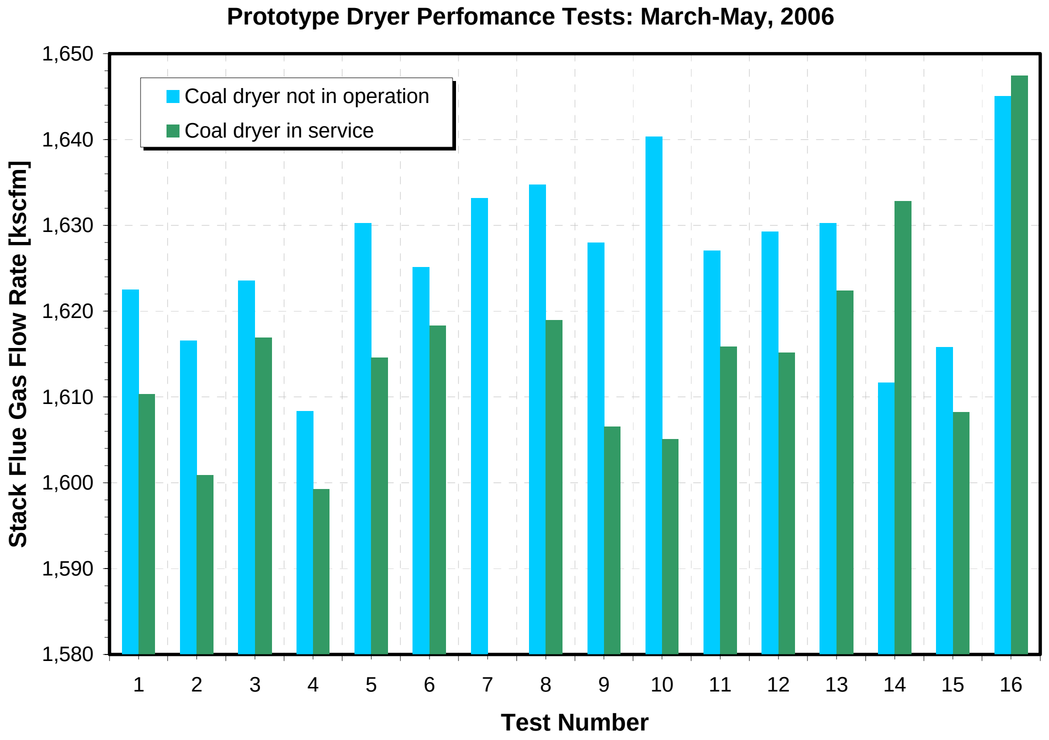

Figure 2-13: Flue Gas Flow Rate in Standard Volumetric Units

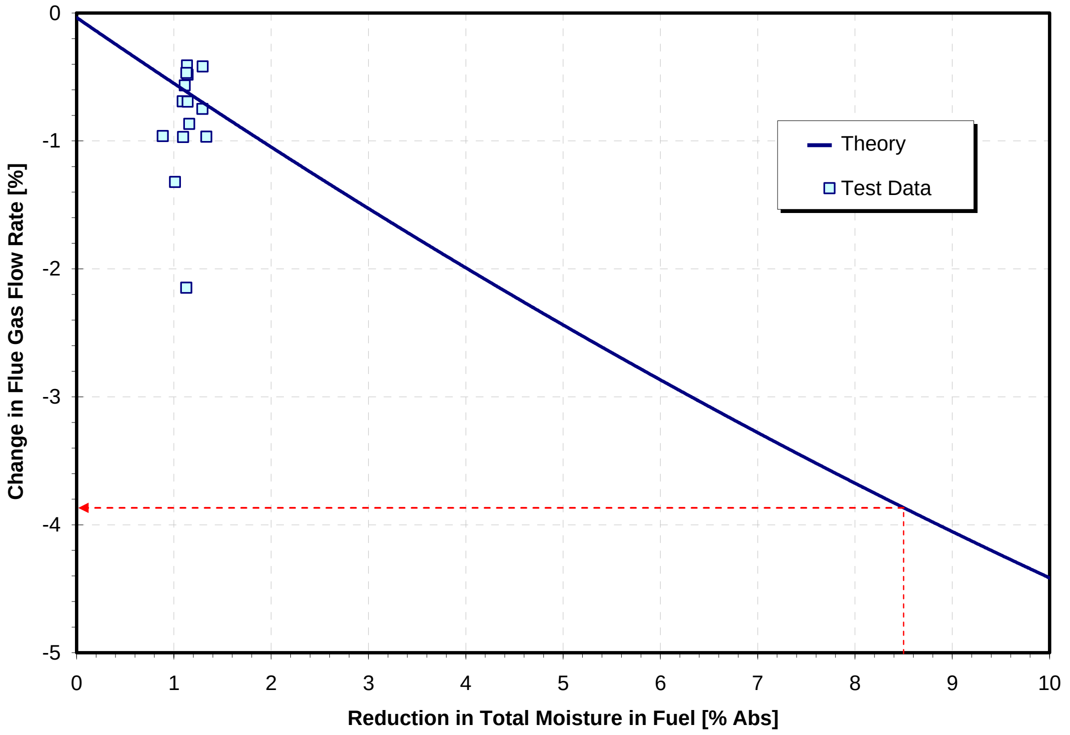

Figure 2-14: Comparison of Measured and Predicted Reduction in Flue Gas Flow Rate

Table 2-3

Flue Gas Flow Rate and Temperature, and Scrubber ΔP

Description	Units	Average Dry	Average Wet	% Change WRT Wet	Change WRT Wet
FLUE GAS FLOW RATE	kscfm	1,613	1,625	**-0.73**	
FLUE GAS TEMP	^{o}F	180	184		**-4.1**
Flue gas flow rate	kacfm	1,922	1,949	**-1.36**	
Flue gas flow rate	klbs/hr	7,101	7,140	**-0.55**	
U2 SCRUBBER DIFF PRESS	" wg	5.46	5.50	**-0.83**	**-0.05**

Table 2-3 also summarizes the values of the flue gas temperature at the stack inlet and the differential pressure, ΔP, across the wet scrubber. The flue gas flow rate, reported in standard volumetric units (kscfm), was converted to actual volumetric units (kacfm) and to mass units (klbs/hr) using the flue gas density values from Table 2-4. With a partially dried coal, the density of the flue gas is approximately 0.8 percent higher compared to the flue gas density corresponding to the wet coal.

Table 2-4

Flue Gas Density Calculation

Description	Units	Mass-Average Dry	Average Wet	% Change WRT Wet	Absolute Change WRT Wet
Flue gas molecular weight	kg/mole	28.754	28.702	**0.18**	
Actual flue gas temperature	Deg. C	82.16	84.41		**-2.25**
Actual flue gas temperature	K	355.31	357.56		**-2.25**
Gas constant	J/mole-K	289.14	289.67	**-0.18**	
Ambient pressure	N/m^2	101,300	101,300		
Flue gas density	kg/m^3	0.9860	0.9781		
Flue gas density	**lb/ft^3**	**0.06156**	**0.06106**	**0.82**	
Standard temperature	Deg.C	25	25		
Standard temperature	K	298.15	298.15		

The results from Table 2-3 show that with the partially dried coal, the volumetric flue gas flow rate, at actual conditions, decreased 1.36 percent compared to that with wet coal. The reduction in mass flow rate of flue gas is lower, 0.55 percent, due to the increase in flue gas density with partially dried coal. The measured reduction in flue gas flow rate is close to the theoretically calculated value of 0.65 percent.

With partially dried coal, the flue gas temperature at the stack inlet is lower compared to that with wet coal by approximately 4.3°F (2.25°C). This lower temperature decrease can be explained by the fact that with reduced flue gas flow rate with partially dried coal, a larger fraction of flue gas passes through the wet scrubber (where its temperature is decreased to a value close to the saturation temperature) while a smaller flue gas fraction bypasses the scrubber, compared to that with wet coal operation. The bypass and scrubbed streams mix downstream of the scrubber before entering the stack, resulting in inlet stack temperature being higher than saturation temperature. Measured values of flue gas temperature at the stack inlet are presented in Figure 2-15. The red bar indicates an erroneous temperature reading.

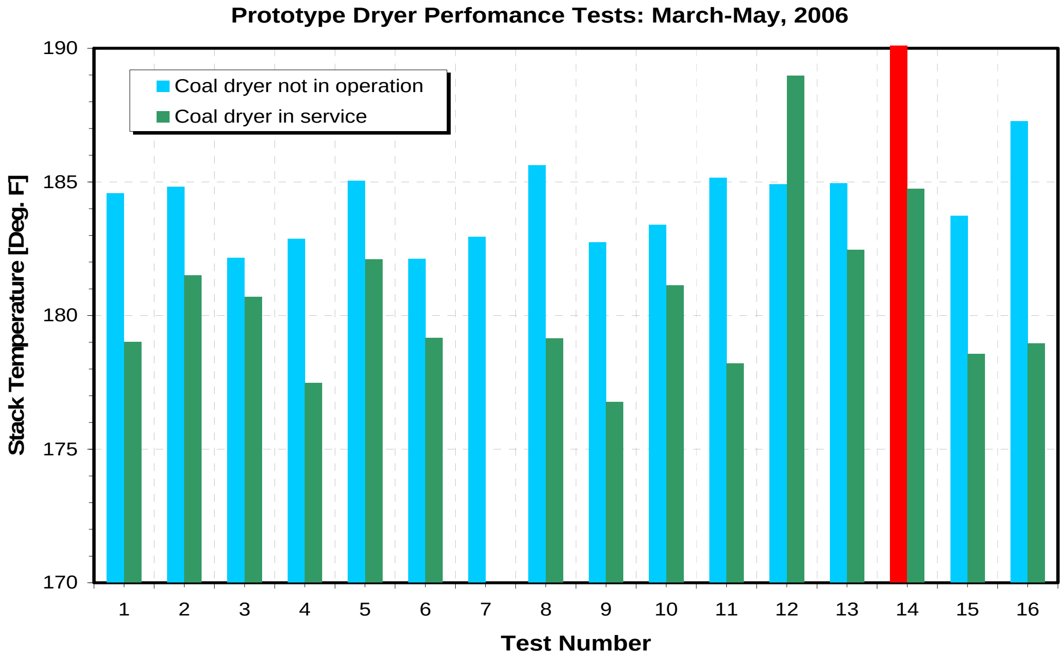

Figure 2-15: Flue Gas Temperature at Stack Inlet

The air flow through the forced draft (FD) and primary air (PA) fans at CCS is, at present, controlled with inlet guide vanes (IGV). Flow control through the induced draft (ID) fans at Coal Creek is accomplished by the inlet damper (ID). With the IGV and ID methods of flow control, a full reduction in fan power due to the reduced air and flue gas flow rates with partially dried coal is not possible. Variable speed fan drives (VSD) are needed to achieve the maximum reduction in fan power with partially dried coal.

With the presently used fan flow control methods at CCS, the FD fan power remained virtually constant (2,056 vs. 2,049 kW) for both the partially dried and wet coals. For the case of partially dried coal, the ID fan power was reduced 1.43 percent (169 kW).

7.4: Calculation of the Average Boiler Efficiency Improvement From Plant Data

By using the definition of boiler efficiency, η_B, shown below, the improvement in this parameter due to firing of partially dried coal can be determined directly from the measured plant data, using the input/output method without performing boiler efficiency calculations. Since the input/output approach suffers from large errors due to uncertainties (random errors) in coal flow rate and HHV measurement, this approach is not suitable for determining boiler efficiency improvement for individual performance tests. Instead, the input/output approach was used to calculate average efficiency improvement for all 16 performance tests, where individual test uncertainties averaged out reducing, therefore, the overall test uncertainty.

By definition:

$\eta_B = Q_T/Q_{Fuel}$ Eqn. 2-4

where:

Q_T	Boiler thermal duty (heat transferred to the steam turbine cycle)
Q_{Fuel}	Heat input with fuel, in this case coal:

$Q_{Fuel} = M_{Fuel}\ HHV$ Eqn. 2-5

where:

M_{Fuel}	Fuel (coal) flow rate
HHV	Fuel (coal) higher heating value

The relative improvement in boiler efficiency, $\Delta\eta_{/}\eta_{B,Wet}$, can then be determined as:

$\Delta\eta_{/}\eta_{B,Wet} = Q_{T,Dry}/Q_{T,Wet} \times Q_{Fuel,Wet}/Q_{Fuel,Dry} - 1$ Eqn. 2-6

Using results from Table 2-5 show, the improvement in boiler efficiency due to firing of partially dried coal, calculated by the input/output method is:

$\Delta\eta_{/}\eta_{B,Wet} = 0.00535 \pm 0.000315$

Expressed on a relative basis, the improvement in boiler efficiency $\Delta\eta_{/}\eta_{B,Wet}$ is equal to 0.535 ± 0.0315 percent.

Table 2-5

Boiler Efficiency Improvement Calculated From the Plant Data

Description	**Units**	**Mass-Average Dry**	**Average Wet**	**% Change WRT Wet**	**Absolute Change WRT Wet**
$Q_{T,dry}/Q_{T,wet}$	ratio			1.002962	
$Q_{fuel,wet}/Q_{fuel,dry}$	ratio			1.002388	
$\eta_{B,dry}/\eta_{B,wet}$	ratio			**1.005357**	

The uncertainty in $\Delta\eta/\eta_{B,Wet}$ was determined by assuming typical uncertainty value of ± 3 percent for coal flow rate measurement, ± 1 percent for laboratory determination of coal HHV, and baseline boiler efficiency of 80 percent.

The calculated values of boiler efficiency for the partially dried and wet coals are presented in Table 2-6 and Figure 2-16.

Table 2-6

Boiler Efficiency for Partially Dried and Wet Coal Calculated by Using the Mass and Energy Balance Approach and Paired Performance Test Data

Test	**Total Fuel Moisture, TM [%]**		**DTM**	**Boiler Efficiency [%]**		**Difference**

11	34.92	36.00	**1.08**	78.36	77.93	**0.43**
12	35.99	37.16	**1.16**	78.79	78.60	**0.19**
13	36.19	37.34	**1.14**	78.05	77.59	**0.46**
14	35.91	37.03	**1.12**	78.64	78.56	**0.08**
15	36.71	37.81	**1.10**	78.25	77.90	**0.35**
16	**35.17**	**37.47**	**2.30**	**78.91**	**78.39**	**0.52**
Average	**35.92**	**37.06**	**1.14**	**78.44**	**78.07**	**0.37**
Std. Dev	0.49	0.43	0.31	0.33	0.45	0.18
Std. Error	0.14	0.13	0.09	0.10	0.13	0.05
Random Error	**0.30**	**0.27**	**0.19**	**0.20**	**0.28**	**0.11**

The results show that boiler efficiency achieved by firing partially dried coal is consistently higher compared to the boiler efficiency corresponding to firing wet coal. The average absolute boiler efficiency improvement, $\Delta\eta_B$, calculated from the boiler efficiency values from Table 2-5, excluding test point 16, is:

$$\Delta\eta_B = 0.37 \pm 0.11 \text{ percentage points}$$

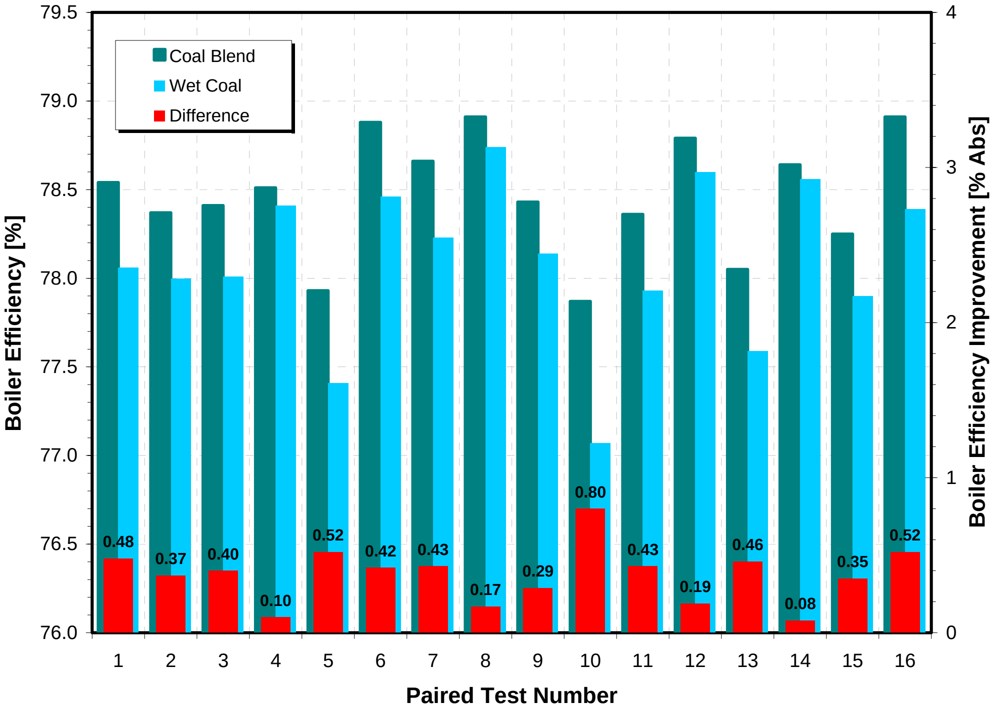

Figure 2-16: Boiler Efficiency for Partially Dried and Wet Coal

This corresponds to $\Delta\eta/\eta_{B,Wet}$ = 1.0047, or a **0.470** percent improvement on a relative basis. Considering the uncertainties in coal composition, HHV, and flow rate measurement, this value is close (within 14 percent) to the relative boiler efficiency improvement of **0.5357** percent calculated by the input/output approach.

Since the uncertainty interval of ± 0.11 percentage points is significantly smaller than the calculated boiler efficiency difference of 0.37 percentage points, the calculated improvement in boiler efficiency is statistically significant.

The comparison of theoretically predicted boiler efficiency improvement and boiler efficiency improvement determined from a series of 16 paired performance tests is presented in Figure 2-17. Theoretical predictions were obtained by applying the mass and energy balance and above-described calculation approach.

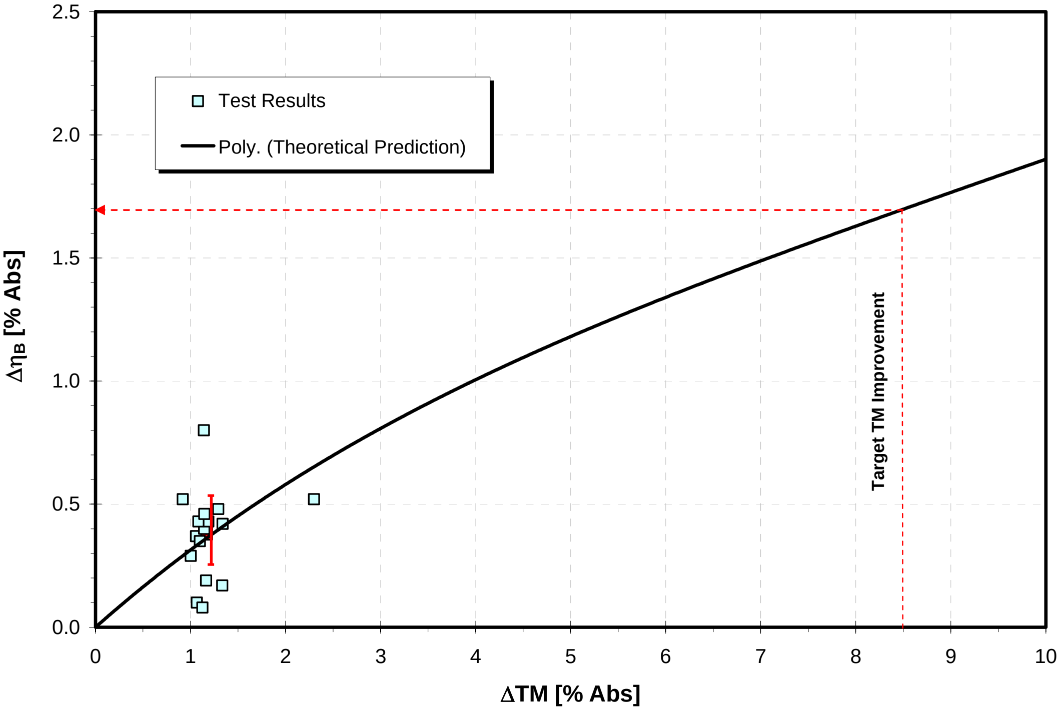

Figure 2-17: Comparison of Predicted and Test Values of Absolute Boiler Efficiency Improvement

The difference between the theoretical calculations and performance test results is that in the theoretical calculations, analytical models for APH thermal performance and fan and mill power were used to determine temperatures of flue gas, PA and SA leaving the APH, and FD, PA, ID and mill power. The coal flow rate was calculated by assuming constant boiler thermal duty, Q_T. When calculating boiler efficiency from the boiler performance test data, measured values of these parameters, obtained in a series of 16 paired performance tests were used.

With the exception of one outlier test point, the results in Figure 2-17 show excellent agreement between theoretical predictions and performance test results. For a target reduction in total coal moisture of 8.5 percent, the predicted improvement in boiler efficiency is 1.7 percent.

7.5: Net Unit Heat Rate

The net unit heat rate is calculated according to the following expression:

$$HR_{net} = HR_{cycle}/[\eta_B(1 - P_{ss}/P_g)] \qquad \text{Eqn. 2-16}$$

where:

HR_{cycle}	Turbine cycle heat rate (8,000 Btu/kWh for CCS)
η_B	Boiler efficiency
P_{ss}	Total measured station service power (mills, fans, crusher, etc.)
P_g	Gross unit power output

The values of net unit heat rate calculated from the paired performance test data for the partially dried and wet coal are presented in Table 2-7 and Figure 2-18.

Table 2-7

Net Unit Heat Rate for Partially Dried and Wet Coal Calculated by Using the Mass and Energy Balance Approach and Paired Performance Test Data

Test	**TM [%]**		**DTM**	**$HR_{net,mix}$**	**$HR_{net,wet\ coal}$**	**ΔHR_{net}**	**ΔHR_{net}**

14	35.91	37.03	**1.12**	10,620	10,629	9	0.08
15	36.71	37.81	**1.10**	10,657	10,705	48	0.45
16	**35.17**	**37.47**	**2.30**	**10,578**	**10,634**	**56**	**0.53**
Average	**35.92**	**37.06**	**1.14**	**10,648**	**10,688**	**40**	**0.37**
Std. Dev	0.49	0.43	0.31	47	64	24	0.23
Std. Error	0.14	0.13	0.09	13	18	7	0.07
Random Error	**0.30**	**0.27**	**0.19**	**29**	**39**	**15**	**0.14**

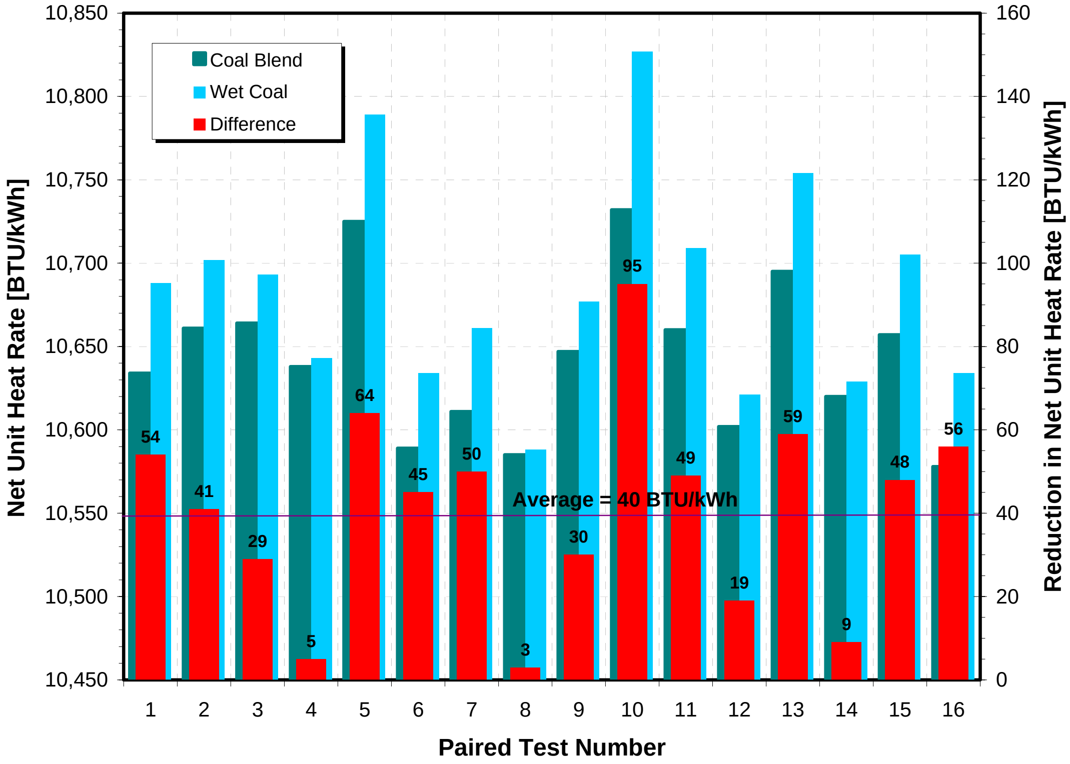

Figure 2-18: Net Unit Heat Rate for Partially Dried and Wet Coal

The results show that the net unit heat rate, HR_{net}, corresponding to the unit operation with partially dried coal is consistently lower compared to HR_{net} obtained with the wet coal. The average improvement in net unit heat rate due to lower fuel moisture, excluding Test 16, is:

$\Delta HR_{net} = 40 \pm 15$ Btu/kWh

On a relative scale this corresponds to a HR_{net} improvement of 0.37 percent. Since the uncertainty interval of ± 15 Btu/kWh is significantly smaller than the calculated heat rate difference of 40 Btu/kWh, the calculated improvement in HR_{net} is statistically significant.

If VSD were used for fan flow control, fan power requirement would be lower than with the presently used fan flow control methods (Table 2-7). With a partially dried coal and VSD drives, the FD fan power would be reduced 0.58 percent, while the ID fan power would be 2.98 percent (350 kW) lower compared to the wet coal and IGV/ID flow control. With VSD drive the PA fan power would be 66 kW lower than with the IGV flow control.

The final result would be a 0.80 percent (197 kW) reduction in total fan power and a 0.50 percent (54 Btu/kWh) total improvement in net unit heat rate (Table 2-8).

Table 2-8

Effect of VSD Fan Flow Control on Fan Power Requirements and Net Unit Heat Rate

8. <u>EMISSIONS</u>

The NO_x and SO_x emissions, flue gas flow rate, and flue gas CO_2 composition, measured by the plant CEM for 16 paired performance tests, are summarized in Table 2-9. As discussed earlier, firing partially dried coal results in lower flue gas flow rate. For the coal moisture reduction of 1.14 percent, achieved in the dryer performance tests, the reduction in flue gas mass flow rate is 0.55 percent.

Table 2-9

NO_x and SO_x Emissions, Stack Flow Rate,
and Flue Gas CO_2 Concentration Measured by the Plant CEM

Description	Units	Mass-Average Dry	Average Wet	% Change WRT Wet	Absolute Change WRT Wet
NOx Emissions	lbs/hr	1,359	1,469	**-7.52**	**-111**
SOx Emissions	lbs/hr	3,641	3,670	**-0.81**	**-30**
Flue Gas Flow Rate	kscfm	1,613	1,625	**-0.73**	**-12**
Flue Gas Flow Rate	klbs/hr	7,101	7,140	**-0.55**	**-39**
Flue Gas CO2	%	11.90	11.87	**0.27**	**0**

8.1: NO_x Emissions

The 7.5 percent average reduction in NO_x mass emissions, measured during the paired performance tests (Figure 2-19), is significantly higher than the percentage reduction in flue gas flow rate. This reduction in NO_x emissions cannot be explained by a lower flue gas flow rate. Instead it is attributed to a lower primary air flow rate to Mill No. 26, which was handling partially dried coal. From combustion optimization tests, performed by the ERC and GRE engineers at Coal Creek in 1997 [10], it is known that NO_x emissions at this plant are quite sensitive to the primary air flow. NO_x decreases as primary air flow is reduced.

The primary air flow rates to Mill 26 and to other mills handling wet coal are presented in Figure 2-20. With partially dried coal, the primary air flow rate to the No. 26 mill was, on average, reduced from 355 to 310 klbs/hr, a 12 percent reduction. Modifications to the coal mills will allow the primary air flow to be decreased even more to 255 klbs/hr. This is expected to result in a further decrease in NO_x emissions.

With the commercial coal drying system in service, i.e., with 100 percent dried coal delivered to the coal mills, and the reduced PA flows to the mills, the reduction in NO_x emissions is expected to exceed 10 percent.

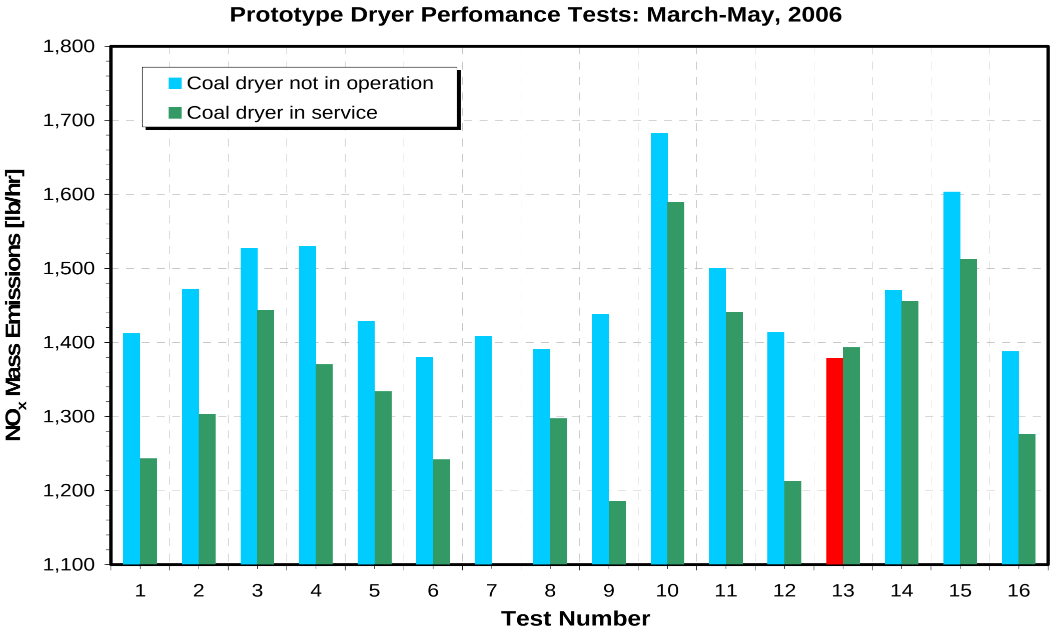

Figure 2-19: NO_x Emissions with Wet and Partially Dried Coal

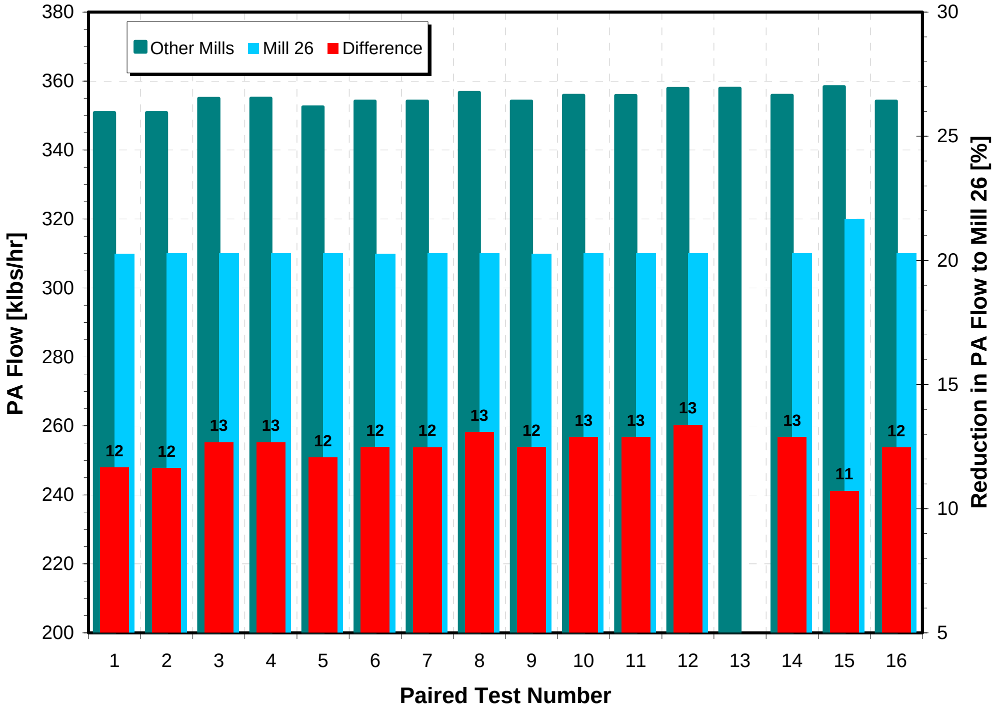

Figure 2-20: Primary Air Flow Rates to the Mills with Wet and Partially Dried Coal

8.2: SO_x Emissions

The measured reduction in SO_x emissions with partially dried coal, measured during the series of 16 paired parametric tests, is approximately 0.8 percent (Table 2-9 and Figure 2-21). The red bar represents a bad reading.

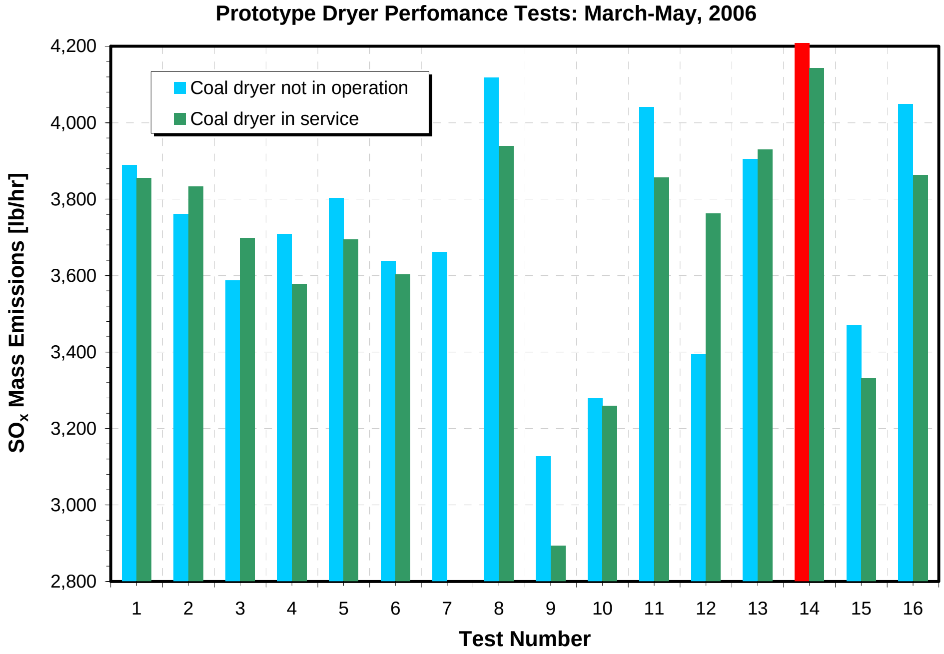

Figure 2-21: SO_x Emissions with Wet and Partially Dried Coal

A closer inspection of the recorded plant data and the results presented in Figure 2-21 points to problems with SO_x measurement that occurred during Tests 12 to 14, where measured SO_x emissions are higher with a partially dried coal compared to the wet coal. These inconsistencies are explained by a malfunctioning SO_x monitor that was providing unreliable SO_x readings for Tests 12 to 14. A comparison of the results for the first 11 paired tests and for all 16 paired tests shows a significant difference in SO_x reduction (1.9 percent for the first 11 tests vs. 0.8 percent for all 16 tests). It is, therefore, reasonable to assume that the actual reduction in SO_x emissions, achieved with partially dried coal, is in the 1.9 percent range.

The percentage reduction in SO_x emissions is larger than the percentage the reduction in flue gas mass flow rate. This is because with a lower flue gas flow rate, the flue gas bypass around the scrubber decreases (CCS is a partially scrubbed unit), resulting in a higher SO_x removal. With 100 percent partially dried coal fired in the boiler, the flue gas flow rate to the wet scrubber will be reduced by an estimated four percent. Combined with lower APH leakage, that would be achieved by using double-edge APH seals, the percentage of the scrubbed flue gas flow will further increase, approaching a zero scrubber bypass configuration. This will result in an additional reduction in SO_x emissions.

Due to a gravitational separation that is taking place in the first dryer stage, the sulfur concentration in the segregated stream is three times higher compared to the product and feed streams. This increase in sulfur content in the segregated stream can be explained by the fact that pyrites, having higher density than coal, are segregated out in the first dryer stage. For the present configuration of the prototype coal drying system at CCS, the segregated stream is returned to and mixed with the product stream from the coal dryer. Therefore, the benefit of sulfur removal in the first dryer stage, is not being realized, and the measured reduction in SO_x emissions is solely due to the lower flue gas and scrubber bypass flows.

The commercial coal drying system is designed to further process the segregated stream. After processing, the segregated stream will not be mixed with the product stream from the commercial dryers. With the segregated stream representing 5 to 10 percent of the dryer feed, the reduction in mass flow rate of sulfur to the boiler would be in the 7 to 12 percent range. By combining reductions due to the lower scrubber bypass and lower sulfur input to the boiler, the potential reduction in SO_x emissions that could be achieved with the commercial coal drying system at CCS operating at 100 percent capacity is expected to be in the 12 to 17 percent range.

Since the calculated reduction in SO_x emissions is very much affected by the accuracy of the measured S concentration levels in the feed, segregated, and product streams, and the segregated stream flow rate, the actual reduction in SO_x emissions will be determined from the plant CEM measurements with the commercial coal drying system at CCS operating at 100 percent capacity.

8.3: CO_2 Emissions

The reduction in CO_2 mass emissions is proportional to the improvement in unit performance (net unit heat rate). For the target moisture reduction of 8.5 percent, the expected reduction in CO_2 emissions is approximately 2.4 percent.

8.4: Mercury (Hg) Emissions

The reduction in Hg emissions, achieved during paired performance tests at CCS, is proportional to the improvement in unit performance, and is estimated to be in the 0.4 percent range.

The segregated stream from the first dryer stage contains approximately 3.5 to 4 times more Hg compared to the product and feed streams, (Figures 2-22 and 2-23). This increase in Hg content in the segregated stream can be explained by the fact that for the Falkirk lignite, a significant portion of mercury is bound to pyrites that are segregated out in the first dryer stage.

With the present configuration of the prototype coal drying system at CCS, the segregated stream is returned to the product stream from the coal dryer. Therefore, the benefit of Hg removal in the first dryer stage on Hg emissions is not realized.

As discussed in Section 8.2, the commercial coal drying system is designed to further process the segregated stream. After processing, the segregated stream will not be mixed with the product stream from the commercial dryers and will not be burned in the CCS boiler. With the segregated stream representing 5 to 10 percent of the dryer feed, the estimated reduction in mass flow rate of mercury to the boiler is in the 13 to 25 percent range (Figures 2-22 and 2-23).

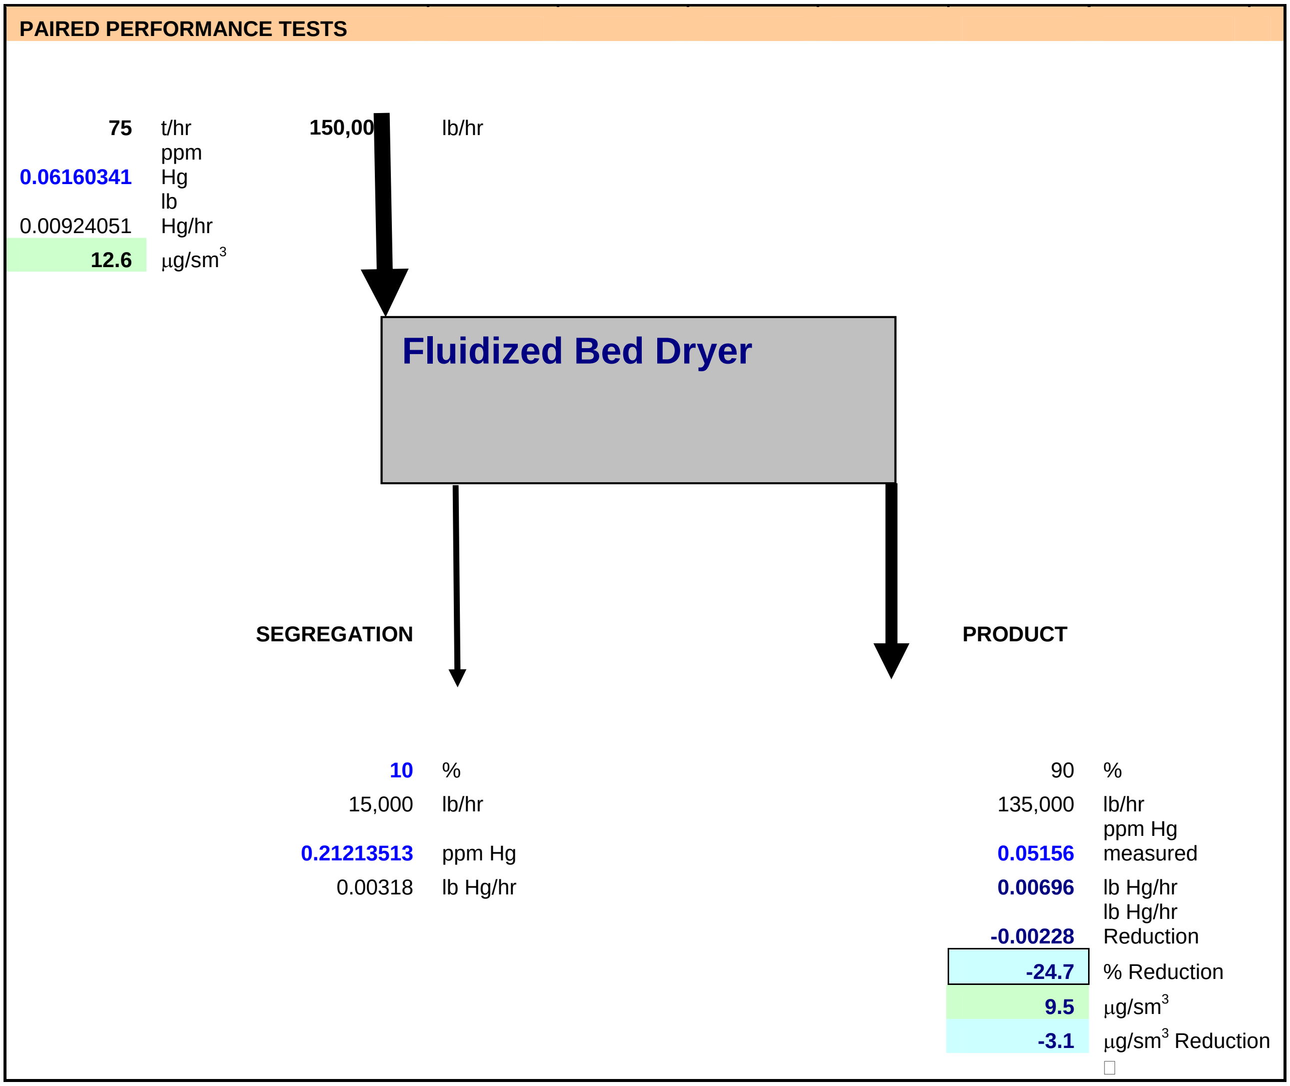

Figure 2-22: Mercury Mass Balance Around FBD – Paired Performance Tests

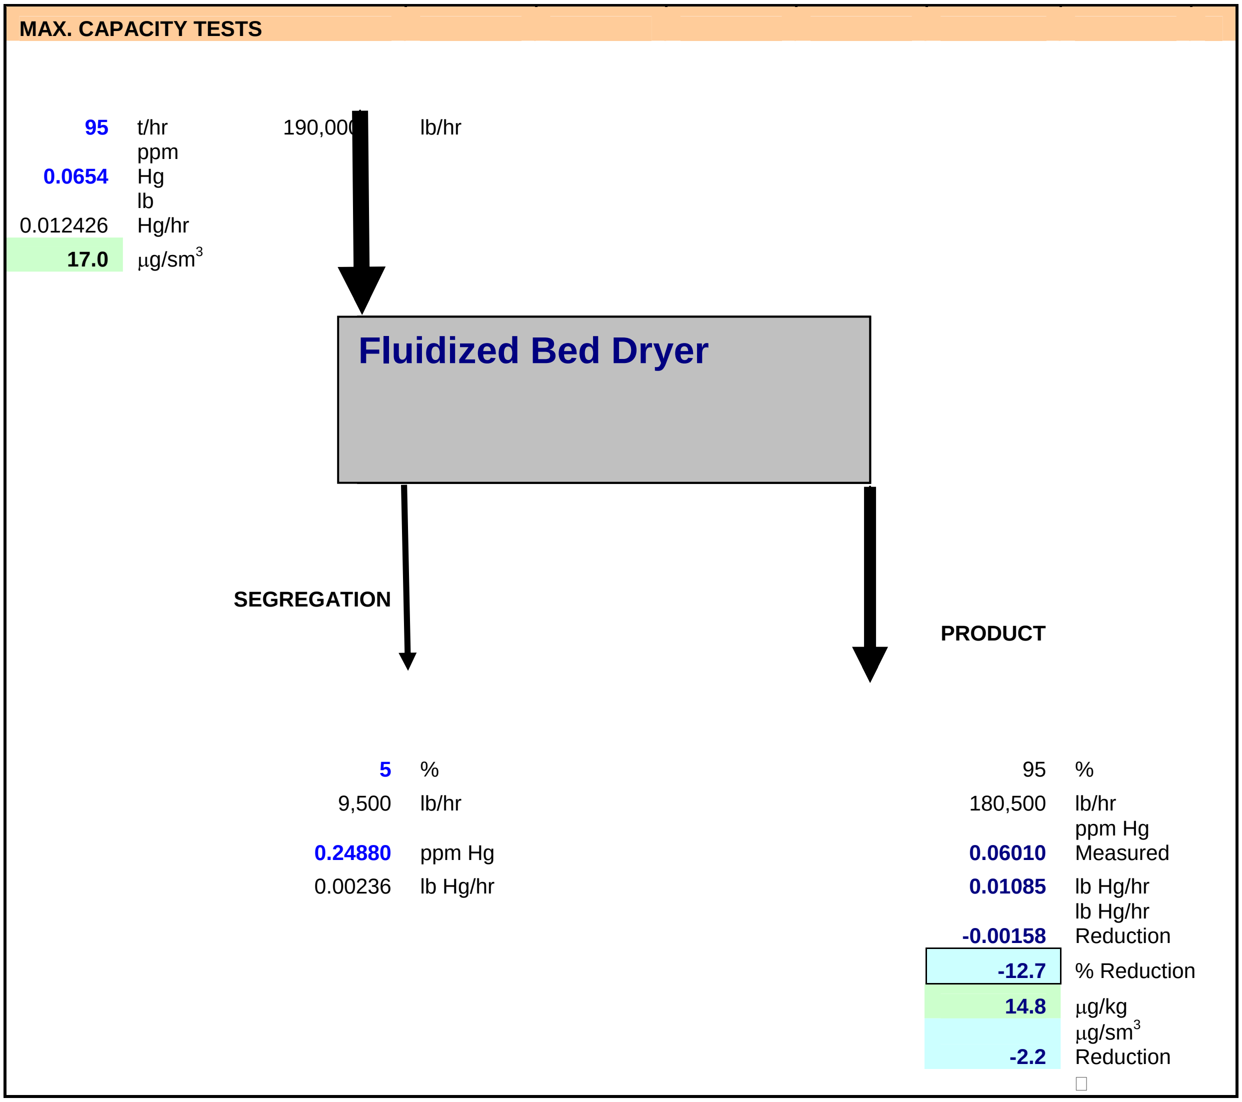

Figure 2-23: Mercury Mass Balance Around FBD – Maximum Capacity Tests

8.4.1: Effect of Flue Gas Moisture on Mercury Speciation

Mercury speciation is, among many other factors, affected by flue gas moisture content and residence time. With the target moisture removal of 8.5 percent, the flue gas moisture content is 2.5 percentage points lower compared to that with wet coal. According to the theoretical gas-phase results in Figure 2-24, this would result in approximately a 20 percent reduction in elemental mercury, Hg^o, in the flue gas [11].

Expressed differently, with a partially dried coal, approximately 20 percent more elemental mercury will be oxidized compared to the wet coal. The oxidized mercury, Hg^{+2}, is water soluble and can be removed in the wet scrubber.

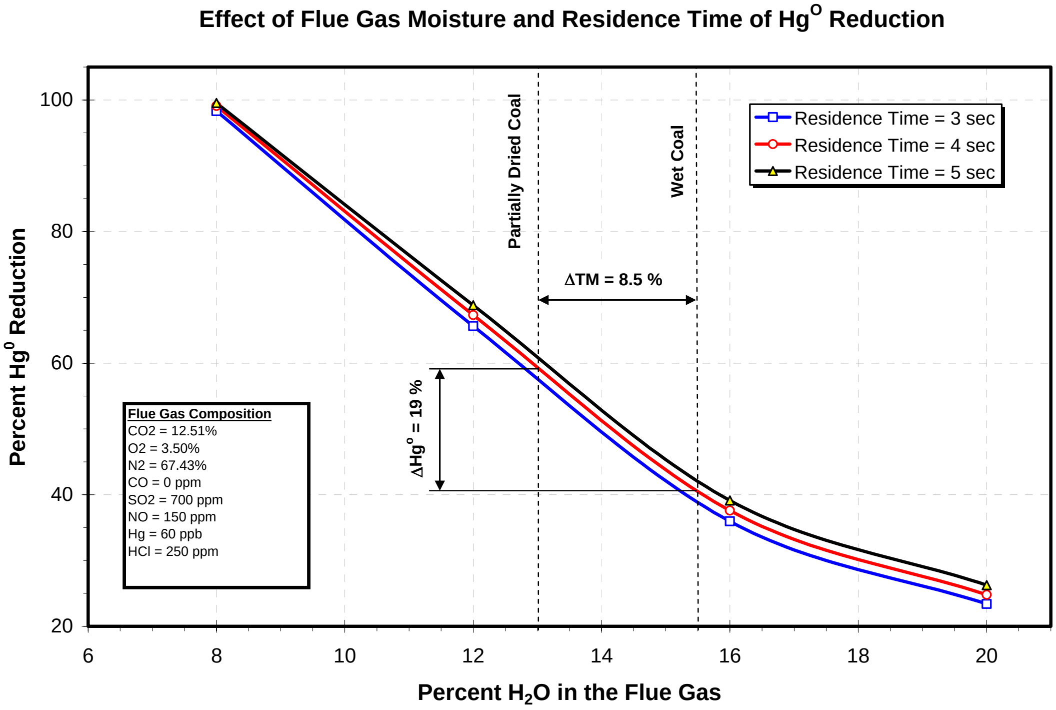

Figure 2-24: Effect of Flue Gas Moisture Content and Residence Time on Mercury Speciation (Theoretical results provided by Dr. Carlos Romero, ERC.)

Also, an increase in residence time has a positive effect on mercury oxidation. This effect is, however, small, of the order of one percent per one second increase in residence time. With a partially dried coal, the residence time will increase due to lower flow rates.

According to [12], the total vapor phase mercury concentration at CCS is in the 15 to 18 $\mu g/Nm^3$ range. This compares favorably to flue gas Hg concentrations calculated from the mercury content in coal and flue gas flow rate, Figures 2-22 and 2-23. Also, according to [12], approximately 65 percent (12 $\mu g/Nm^3$) of the vapor phase mercury at CCS is elemental mercury, Hg^o. Assuming a 20 percent relative reduction in elemental mercury due to lower flue gas moisture content and increased residence time, the reduction in Hg^o in flue gas stream would be 13 percent, or approximately 2.3 $\mu g/Nm^3$, assuming 98 percent Hg removal in the wet scrubber.

By combining a reduction in coal mercury content due to gravitational separation in a fluidized bed coal dryer (13 to 25 percent), and reduction in Hg^o due to the lower flue gas moisture content (13 percent), the total reduction in Hg emissions that could be achieved at CCS with the commercial coal drying system operating at 100 percent capacity, is predicted to be in the 25 to 35 percent range.

Similar to SO_x, reduction in Hg emissions that is achieved by gravitational separation in the coal dryer is very much affected by the accuracy of the measured Hg concentration levels in the feed, segregated, and product streams, and the segregated stream flow rate. The actual reduction in Hg emissions would be determined when the commercial coal drying system at CCS is operating at 100 percent capacity.

9. CONCLUSIONS

A prototype fluidized coal dryer, coal handling, particulate control, and dryer systems were designed, constructed and integrated into Unit 2 at Coal Creek as a Part of Phase 1 of the Lignite Fuel Enhancement project. The project objective was to demonstrate a 5 to 15 percentage point reduction in lignite moisture content by incremental drying using heat rejected from the power plant. Dryer performance was tested at the baseline (75 t/hr) and maximum (100 t/hr) coal feed rates.

The prototype coal drying system at CCS has been in almost continuous fully automatic operation since February 2006. A few minor problems that were easily corrected were encountered. The results obtained in a series of paired performance tests and from regular dryer operation confirm the theoretically predicted dryer performance and unit performance improvement. The achieved reduction in NO_x emissions is larger than expected.

The two-stage design of the dryer, with the first stage acting as a gravitational separator, worked as designed. The segregated stream, discharged from the first stage contained 3 to 3.5 times more sulfur and mercury compared to the product and feed streams. This first stage separation offers a potential for significant reduction in emissions. The segregated stream needs to be further processed to minimize the heat loss, which is proportional to the segregated stream flow rate, and remove additional amounts of sulfur, mercury, and other mineral matter from the dried coal. This will be accomplished in a commercial coal drying system.

In summary, the prototype coal drying system has met and exceeded expectations in terms of performance improvement, emissions reduction, operability, and positive effect on plant operation. It is, therefore, recommended to proceed with the commercial system design, construction, and implementation at CCS.

ERC	Energy Research Center
fg	Flue gas
FBD	Fluidized Bed Dryer
GRE	Great River Energy
h_{fg}	Latent heat of evaporation
Hg	Mercury
Hg^o	Elemental mercury
Hg^{+2}	Oxidized mercury
HHV	Higher heating value of fuel (coal)
HR_{cycle}	Turbine cycle heat rate (inverse of cycle efficiency)
HR_{net}	Net unit heat rate (inverse of unit efficiency)
HT	Heat transfer
HXE	Heat exchanger
ID	Inlet damper
IGV	Inlet guide vanes
M_{air}	Flow rate of air

M_{coal}	Coal flow rate
M_{Dry}	Flow rate of dried coal out of CD26
M_{Fuel}	Fuel flow rate
M_{Total}	Total coal flow rate (wet and dried) to the boiler
M_{Wet}	Flow rate of wet coal to the boiler
MAF	Moisture-and-ash-free
N	Number of independent tests (observations)
NDIC	North Dakota Industrial Commission
Nm^3	Normal cubic meter
NO_x	Nitrous oxide
P	Pressure or power
PA	Primary air
P_G, P_g	Gross unit power output
P_{PA}	PA fan power
P_{ss}	Station service power
Q_1	Heat input to the coal dryer
Q_2	Required heat input to the coal dryer
$Q_{Circulating\ water}$	Heat supplied to the in-bed heat exchanger
$Q_{Coal\ sensitive}$	Sensitive heat input with coal
Q_{air}	Heat input with air stream
Q_{evap}	Fuel moisture evaporation loss
Q_{fuel}, Q_{Fuel}	Heat input with fuel
Q_{loss}	Boiler heat loss
Q_{stack}	Dry gas stack loss
Q_T	Thermal energy transferred to the working fluid in the boiler
$Q_{T,Wet}$	Thermal energy transferred to the working fluid in the boiler – wet coal
$Q_{T,Dry}$	Thermal energy transferred to the working fluid in the boiler – dry coal
RE	Random error (test uncertainty)
S	Best estimate of standard deviation
SA	Secondary air
SO_2	Sulfur dioxide

SO_3	Sulfur trioxide
SO_x	SO_2 and SO_3
t	Student (W. Gosset) variable
T_{coil}	Surface temperature of the in-bed heat exchanger
$T_{coil,avg}$	Average surface temperature of the in-bed heat exchanger
$T_{FA,in}$	Temperature of fluidization air into the coal dryer
TM	Total coal moisture (moisture in coal and coal ash)
VSD	Variable speed drive
WC	Wet coal
X_{Blend}	Composition or HHV of blended coal
X_{Dry}	Composition or HHV of dried coal out of CD26
X_{Wet}	Composition or HHV of wet coal to the boiler
σ	Standard deviation
η_B	Boiler efficiency
Δ	Difference or change
ΔHR_{net}	Change in net unit heat rate
ΔP	Differential pressure or pressure loss
$\Delta\eta_B$	Change in boiler efficiency
$\Delta\eta_{B,TOT}$	Total change in boiler efficiency

Response to question about ammonia in fly ash

Currently Coal Creek Station fly ash is highly desirable due to the physical and chemical characteristics which enable it to create high quality concrete. The ASTM standard states the purchaser shall specify any supplementary optional physical requirements. Due to the odoriferous nature of ammoniated ash it is a characteristic likely to be limited in purchase orders. Ash with high levels of ammonia is less desirable by concrete manufacturers due to the strong odor released from the ammoniated ash. Ammonia release from ash impacts ambient air quality and indoor air quality or presents a direct exposure hazard. Fly ash will emit ammonia as the ash is transferred, transported or mixed and concrete will emit ammonia – as the ammonia "off-gases" or volatilizes when the fly ash is transferred, transported, or mixed for concrete. Tests conducted under DOE funding suggest that the ammonia loss in concrete occurs in two phases: first a rapid initial release within 24 hrs.; then a slower linear release rate – which occurred throughout the 3 week test period. Based on the measurements and calculations it was determined that over 80% of the ammonia remained in the concrete at the conclusion of the test period. This leaves a potential for ammonia release during future rainfall events when the water volatilizes the ammonia. This could be very hazardous in occupied spaces. [See the exposure description below.] The study does not encourage the use of ammoniated ash, but recommends that ammonia concentration in fly ash be kept below 100 mg/kg for concrete used in enclosed spaces and below 200 mg/kg for concrete used in other applications.

Ammonia is considered a toxic air pollutant by the environmental and health regulatory agencies in North Dakota, Minnesota, and other surrounding states for which the ammoniated ash would be handled and processed. In North Dakota, the Department of Health's Air Toxics Policy establishes acute health risk standards. The ambient ammonia concentration thresholds are 0.49 mg/m^3 (0.66 ppm) on a 1-hour average and 0.35 mg/m^3 (0.47 ppm) on an 8-hour average. Any concentration above these levels would exceed the State's acceptable level of non-carcinogenic risk.

Ammonia is considered an upper respiratory irritant for inhalation health effects. The EPA's Integrated Risk Information System (IRIS) has a reference concentration (RfC) of 0.1 mg/m^3 (0.14 ppm) for acute exposure to ammonia, and the Occupational Safety and Health Administration (OSHA) has set an 8-hour exposure limit of 25 ppm and a 15-minute exposure limit of 35 ppm.

A majority of the Coal Creek Station market resides in the upper Midwest. Fly ash created during the off season for construction is either used in internal enclosed applications or is stored (e.g. pre-cast concrete blocks or panels). The storage and transfer of ammoniated ash in enclosed facilities could have the potential to produce high concentrations of ammonia in the occupied buildings. In an example from an Electric Power Research Institute paper, if the assumption is made that fly ash contains 100 ppm by weight of ammonia, then one ton of fly ash, evolving all of the ammonia present, can produce 90,000 cubic feet of air (at 68 F, 1 atm) that contains 50 ppmv of ammonia (the upper odor threshold). When given the option concrete manufacturers will purchase a non ammoniated ash over the ammoniated ash due to the odor produced when mixing and pouring the concrete.

In addition to the stated health risk criteria, ammonia is a highly odoriferous compound that is regulated by many localities and states, including in North Dakota (see NDCC 23-25-11). Of particular concern is the risk of odors that disperse to nearby locations off-site from Coal Creek Station. Blue Flint Ethanol is located next to Coal Creek Station, and their property is located 850 feet from the fly ash dome and related ash handling activities. Volatilized ammonia represents an odor and health concern at areas proximate to the plant and at endpoint locations where the ash/cement is used. These risks would need to be better understood and addressed before the ash, as modified, is beneficially used for high quality concrete rather than go to a landfill or other disposition.

Subject: Additional Information on Ammonia in Fly Ash

Lew,

Great River Energy respectfully submits the following text in response to your request for additional information on the concentration of ammonia in fly ash during the August 21, 2008 conference call. A review of the papers and studies completed on ammoniated ash from two of the top electric power research organizations in the US (EPRI and UND-EERC) found that very little if any work has been completed to date with respect to lignite coal combustion and SCR or SNCR NO_X control equipment. GRE made direct requests of individuals in charge of research in this area. Several studies have been conducted but at least one was inconclusive for lignite fly ash. The SCR catalyst research included in the original Coal Creek Station BART analysis in Appendix G had conclusive information about SCR use with lignite coal combustion but only evaluated the performance of the SCR catalyst and mercury ionization. It did not include an analysis of the ammonia in the ash. One other study by EERC was evaluating the leaching of specific constituents in ammoniated fly ash but the results were not conclusive for ND lignite since the method used to ammoniate the fly ash was unsuccessful. Additional studies were not discovered. Predicting the ammonia in ash is extremely difficult due to the many factors influencing the adsorption and deposition of ammonia in fly ash. Some of the factors include coal processing – fineness, coal heating value, ash mineral composition, ammonia slip, and other boiler settings responsible for influencing the formation of SO_3 in the flue gas. For example, SO_3 production promotes the formation of ammonium sulfates driving the ammonia toward fly ash deposition; therefore any plant operating conditions which influence SO_3 production would also influence the adsorption and deposition of ammonia in fly ash. Each of these physical and combustion characteristics is very different between the various ranks of coals. One study illustrated the variability of ammonia adsorption throughout an ESP with concentrations ranging from 51 ppm_w to 740 ppm_w. (This test used a 4 ppm_w injection rate for ammonia and also has SO_3 injection.) The same study also found the ammonia concentration variability within an ESP to range from 3 ppm_w to 30 ppm_w from another SCR controlled unit. Both tests were conducted at facilities burning eastern bituminous coal. This specific example illustrates the site specific qualities associated with ammonia injection pollution control technology.

If you require further information please feel free to give me a call. Thank you.

ENVIRONMENTAL & COAL TECHNOLOGY

PROJECT FACTS

UNIVERSITY OF KENTUCKY
CENTER FOR APPLIED ENERGY RESEARCH

AMMONIATED FLY ASH

Objective

The goal of this project was to develop practical guidelines for handling and using ammoniated fly ash in concrete, in order to prevent a decrease in the use of fly ash for this application. The objective was to determine the amount of ammonia that is released, over the short- and long-term, from concrete that contains ammoniated fly ash.

Background

The Clean Air Act Amendments of 1990 require large reductions in NO_x emissions from coal-fired electric utility boilers. This will require ammonia injection, such as in selective catalytic reduction (SCR), in many power plants, resulting in ammonia deposition on fly ash. The presence of ammonia could create a barrier to fly ash utilization in concrete because of odor concerns. Although there have been limited studies of ammonia emission from concrete, little is known about the quantity of ammonia emitted during mixing and curing, and the kinetics of ammonia release. This is manifested as widely varying opinions within the concrete and ash marketing industry regarding the maximum acceptable levels of ammonia in fly ash. Therefore, practical guidelines for using ammoniated fly ash are needed in advance of the installation of many more SCR systems.

Conclusion

Ammonia release from mortar and concrete during mixing, placement, and curing was measured. Short-term levels in the air were found to be noticeable; however longterm effects were minimal. Work initially focused on laboratory mortar experiments to develop fundamental data on ammonia diffusion characteristics. Larger-scale laboratory experiments were then conducted to study ammonia emission from concrete containing ammoniated fly ash. The final phase comprised monitoring ammonia emissions from large concrete slabs. The data indicated that only 10 - 20% of the initial ammonia diffused from the concrete during 30-40 minutes of mixing, depending on the mix proportions and batch size. When placing concrete in an enclosed space, with negligible ventilation, it is recommended that the ammonia concentration in the concrete mix water should not exceed 110 mg NH_3/L, if the NIOSH exposure limit of 25 ppm in the air is not to be exceeded. If even a modicum of ventilation is present, then the maximum ammonia concentration in the concrete water would be approximately 170 mg/L. Long-term experiments indicated that ammonia diffusion from concrete was relatively slow, with greater than 50% of the initial ammonia content remaining in a concrete slab after 1 month. In general, during the mixing and placement of ammonia-laden concrete, no safety concerns were encountered. After one to two days, the ammonia level decreases to a point where it cannot be smelled. The only location where the ammonia concentration attained high levels (i.e. > 25 ppm in the air) was within the concrete mixing drum.

These findings are being distributed throughout the industry. The other project participants represent some of the country's largest ash marketers and a major utility; and will include these recommendations during interactions with cement companies. It is further hoped that the information will be used to adopt standards for use of ammoniated fly ash.

GREAT RIVER
ENERGY℠

February 9, 2010

Lewis Dendy
North Dakota Department of Health
Division of Air Quality
918 East Divide Avenue, 2nd Floor
Bismarck, ND 58501-1947

Dear Lew,

Great River Energy (GRE) respectfully submits our response to questions raised by US EPA concerning ammonia in fly ash relevant to our Coal Creek Station (CCS). To address the issues raised by Amy Platt of US EPA in a November 30, 2009 email message to Tom Bachman of NDDH, GRE provides the following responses:

1. Response to Amy Platt's email
2. Fly Ash usage and properties

Response to Amy Platt's email

Amy Platt's email references Dynegy's Baldwin Energy Complex and Progress Energy's Roxboro Generating Station as facilities that have post combustion NOx control and market their fly ash. Both facilities have Selective Catalytic Reduction (SCR) installed, not Selective Non-Catalytic Reduction (SNCR) technology. It is typical for SCR technology to operate with lower ammonia injection and slippage rates than comparable SNCR technology. With SCR technology additional mixing and chemical reaction assistance is introduced in the catalyst packing resulting in reduction in NOx emissions. SNCR technologies require additional ammonia injection to ensure contact with the NO_X molecules in the flue gas, as they do not benefit from additional mixing or the benefit of enhanced chemical reactions provided by the catalyst packing. Headwaters Resources, GRE's fly ash marketer, on average sees ammonia content in ash from 200-600 ppm for SNCR units and from 50-400 ppm for SCR units. *See Attachment 3 section.*

Dynegy's 1,800 MW Baldwin Energy Complex has 3 units burning Powder River Basin (PRB) coal. Two of the units have SCR installed, the third unit has no post-combustion NO_X control technology. Headwaters Resources, GRE's fly ash marketer, is also the ash marketer for the Baldwin Energy Complex. Headwaters only markets ash from the one pulverized coal unit that does not have either SCR or SNCR installed and therefore the ash sold does not contain ammonia. Please see attached letter from Herbert Moeckel of Headwaters Resources. *In Attachments 1 section*.

Currently there are no installations of SCR or SNCR burning North Dakota Fort Union lignite. As GRE does not have any data or experience with ammoniated ash we have asked our fly ash marketer, Headwaters Resources, to respond to Amy Platt's chemistry statement that alkaline ashes experience lower uptake of ammonia. Headwaters has extensive experience with ammoniated ash and they have observed higher ammonia odor emissions from a plant (East Lake Plant, OH) producing a higher alkaline ash. The mechanism for this higher evolution of ammonia has not been identified and is currently being investigated. *See email thread of December 29, 2009-in Attachment 2 section.* Without empirical evidence on uptake of ammonia on ash from ND lignite GRE cannot assume ammonia slippage rates or retention rates on fly ash. We have also presented the question about expected ammonia in ash for lignite units to Tony Facchiano, Sr. Program Manager at the Electric Power Research Institute (EPRI) and although they have done work for other types of coal they have not conducted research with ND lignite and would not be able to correlate the ammonia in ash with ammonia slip at this time.

As there are no data from Fort Union lignite on SNCR ammonia retention in ash we have provided testimony from GRE customers. As noted by our customers, ammonia-impregnated ash would have an economic impact not only on GRE but also to our marketers who sell the ash. *See enclosures from Lafarge and GCC of America in the Attachment 1 section.*

Fly Ash

Fly ash for use in concrete is classified in 3 classes: Class N – raw or calcined natural pozzolans that comply with ASTM C618-08; Class F - typically produced from burning anthracite or bituminous coal, but lignite also; Class C – typically produced from burning lignite's, but may also be produced from burning anthracite or bituminous coal as long as the total calcium contents are higher than 10% and the ash has some cementitious properties. CCS ash is classified as a Class F ash. Introduction of ammonia will not affect the class of our fly ash but will decrease the desirability and thus the marketability of our ash if the customer perceives a health risk or is able to procure the same material without the objectionable qualities.

The original investments made in the infrastructure for the marketing of fly ash was predicated on the fact that CCS is a mine mouth plant with a consistent coal source which is producing a high quality fly ash which is very desirable in the concrete market. The introduction of undesirable characteristics into the fly ash, such as an odor or inhalation risk, will force our concrete customers to pursue alternate marketers for their feedstock. *See testimonials from Headwaters Resouces, Lafarge, and GCC in the Attachments 1 section.*

Please contact me at 763-445-5208 regarding any questions or comments.

Sincerely,

GREAT RIVER ENERGY

Adding Value to Energy

January 28, 2010

Mr. Al Christianson
Manager, North Dakota Business
Development & Governmental Affairs
1611 East Century Avenue
Suite 200
Bismarck, ND 58503

Dear Mr. Christianson:

I am writing in regards to the Dynegy Midwest Generation – Baldwin Energy Complex located in Baldwin, Illinois. Headwaters Resources is the marketing company for all five Dynegy Midwest Generation plants located in Illinois.

The Baldwin Energy Complex is composed of three – 600 MW units, totaling 1800 MW. Units 1 and 2 are cyclone fired boilers and Unit 3 is a pulverized coal boiler, all three units are burning PRB coal. Units 1 and 2 are equipped / operating with an SCR and Unit 3 has neither a SCR or SNCR installed.

Headwaters Resources has mainly marketed the cyclone boiler fly ash produced from Units 1 and 2 into the cement industry as a raw feed ingredient since 1998. Since 2000, we were able to market approximately 17,000 tons of this material into "flowable fill" on a few mine subsidence projects in the East St. Louis, Illinois area. We have performed ammonia testing on the fly ash produced from Unit 1 and 2 utilizing the Headwaters SOP using dragger tubes. This material fluctuates between 35 and 125 ppm ammonia in the fly ash. The ammonia odor was noticeable when used on the flowable fill mixes which contained high volumes of fly ash per yard. The ammonia odor did not have an impact on our sales agreement with Buzzi Unicem, since they were using the material as a raw feed ingredient in the production of cement. Starting in July 2009 new mercury regulation forced the power stations in Illinois to use activated carbon injection to reduce mercury emissions. Units 1 and 2 did begin activated carbon injection in July 2009 at which time the material was no longer allowed to be used in the production of cement. At this time 100% of the fly ash material produced from these units is being disposed of in an on site impoundment. Dynegy is constructing SDA scrubbers which should be complete by 2013, at which time the injection point of the activated carbon will be moved allowing the use of the fly ash material in cement production. The fly ash produced from these two units is not suitable for use in concrete.

Unit 3 at the Baldwin Energy Complex was granted a temporary variance which did not force this unit to inject activated carbon until the SDA / Bag house is operational at the end of 2010. Headwaters Resources has marketed the ASTM C618 Class C fly ash produced from unit 3 into ready mix concrete, concrete paving, and soil stabilization since 1998.

Please feel free to contact me at 612-963-7093 regarding any questions or comments.

Al,

We would like to take this opportunity to express concern about GRE's potential injection of ammonia into the flue gas during coal burning operations as an effort to reduce NOx emissions. As a wholesale marketer and end-user of your fly ash from the Coal Creek facility in North Dakota, our concern surrounds the impact this process will have on the fly ash when used in concrete.

The ammonia in fly ash is not present as ammonia gas. Rather, it is in the fly ash as ammonium sulfate. Once in the high alkaline environment of concrete the ammonia is released. This becomes a problem because of the odor, especially in enclosed spaces such as residential basements. The smell of ammonia is objectionable and would potentially impact external fly ash sales for GCC of America and internal use in the concrete operations owned by GCC Ready Mix..

Our professional experience with this situation in the past had been limited to the senses, i.e. eye and nose irritation and unpleasant odor. The corrective action taken was at the expense of the concrete producer, causing those customers to do business elsewhere.

We value our relationship with your company and prefer to use your product because of its quality and performance. Please do not allow these attributes to be compromised. If you should have any questions, or if we may be of further assistance, please contact either of us our Denver offices at (303) 739-5900.

Adding Value to Energy™

January 11, 2010

Mr. Al Christianson
Manager, North Dakota Business
Development & Governmental Affairs
1611 East Century Avenue
Suite 200
Bismarck, ND 58503

Dear Mr. Christianson:

The Eastlake power plant in Eastlake, Ohio had a SNCR installed over 2 years ago. Prior to the installation the plant produced a high quality F-ash which was sold out every year during the construction season. The ammonia level was between 200-400 PPM after the installation which was when the problems started. Anything over 100 PPM seemed to be a noticeable at this plant.

We started shipping the material when it was in the 100-200 PPM range and the customers, batch plants and several contractors started calling with complaints especially in confined spaces such as buildings and basements. In one case a Ready Mix plant employee stuck his head in the back of the truck to add air entraining agent and it burned his eyes. He spent the night in the emergency room getting his eyes washed out not knowing it was the fly ash causing the ammonia smell.

We quit shipping anything over 100 PPM and business started dropping off; contractors did not want fly ash in their mixes. Since you're only checking a small amount of ammonia in the load it would test for less than 100 PPM but in some cases the Ready Mix producer still had problems which indicated the entire load was not less than 100 PPM. We shut down a block plant and the customer made us take the fly ash out of his silo and he quit buying fly ash from us.

Subject: Ammonia Injection in Fly Ash

Lafarge has used fly ash from power sources where SNCR ammonia injection units have been installed. We have found that when the ammonia levels exceed 40 parts per million in the fly ash that the consumer notices the ammonia and find it to be objectionable.

Lafarge is concerned that if ammonia injection units are installed at Great River Energy's Coal Creek Station it may cause the fly ash that is produced to be unmarketable. Lafarge currently purchases a large percentage of the fly ash that is produced at this station and would be placed at an economic disadvantage if we were no longer able to market this high quality ash to our ready mix customers.

This would cause our customers in turn to be at an economic disadvantage if they had to use fly ash from another source that is further away or use slag cement that perhaps would be more expensive than Coal Creek ash.

Al: Attached is Bruce's response to your latest inquiry. It appears that we are still waiting on Mr. O'Conner (EPRI) to review our data on Sammis and East Lake ash. The attached brochure from STI may be helpful in the comparison of SNCRs and SCRs in regard to ammonia being introduced into the ash. I don't know if this is sufficient for your needs. If not, I suggest that we (Diane, you, and I) get on a conference call with Bruce to discuss what else we may be able to provide. Just let me know. Thanks.

Subject: RE: Where are we at?

Jerry,

There was no official document generated by EPRI to circulate on this issue. The curious finding that the more alkaline ashes had higher ammonia odor emissions was reported to EPRI but the reason for the finding was never identified. Dave O'Connor at EPRI will review our data showing the data on Sammis and East Lake comparisons.
The data from our East Lake plant with SNCR and higher alkaline ash should be available shortly to compare with the much lower levels of ammonia from an SNCR associated with low alkalinity ash at Sammis.

STI found it necessary to develop an ammonia removal/treatment system in addition to the carbon removal system they operate at several locations. I do not know if the Roxboro plant uses this system but I would point out that with the storage dome at Coal Creek, the ammonia levels that could accumulate would be extremely hazardous. A little know fact is that ammonia is an explosive gas at certain levels when it accumulates with air present. See attached STI brochure on ammonia removal. In that brochure they support the fact that SNCR units will introduce much more ammonia to the ash than SCRs but both can prevent ash from being used in the market.

Executive Summary

This report describes the background and methods for the selection of the Best Available Retrofit Technology (BART) as proposed by Great River Energy (GRE) for the Stanton Station located in Stanton, ND. Stanton Station's BART eligible Unit 1 is a front-wall fired boiler that started operation in 1966. The boiler is currently permitted to burn both Lignite and Powder River Basin (PRB) coal. Stanton Station has one turbine with a capacity of up to 188 megawatts. Preliminary visibility modeling conducted by the North Dakota Department of Health (NDDH) found that the Stanton Station emissions 'cause or contribute to visibility impairment' in a federally protected Class 1 area, therefore making the facility subject to BART.

Guidelines included in 40 CFR §51 Appendix Y were used to determine BART for Unit 1. The existing pollution control equipment includes an ESP for particulate matter and low NOx burners (LNB) for NOx control. The CALMET/CALPUFF/CALBART dispersion modeling sequence was used to assess the post-BART visibility impacts associated with the proposed BART emission limits.

Stanton Station is currently permitted to burn either Lignite or Powder River Basin (PRB) coal. The BART analysis was originally premised on Lignite as a worse case fuel. At the request of NDDH, GRE includes PRB as an operational control that is evaluated in conjunction with traditional controls. Great River Energy intends to burn a single fuel on an annual basis. Therefore, the BART controls and corresponding emission rates are determined to be fuel specific without consideration for blending. Based on the results of visibility modeling, economic impacts analyses and consideration for other non-air quality energy and environmental factors, GRE establishes the following as BART:

- For Particulate matter (PM), the BART emission limit is 0.1 lb/MMBtu based upon the existing ESP. Additional PM controls, including condensable PM (CPM) controls, would provide insignificant visibility improvement and require significant capital expenditures. Therefore, the current PM performance standard of 0.1 lb/MMBtu is considered BART for either Lignite or PRB.

- Overfire air (OFA) and Low NOx Burners (LNB) is considered BART to control NOx with a proposed 30-day rolling emission rate of 0.35 lb/MMBtu under normal operational conditions on either fuel.

- SO_2 emissions will be reduced using a non-specific dry scrubbing technology. The scrubber is being designed to achieve 90% removal with a proposed BART limit of 0.24 lb/MMBtu on a 30-day rolling basis for Lignite fuel. Stanton Station is also permitted to burn Powder River Basin (PRB) coal, which is currently a lower sulfur fuel. As discussed in Section 5, Dry Sorbent Injection (DSI) with the existing ESP is considered BART for PRB with a corresponding 30-day rolling emission rate of 0.36 lb/MMBtu.

BART Emission Limits

Pollutant	Existing Permit Limit	BART Limit
PM_{10}	0.10 lb/MMBtu	0.10 lb/MMBtu
NOx	0.46 lb/MMBtu	0.35 lb/MMBtu
SO_2 Lignite	3.0 lb/MMBtu	0.24 lb/MMBtu
SO_2 PRB	3.0 lb/MMBtu	0.36 lb/MMBtu

The proposed BART controls will result in visibility improvements of 60% to 70% for both the 90th and 98th percentile comparisons. According to Pre-BART modeling, Unit 1 is estimated to contribute 1.675 Δ-dV to background at Theodore Roosevelt National Park's (TRNP) South unit in the year 2002, which is the worst case meteorological conditions of the baseline years, with 29 days above 0.5 Δ-dV. Modeling with the proposed BART controls for TRNP South shows an improvement of 1.0 Δ-dV, or a contribution of only 0.666 Δ-dV above background, with 13 days above 0.5 Δ-dV. These reductions represent a significant improvement to assist the state in meeting its reasonable progress goals.

Additional Considerations and Associated Potential Reductions

Great River Energy is evaluating other generation options at Stanton Station including the installation of a new clean coal technology (i.e., integrated gasification combined cycle (IGCC) system capable of carbon capture and sequestration (CCS). If installed, IGCC would allow for either early Unit 1 retirement or significantly reduced utilization while IGCC is brought on-line. The current BART economic evaluations assume at least 20 years of capital depreciation levelized across projected pollution reductions. Clearly, Unit 1 early retirement would completely affect the BART cost effectiveness determinations contained in this evaluation.

Based on our conversations with the NDDH staff on October 31, 2007, the installation of a 'clean coal technology' will require additional air permitting in which proposed BART controls could be re-evaluated in light of lesser Unit 1 utilization. Obviously, Unit 1 retirement in support of a 'clean coal technology' would need to provide comparable, if not greater, visibility improvements. Great River Energy will need to commit to either the IGCC technology or spray dry baghouse technology well in advance of applicable BART requirements in 2013.

If Great River Energy does not pursue a clean coal alternative generation project, the spray dry baghouse will be installed to cover the range of fuels permitted at Stanton at $79 million in 2005 dollars. Even though BART is considered DSI with existing ESP for PRB, Great River Energy would offer additional reductions with construction of the spray dry baghouse and comply with 0.15 lb/MMBtu SO_2 emission limit on a 30-day rolling basis for PRB. This emission rate is inclusive of both the expected dry scrubbing effectiveness with baghouse and the PRB sulfur ranges discussed in Appendix E. Further, with respect to PM emissions based on installation of a baghouse, Great River Energy would offer additional reductions, and comply with a 0.07 lb/MMBtu or 0.05 lb/MMBtu emission rate, for Lignite and PRB, respectively. These additional particulate reductions incorporate the relative ash differences between the fuels and additional particulate control provided by the baghouse.

Stanton Station Unit 1- Additional Reductions to Support Visibility Improvements

Pollutant	Permit Limit	Alternative Lower Limit
PM_{10} Lignite	0.10 lb/MMBtu	0.07 lb/MMBtu
PM_{10} PRB		0.05 lb/MMBtu
NOx	0.46 lb/MMBtu	0.35 lb/MMBtu
SO_2 Lignite	3.0 lb/MMBtu	0.24 lb/MMBtu
SO_2 PRB	3.0 lb/MMBtu	0.15 lb/MMBtu

For reasonable glide path modeling, NDDH can choose to use the higher values between projected PRB and Lignite emission rates rather than the BART emission rates. For PM, this would mean a 0.07 lb/MMBtu emission rate based on lignite. The additional PM reduction does not provide a significant modeled improvement as discussed in Section 7. For SO_2, the modeling value is 0.29 lb/MMBtu, which is based upon the 30-rolling limit of 0.24 lb/MMBtu, as a worse case, 24-hr maximum value. For NOx, there is no proposed difference between BART controls for the permitted fuels at a 30 day rolling emission rate of 0.35 lb/MMBtu. Consequently, the modeled value is 665.3 lb/hr as a 24-hr maximum. The most favorable combined effect of all proposed additional reductions results in an average incremental improvement of only ~ 0.1 dV.

1.0 Introduction

On July 15, 2005, the U.S. Environmental Protection Agency (EPA) published the final rules for regional haze and best available retrofit technology (BART). The BART rules[1], originally promulgated in September 1999, were in effect as of September 6, 2005.

The rules require that each state develop a Regional-Haze State Implementation Plan (RH SIP) to improve visibility impairment in federally-protected national parks and wilderness areas (Class I areas). The SIP must require BART on all BART-eligible sources and mandate a plan to achieve natural background visibility by 2064. Figure 1-1 illustrates the 6 BART eligible units and 4 Class 1 areas in North Dakota. Each state must submit an RH SIP by December 17, 2007 that includes milestones for establishing reasonable progress towards the visibility improvement goals, and plans for the first five-year period. Upon submission of the SIP, states must make the requirements for BART sources enforceable through rules, administrative orders or Title V permit amendments.

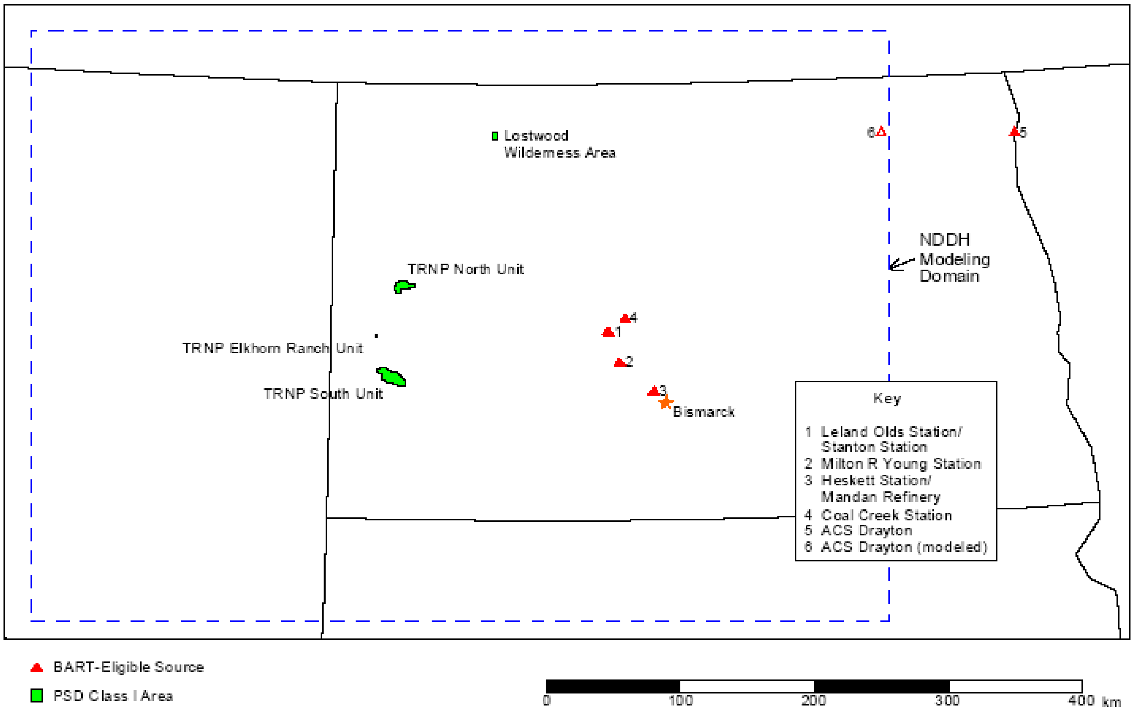

Figure 1-1 North Dakota's BART Geography: The North Dakota SIP will address the 4 PSD Class I Areas and 6 BART Eligible Units illustrated above. (Source *Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota, Final version)*

---

[1] 40 CFR §51 and Clean Air Act §169A and 169B

By definition, reasonable progress means that the 20 best-visibility days must get no worse, and the 20 worst-visibility days must become as good as the 20 worst days under natural conditions. Assuming a uniform rate of progress, the default glide path, as illustrated in Figure 1-2, would require 1 to 2 percent improvement per year in visibility on the 20 worst days. The state must submit progress reports every five years to establish their advancement toward the Class 1 area natural visibility backgrounds. If a state feels it may be unable to adopt the default glide path, a slower rate of improvement may be proposed on the basis of cost or time required for compliance and non-air quality impacts.

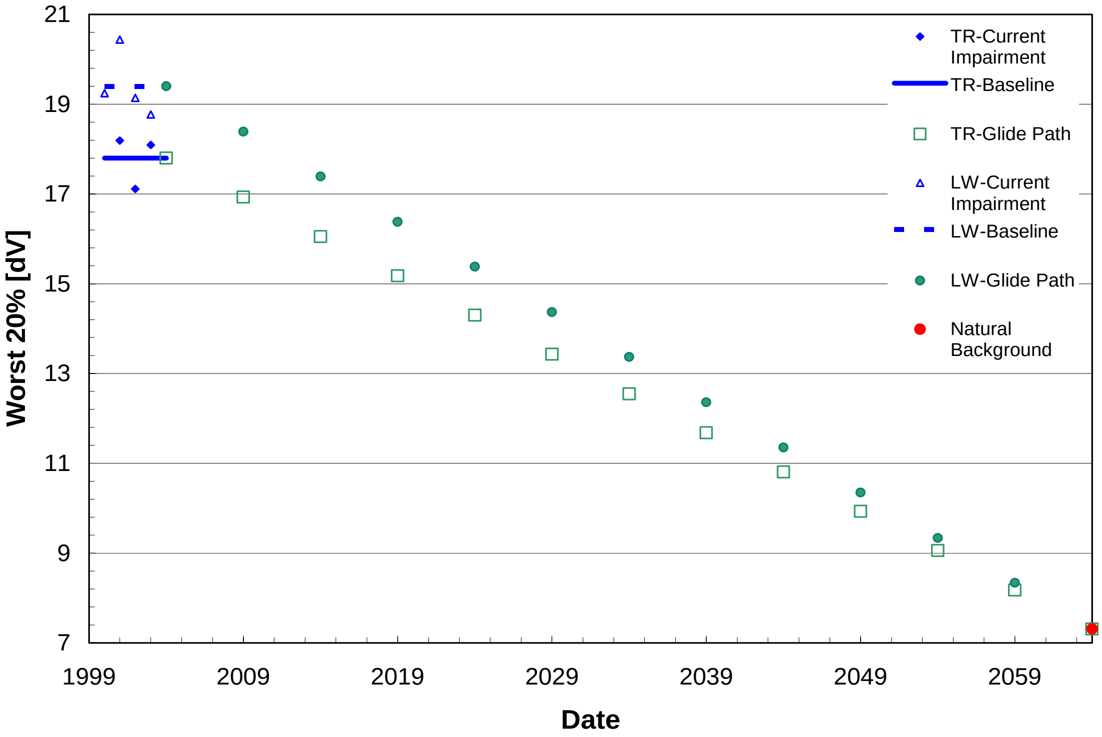

Figure 1-2 Theodore Roosevelt NP and Lostwood WA, ND. Current impairment includes both natural and anthropogenic contributions. (Data from VIEWS database trend analyzer, http://vista.cira.colostate.edu/views/web/AnnualSummaryDev/Trends.aspx DOA 06 Dec 2005)

1.1 BART Eligibility

BART eligibility is established on the basis on 3 criteria. In order to be BART eligible, sources must meet the following three conditions:

1. Contain emission units in one or more of the 26 listed source categories under the PSD rules (e.g., fossil-fuel-fired steam electric plants larger than 250 MMBtu/hr, fossil-fuel boilers larger than 250 MMBtu/hr, petroleum refineries, coal cleaning plants, sulfur recovery plants, etc.)
2. Were in existence on August 7, 1977, but were not in operation before August 7, 1962

3. Have total potential emissions from the emission units meeting the two criteria above greater than 250 tons per year for at least one visibility-impairing pollutant

Under the BART rules, large sources that have previously installed pollution-control equipment required under another standard (e.g., MACT, NSPS and BACT) will be required to conduct visibility analyses. Installation of additional controls may be required to further reduce emissions of visibility impairing pollutants such as PM, PM_{10}, $PM_{2.5}$, SO_2, NOx, and possibly VOCs and ammonia. Sources built before the implementation of the Clean Air Act (CAA), which had previously been grandfathered, may also have to conduct such analyses and possibly install controls, even though they have been exempted to date from any other CAA requirements.

Once BART eligibility is determined, a source must then determine if it is ‘subject to BART.’ A source is subject to BART if emissions ‘cause or contribute’ to visibility impairment at any Class I area. Visibility modeling conducted with CALPUFF or another EPA-approved visibility model is necessary to make a definitive visibility impairment determination (>0.5 deciviews). Sources that do not cause or contribute to visibility impairment are exempt from BART requirements, even if they are BART-eligible.

1.2 BART Determinations

Each source that is subject to BART must determine BART on a case-by-case basis. Even if a source was previously part of a group BART determination, individual BART determinations must be made for each source. The BART analysis takes into account six criteria and is analyzed using five steps. The six criteria that comprise the engineering analysis include: the availability of the control technology, existing controls at a facility, the cost of compliance, the remaining useful life of a source, the energy and non-air quality environmental impacts of the technology, and the visibility impacts.[2] The five steps of a BART analysis are:

Step 1 - Identify all Control Technologies
The first step in the analysis is to identify all available retrofit control technologies for each applicable emission unit.

Step 2 - Eliminate Technically Infeasible Options
In the second step, the technical feasibility of each control option identified in step one is evaluated with respect to source-specific factors. Technically infeasible technologies are eliminated from further consideration.

Step 3 - Evaluate Control Effectiveness
In step three, the remaining controls are ranked based on the control efficiency at the expected emission rate (post BART) as compared to the

---

[2] 40 CFR 51 Appendix Y

emission rate before addition of controls (pre-BART) for the pollutant of concern.

Step 4 - *Evaluate Impacts and Document Results*
In the forth step, an engineering analysis documents the impacts of each remaining control technology option. The economic analysis compares dollar per ton of pollutant removed for each technology. In addition it includes incremental dollar per ton cost analysis to illustrate the economic effectiveness of one technology in relation to the others. Finally, Step Four includes an assessment of energy impacts and other non-air quality environmental impacts.

Economic impacts were analyzed using the procedures found in the EPA Air Pollution Control Cost Manual-Sixth Edition (EPA 452/B-02-001). Vendor cost estimates for this project were used when applicable. Equipment cost estimates from the EPA Control Cost Manual or EPA's Air Compliance Advisor (ACA) Air Pollution Control Technology Evaluation Model version 7.5 were used if no vendor data were available. The source of the control equipment cost data are noted in each of the control cost analysis worksheets as found in Appendix A.

Step 5 - *Evaluate Visibility Impacts*
The fifth step requires a modeling analysis conducted with EPA-approved models such as CALPUFF. The modeling protocol[3], including receptor grid, meteorological data, and other factors used for this part of the analysis were provided by the North Dakota Department of Health. The model outputs, including 98th and 90th percentile visibility impairment days are used to establish the degree of improvement that can be reasonably attributed to each technology.

The established BART for Unit 1 was selected based on the results of information obtained in Steps 4 and 5.

---

[3] *Protocol for BART-Related Visibility Modeling Analyses in North Dakota*, Final Version, November, 2005.

2.0 Stanton Station BART Determination

As defined by federal guidance and Section 33-25-25-01 of North Dakota's Air Pollution Control Rules, a source "causes or contributes to visibility impairment" if the 98th percentile of any year's modeling results meets or exceeds the threshold of five-tenths of a deciview (dV) at a Class I area receptor. The pre-BART modeled emission rates for eligible sources represent the highest 24-hour average emissions from the years 2000 through 2002. Pre-BART evaluations conducted by the North Dakota Department of Health using the CALPUFF[3] visibility model identified 6 'subject to BART' sources, including Stanton Station, that cause or contribute to visibility impairment in North Dakota.

Using a streamline method for BART determination, BART eligible sources at Stanton Station can be divided into groups based on function, utilization and actual emissions.

2.1 BART Eligible Units

Great River Energy's (GRE) Stanton Station is located on the bank of the Missouri River near Stanton, ND. Stanton Station has one main turbine generator that is run by Unit 1 and Unit 10. The 'BART Eligible' Unit 1 coal-fired boiler has a dry bottom, front wall fired configuration with ratings of 1,800 MMBtu/hr; or an output of 188 megawatts on PRB. Stanton Station is currently permitted to fire both Lignite and PRB coal. For Unit 1, PM is currently controlled with an electrostatic precipitator (ESP). NOx is controlled with low NOx burners (LNB). There are no post combustion SO_2 controls. The use of two coals with different sulfur contents offers a degree of complexity in terms of SO_2 emissions for Unit 1. To respond to NDDH's request, PRB has been included as an operational control in conjunction with post combustion control technologies. GRE does not intend to blend fuels. Therefore, BART controls and associated limits can be determined based upon each fuel, cost effectiveness and most importantly, expected deciview improvements.

At least three sets of emission parameters must be considered to successfully determine BART. As noted in Table 2-1, the current Title V permitted emission limits represent the maximum allowable emission rates. The baseline actual emissions are derived from historical emissions inventories (2000-2004) and represent the 2 highest years for each pollutant. They are used in comparison with design basis emission rates for potential retrofit technologies as noted in Appendix A. The 'BART Screen' emission rate represents the maximum 24-hour average emission rate, for 2000-2002, and it is used as a baseline for visibility modeling analysis. Table 2-1 describes these three data parameters for Unit 1. It is important to note that Stanton is not categorically subject to presumptive BART limits because Unit 1 has a capacity of less than 200 megawatts and the total facility capacity is less than 750 megawatts. Therefore, the presumptive limits are viewed as guidance levels only.

Table 2-1 Unit 1 Emission Bases

Pollutant	Permit Limit	Baseline Actual	BART Screen	Proposed BART Limit
PM_{10}	0.10 lb/MMBtu	33 lb/hr[4] 0.02 lb/MMBtu	36 lb/hr 0.02 lb/MMBtu	0.10 lb/MMBtu
NOx	0.46 lb/MMBtu	554 lb/hr 0.44 lb/MMBtu	669 lb/hr 0.37 lb/MMBtu[5]	0.35 lb/MMBtu
SO_2 - Lignite	3.0 lb/MMBtu	2,267 lb/hr 1.82 lb/MMBtu	3,420 lb/hr 1.90 lb/MMBtu	0.24 lb/MMBtu
SO_2 PRB	3.0 lb/MMBtu	2,267 lb/hr 1.82 lb/MMBtu	3,420 lb/hr 1.90 lb/MMBtu	0.36 lb/MMBtu

The ‘Baseline Actual’ and ‘BART Screen’ emissions included in Table 2-1 reflect an average utilization of 68% for Unit 1. The swinging of Unit 1 significantly affects NOx emission rates. Under normal station operating conditions, Unit 10 is run at full utilization while Unit 1 varies (swings) to meet Midwest ISO (MISO) power demands. Unit 1 has a wider range than Unit 10 to swing to meet load. Because of this variable load, the lb/MMBtu emission rate may increase over a rolling period, but the overall lb/hr emission rate remains less than what is derived from converting the lb/MMBtu emission rate with the full boiler duty of 1,800 MMBtu/hr. The lb/hr emission rate is arguably a more appropriate metric since it is ultimately used for regional haze modeling. However, since the presumptive levels are expressed in lb/MMBtu units, the proposed BART emission rate is proposed in the same units as 0.35 lb/MMBtu.

The BART analysis, as described in Section 1.2 of this document, will be presented on a pollutant-by-pollutant basis for Unit 1 with the exception of the assessment of visibility impacts for SO_2 and NOx (Step 5). The visibility analysis for SO_2 and NOx was performed using a multi-pollutant approach, and can be found in Section 7.0 of this document. Stanton Station is currently permitted for PRB and Lignite coal.

2.2 Other BART Eligible Units

Other than Unit 1, the remaining BART eligible emission units at Stanton are exempt from BART analysis because they do not cause or contribute to visibility impairment, and are included under one of the following three categories.

i. Additional Capacity

Stanton Unit 10 is a second coal fired boiler with a nominal rating of 642 MMBtu/hr that was operational in 1982. As such, it is not subject to BART. Unit 10 emissions are currently controlled with a spray dry scrubber in

---

[4] Emission rate differs from BART screen value due to rounding.

[5] The maximum lb/hr emissions rate was required for pre-BART visibility modeling. The 0.37 lb/MMBtu emission rate was back calculated based on the maximum capacity of 1800 MMBtu/hr.

addition to a baghouse. Emissions from Unit 10 are vented through a common stack with Unit 1.

Given the higher PRB Btu content, Stanton Station has additional steam capacity on this fuel. In addition to evaluating IGCC, Great River Energy is evaluating maximizing generation on Unit 1, which would make Unit 10 available for additional capacity. Obviously, any new generation will require a separate permitting action from the BART analysis.

ii. *Low Utilization Units*

Based on the hours of operation, some emission units can be classified as low emitters. Table 2-2 lists the emergency and auxiliary units at Stanton and their 2005 actual or estimated emissions. Both restricted and limited operation of these units makes additional controls economically infeasible. There would be no measurable visibility improvement associated with installing controls on these low utilization units. No further BART analysis is required.

Table 2-2 Stanton Station Low Utilization Units

Unit Description	Fuel	Maximum Heat Input	Hours of Operation	NOx (tpy)	SO_2 (tpy)	PM (tpy)	PM_{10} (tpy)	Source
Auxiliary Boiler (EUI 3)	No. 2 Fuel Oil	38 MMBtu/hr	93	0.14	0.36	0.01	0.02	2000-2004 averaged actual emissions.
Emergency Diesel Generator (EUI 4)	No. 2 Fuel Oil	10.35 MMBtu/hr	500	8.00	1.30	0.20	0.20	Potential to emit based on 500 hours of operation.[6]
Emergency Fire Pump Engine (EUI 5)	No. 2 Fuel Oil	370 hp	350	1.93	0.13	0.14	0.14	Estimated emission based on 350 hours of operation.[6]

iii. *Material Handling and Fugitive Sources*

All material handling units (EUI M1 through EUI M5 as listed in the Title V Permit), including coal and lime handling operations and fly ash silos, are controlled through the use of fabric filter baghouses. Baghouses are currently recognized as best available control technology (BACT) for PM emitting sources. No further BART analysis is required for emission units employing BACT or equivalent controls.

---

[6] Annual emissions are conservatively estimated based on potential to emit at 500 hours per year according to EPA definition for emergency-only generators. The fire pump is restricted to 500 hours per year in the Title V permit. Actual emissions are conservatively estimated at 350 hours per year.

In step three of the BART guidance, the Federal Register[7] states, "Fugitive emissions, to the extent quantifiable, must be counted." The emissions from the coal storage sources listed in Table 2-3 consist of PM only. Because sulfates and nitrates are the primary contributors to visibility impairment, PM sources will not significantly contribute to visibility impairment in Class I areas. The tanks, and other units with no specific permit limits listed below (EUI T1 through EUI T8), are classified as insignificant activities. There would be no measurable visibility improvement associated with installing controls on these sources. For this reason, no further BART analysis is required.

Table 2-3 Stanton Station Fugitive Sources

Fugitive Source/Insignificant Activity Name
FS 1 Active coal storage pile
FS 2 Inactive coal storage pile
T1 and 2 Fuel Oil Storage Tanks (2)
T3 Main Generator Transformer
T4 Spare Main Generator Transformer
T5 Spare Startup Transformer
T6 Sulfuric Acid Storage Tank
T7 Caustic Storage Tank
T8 Turbine Oil Vapor Extractor

[7] Federal Register / Vol. 70, No. 128 / Wednesday, July 6, 2005 / Rules and Regulations.

3.0 Particulate Matter (PM) BART Analysis

Historical particulate emission tests show that under normal operation, Stanton Station Unit 1 emits PM below the permitted limit. The existing ESP controls filterable particulate at 98% or more.

EPA has interpreted 'total particulate' to include condensable particulate matter (CPM) and NDDH has requested that CPM be addressed as part of the BART analysis. As such, Section 6 provides an estimation of CPM. It concludes that CPM emissions from Unit 1 do not significantly impact visibility impairment and will be reduced by the proposed SO_2 BART controls. Further, pre-BART modeling demonstrates that Unit 1 PM contribution to visibility impairment is negligible in comparison to the impairment attributed to sulfates and nitrates.

As illustrated in Section 7.0, Unit 1 post-BART modeling shows a 1.0 Δ-dV improvement in visibility for the proposed SO_2 and NOx controls as compared to a maximum 0.02 Δ-dV improvement for particulate controls[8]. This incremental improvement is an order of magnitude less than the perceptibility threshold set by EPA. It is statistically insignificant given the uncertainty associated with the modeling. Therefore, additional PM controls are not warranted.

3.1 Identify PM Control Options

Table 3-1 lists the available retrofit PM options for Stanton Unit 1.

Table 3-1 Available PM Control Technologies

PM Control Options
ESP – Current Control
WESP
Mechanical Collector (Multiclone)
Fabric Filter/Baghouse

3.2 Eliminate Infeasible PM Control Options

3.2.1 Electrostatic Precipitator (ESP)

An electrostatic precipitator applies electric forces to separate suspended particles from the flue gas stream. In an ESP, an intense electrostatic field is maintained between high-voltage discharge electrodes, which are typically wires or rigid frames, and grounded collecting electrodes, which are typically plates. A corona discharge from the discharge electrodes ionizes the gas passing through the precipitator, and gas ions subsequently ionize the particles. The electric field drives the negatively charged particles to the collecting electrodes. Periodically, the collecting electrodes are rapped mechanically to dislodge collected particulate

---

[8] 98th percentile comparison of modeling results.

matter, which falls into hoppers for removal. Collector dust is removed from the precipitator for disposal or recycling.

ESP control efficiency under normal load conditions is typically in the range of 98% to 99%+. Reduced efficiencies will occur when the inlet particle concentration is low. Outlet particle concentrations can be reduced to as low as 0.005 gr/dscf. The actual outlet concentration will depend on the size range and nature of the particles. An ESP is currently used to control particulate emissions from the Unit 1. According to BART, ESP replacement or modification is technically feasible.

3.2.2 Wet Electrostatic Precipitator (WESP)

A wet electrostatic precipitator operates in the same manner as a dry ESP; it applies electric forces to separate suspended particles from the flue gas stream. In a WESP, an intense electrostatic field is maintained between high-voltage discharge electrodes, which are typically wires or rigid frames, and grounded collecting electrodes, which are typically plates. A corona discharge from the discharge electrodes ionizes the gas passing through the precipitator, and gas ions subsequently ionize the particles. The electric field drives the negatively charged particles to the collecting electrodes. Particle removal in a WESP is accomplished with water sprays instead of mechanical cleaning methods. As a result of using water sprays, WESPs generate wastewater that must be treated to remove suspended particles and dissolved solids.

Since WESPs use electrical forces for particle collection, the electrical properties of the particles can adversely impact WESP operation. Particles with high resistivity may not readily accept an electric charge and will be difficult to collect. Particles with high conductivity or magnetic properties will strongly adhere to the collection plates and be difficult to remove; WESP water sprays may reduce this problem. However, WESP water spray systems will require more maintenance than dry ESP’s in order to keep the water spray system working properly.

WESP control efficiency under normal loading conditions is typically in the range of 98% to 99%+. Reduced efficiencies will occur when the inlet particle concentration is low. Outlet particle concentrations can be reduced to as low as 0.005 gr/dscf. The actual outlet concentration will depend on the size range and nature of the particles. WESP technology has been demonstrated on similar coal-fired boilers. Therefore, replacement of the existing ESP with a WESP is technically feasible as BART for Unit 1.

3.2.3 Mechanical Collector

Cyclone separators are designed to remove particles by inducing a vortex as the gas stream enters the chamber, which causes the exhaust gas stream to flow in a spiral pattern. Centrifugal forces cause the larger particles to concentrate on the outside of the vortex and consequently slide down the outer wall and fall to the bottom of the cyclone, where they are removed. The cleaned gas flows out of the top the cyclone.

There are two principal types of cyclones: tangential entry and axial entry. In tangential entry cyclones, the exhaust gas enters an opening located on the tangent at the top of the unit. In axial flow cyclones, the exhaust gases enter at the middle of one end of a cylinder and flows through vanes that cause the gas to spin. A peripheral stream removes collected particles while the cleaned gas exits at the center of the opposite end of the cylinder.

Overall cyclone control efficiencies range from 50% to 99% with higher efficiencies being achieved with large particles and low efficiencies for smaller particles (< PM_{10}). Mechanical separators are often used upstream of other PM control devices to reduce the loading on the primary control device. This improves overall control efficiency and may reduce the overall cost of the control system when the exhaust is heavily laden with particulate matter.

According to a 2005 report by EPRI[9] on the current controls used for coal-fired power plants, mechanical collectors have only been permitted for use on one similar unit that is not yet operational. Due to the fact that a multiclone has not been successfully demonstrated on a comparable unit, it is a technically infeasible retrofit for Unit 1, and will not be considered further in this analysis.

3.2.4 Fabric Filter/Baghouse

A fabric filter or baghouse consists of a number of fabric bags placed in parallel inside of an enclosure. Particulate matter is collected on the surface of the bags as the gas stream passes through them. The dust cake, which forms on the filter from the collected particulate, can contribute significantly to increasing the collection efficiency.

Two major fabric filter types are the reverse-air fabric filter and the pulse-jet fabric filter. In a reverse-air fabric filter, the flue gas flows upward through the insides of vertical bags that open downward. The particulate matter thus collects on the insides of the bags, and the gas flow keeps the bags inflated. To clean the bags, a compartment of the fabric filter is taken off-line, and the gas flow in this compartment is reversed. This causes the bags to collapse and the collected dust falls from the bags into hoppers. Shaking or other methods are sometimes employed to dislodge the dust from the bags. The cleaning cycle in a reverse-air fabric filter typically lasts about three minutes per compartment. Because reverse-air cleaning is gentle, reverse-air fabric filters typically require a low air-to-cloth ratio of 2 ft/min. In a pulse-jet fabric filter, dirty air flows from the outside of the bags inward, and the bags are mounted on cages to keep them from collapsing. Dust that collects on the outsides of the bags is removed by a reverse pulse of high-pressure air. This cleaning does not require isolation of the bags from the flue gas flow, and thus may be done on-line.

---

[9] *Status and Performance of Best Available Control Technologies*, EPRI, Palo Alto, CA: 2005. 1008114

The main operating concern for a baghouse is that its operating temperature is limited by the bag material. Most filter materials are limited to 200ºF – 300º F. Some materials like glass fiber or Nomex may be operated at 400ºF, but are more expensive.

Baghouse control efficiency under normal loading conditions is typically in the range of 98% to 99%+. Reduced efficiencies will occur when the inlet particle concentration is low. Outlet particle concentrations can be as low as 0.005 gr/dscf. However, like ESPs, outlet concentrations will depend on the size range and nature of the particles being filtered. Baghouses are currently considered BACT and are commonly used to control particulate emissions from coal-fired boilers. Therefore, they are technically feasible as BART for Unit 1.

3.3 Evaluate the Effectiveness of Feasible PM Options

Based on the current degree of control being achieved on Unit 1, a new ESP, WESP and baghouse technologies are estimated to reasonably provide a 20% reduction in actual emissions from existing annual average emissions[10]. Table 3-2 describes the expected emissions from each of the three remaining control options.

Table 3-2 Control Effectiveness of Technically Feasible PM Control Options

Control Technology	Expected Control Efficiency[10]	Controlled Emissions lb/MMBtu
Dry ESP	20%	0.015
Polishing WESP	20%	0.015
Baghouse	20%	0.015

3.4 Evaluate the Impacts of Feasible PM Options

As illustrated above in Table 3-2, the three technically feasible options are estimated provide identical degrees of increased control. Therefore, in order to differentiate, the economic and environmental impacts for each are presented below.

3.4.1 Economic Impacts

Each technology is estimated to provide controlled emissions of about 73 tons per year, which is a theoretical 20% (17 ton) improvement from the pre-BART historical baseline. The high cost of PM control retrofits in combination with the small reduction in emissions results in a high dollar per ton cost. Table 3-3 details

---

[10] Control efficiency reflects improvement beyond the performance of the existing ESP. Historic particulate performance test results suggest that sampling variability is expected depending on the test method. This indicates that an additional 20% control represents a high performance estimate for potential retrofit controls.

the expected costs associated with each technology based on the EPA cost model and site specific information. Due to site space constraints, the retrofit of PM controls at Stanton Station would require significant additional expenses that were not included in the control cost evaluation below. Therefore, the cost estimates are best case.

Table 3-3 PM Control Cost Summary

Control Technology	Installed Capital Cost (MM$)	Annualized Operating Cost (MM$/yr)	Pollution Control Cost ($/ton)
Polishing WESP	$6.90	$2.03	$119,268
Baghouse	$33.65	$4.98	$292,702
Dry ESP	$38.57	$5.80	$340,570

Because the technologies provide identical levels of control, an incremental analysis of the costs is not beneficial. All three options require significant capital investments and large increases in expected operation and maintenance costs. The pollution control costs confirm that additional particulate control for Unit 1would involve an unjustified investment for only an estimated 20% reduction in already low particulate emissions. Economically, additional controls are not justified for achieving regional haze visibility improvements.

3.4.2 Energy and Environmental Impacts

Generally, there are no other energy or non-air quality environmental impacts that would discourage the use of a new ESP, WESP or baghouse as BART. For the WESP, however, there are additional waste water environmental impacts that would need to be addressed. All three options would require energy usage comparable to the existing ESP. The flyash systems needed to handle the solid waste generated by particulate controls are already in place at Stanton, but some modification and additional costs could be expected. In short, there are generally no significant energy or environmental impacts that would preclude installation of the feasible PM controls.

3.5 PM Visibility Impacts

Most importantly, the visibility impact analysis demonstrates that additional PM controls provide negligible improvements in the Class 1 areas. Figure 3-1 illustrates the visibility improvement of particulate controls. Reducing PM emissions from the existing permit limit of 0.1 lb/MMBtu to 0.015 lb/MMBtu results in a maximum visibility improvement of only 0.02 Δ-dV or an average visibility improvement of 0.01 Δ-dV. This improvement is completely insignificant in comparison to the improvement attributed to SO_2 and NOx control as illustrated in Section 7.0. It is an order of magnitude less than EPA's perceptibility threshold and is statistically unreliable given the myriad of modeling assumptions and uncertainties. Therefore, from a visibility impact perspective, additional PM controls, including lowering the permitted limited, are not justified for visibility improvements.

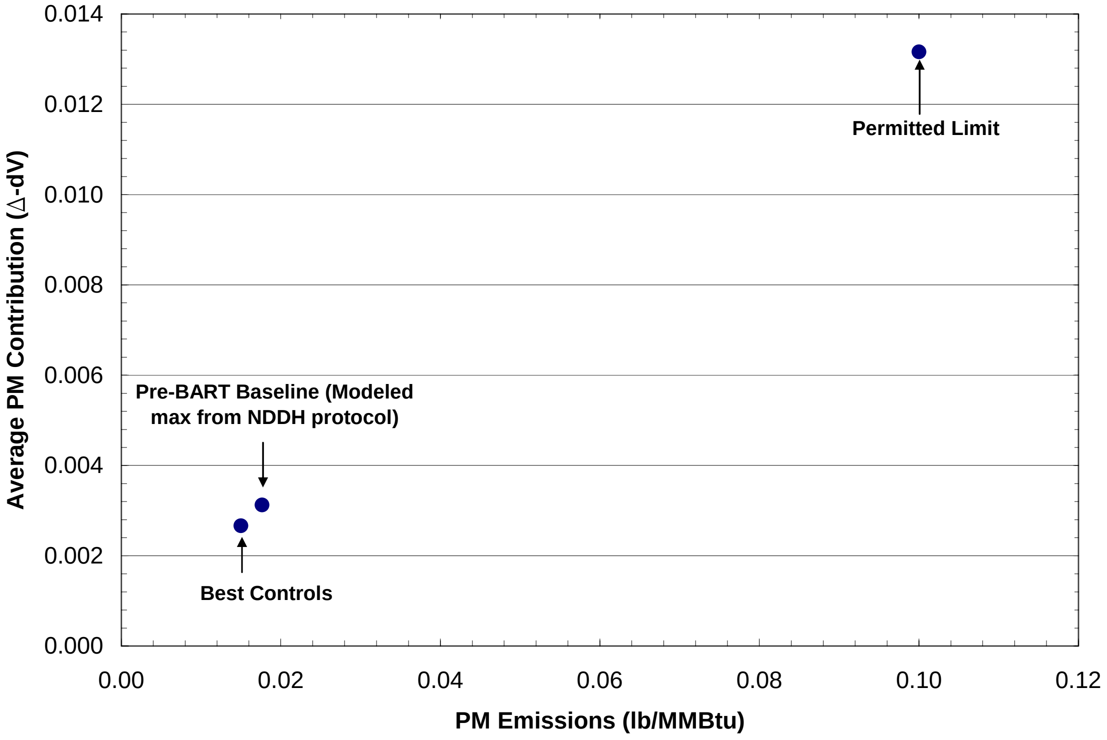

Figure 3-1 Three modeled scenarios illustrate the negligible visibility impacts attributed to particulate matter. All scenarios except for "Pre-BART" were modeled with NOx and SO_2 at their respective proposed BART emission rates. Results represent the average PM visibility impairment contributions from Lostwood Wilderness Area, Theodore Roosevelt National Park (TRNP) South Unit, and TRNP North Unit on the 98th percentile from 2002.

3.6 Proposed BART for PM

Based on the above analysis and the visibility impacts found in Figure 3-1 and Section 7.0, BART is 0.1 lb/MMBtu for particulate emissions based upon the existing ESP. A modification to the existing ESP or the retrofit to another technically feasible control is not cost effective on a dollar per ton basis. Also, most importantly, any additional particulate reductions will provide negligible improvement in visibility. GRE will follow the existing PM CAM plan to comply with the 0.1 lb/MMBtu limit as BART.

PRB BART controls for SO_2 involve the use of dry sorbent injection with the existing ESP, which will lead to additional particulate loading. It is further supportive of maintaining the existing PM permit limit of 0.1 lb/MMBtu. The Unit 1 ESP will continue to operate with automated controls at greater than 98% effectiveness.

Although historical EPA Method 17 particulate emission tests show that Unit 1 can perform below 0.1 lb/MMBtu, a lower BART emission limits is not warranted for the purpose of providing regional haze visibility improvements.

BART PM Emission Limit

Pollutant	Permit Limit	BART Limit
PM_{10}	0.10 lb/MMBtu	0.10 lb/MMBtu

4.0 Nitrogen Oxides (NOx) BART Analysis

Historical NOx emissions for Unit 1 on Lignite are controlled with low NOx burners (LNB) to approximately 0.44 lb/MMBtu. Unit 1 NOx emissions are affected by regional electricity needs as set by MISO and by plant operational protocols. In other words, Stanton's Unit 10 operates at full capacity and Unit 1 is used to meet the remaining power requirements. Unit fluctuations to meet electricity demands from MISO result in variable NOx emissions from Unit 1, with an average utilization of 68%.

There are three mechanisms by which NOx production occurs: thermal, fuel and prompt NOx. Fuel bound NOx is a primary concern with solid and liquid fuel combustion sources; it is formed as nitrogen compounds in the fuel are oxidized in the combustion process. The secondary mechanism of NOx production is through thermal NOx formation. This mechanism arises from the thermal dissociation of nitrogen and oxygen molecules in combustion air. The thermal oxidation reaction is as follows:

$$N_2 + O_2 \rightarrow 2NO \qquad (1)$$

Downstream of the flame, significant amounts of NO_2 can be formed when NO is mixed with air. The reaction is as follows:

$$2NO + O_2 \rightarrow 2NO_2 \qquad (2)$$

Thermal oxidation is a function of the residence time, free oxygen, and peak reaction temperature. Prompt NOx is a form of thermal NOx which is generated at the flame boundary. It is the result of reactions between nitrogen and carbon radicals generated during combustion. Only minor amounts of NOx are emitted as prompt NOx.

4.1 NOx Control Options

Table 4-1 lists the available retrofit NOx options for Stanton's Unit 1.

Table 4-1 Available NOx Control Technologies

NOx Control Options
Pre-Combustion Controls
• Fuel Switching
Combustion Controls
• External Flue Gas Recirculation
• Overfire Air
• Low NOx Burners
Post Combustion Controls
• Selective Catalytic Reduction (SCR) - High Dust - Low Dust
• Selective Non- Catalytic Reduction (SCNR) - NOxOUT®
• Low Temperature Oxidation - Tri-NOx® - LoTOx
• Non Selective Catalytic Reduction
• Novel Multi-pollutant Controls - Rotating Opposed Fire Air (ROFA ®) - Electro-Catalytic Oxidation - Pahlman Process

4.2 Eliminate Infeasible NOx Control Options

4.2.1 Pre-Combustion Controls

Fuel Switching

Fuel switching represents a viable pre-combustion method of reducing NOx emissions through the use of coals with higher BTU content. Historically, Unit 1 has burned Lignite coal, but is currently permitted to burn both Lignite and PRB coals. The PRB fuel switch has reduced NOx emissions from the Lignite base case on an annual basis.

4.2.2 Combustion Controls

Various combustion controls exist for Unit 1 NOx reduction. However, as discussed in this section, there are essentially only a few feasible controls that include overfire air (OFA), low NOx burners (LNB) adjustment and SNCR. Combustion tuning is an inherent part of any LNB/OFA installation.

External Flue Gas Recirculation (FGR)

Flue gas recirculation is a flame-quenching technique that involves recirculating a portion of the flue gas from the economizer or air heater outlet and returning it to the furnace through the burner or windbox. The primary effect of FGR is to reduce the peak flame temperature through adsorption of the combustion heat by the relatively inert flue gas, and to reduce the oxygen concentration in the combustion zone. FGR reduces thermal NOx generation in high-temperature emission sources.

Additional ductwork and a blower would be required to recirculate flue gas. These elements must fit in the limited space around the burner's coal mill. The space constraints and the lowered flame temperature created by FGR make it incompatible with the existing combustion controls on Unit 1. The addition of FGR could further result in reduced boiler capacity. Flue gas recirculation is therefore a technically infeasible control option and will not be considered further.

Overfire Air (OFA)

Overfire air diverts a portion of the total combustion air from the burners and injects it through separate air ports above the top level of burners. OFA is the typical NOx control technology used in coal-fired boilers and is primarily geared to reduce thermal NOx. Staging of the combustion air creates an initial fuel-rich combustion zone for a cooler fuel-rich combustion zone. This reduces the production of thermal NOx by lowering combustion temperature and limiting the availability of oxygen in the combustion zone where NOx is most likely to be formed. Based on engineering analyses[11] performed on Unit 1, OFA is compatible with the existing LNB and is a technically feasible option for further NOx reduction. However, Alstom's design targets have some uncertainty because Unit 1 has a relatively short firebox, which may make OFA less effective than on other larger units. Further, with OFA, there is a potential for increased carbon monoxide (CO) emissions from Unit 1, especially on Lignite, as noted on Page 2-1 of the Alstom Report, which will limit the NOx reduction effectiveness.

Low NOx Burners (LNB)

LNB technology utilizes advanced burner design to reduce NOx formation through the restriction of oxygen, flame temperature, and/or residence time. LNB is a staged combustion process that is designed to split fuel combustion into two zones. In the primary zone, NOx formation is limited by either one of two methods. Under staged air rich (high fuel) condition, low oxygen levels limit flame temperatures resulting in less NOx formation. The primary zone is then followed by a secondary zone in which the incomplete combustion products formed in the primary zone act as reducing agents. Alternatively, under staged fuel lean (low fuel) conditions, excess air will reduce flame

---

[11] *NOx Reduction Technologies Firing Powder River Basin Coal*. Alstom Power Inc. March 8, 2006. (Appendix D)

temperature to reduce NOx formation. In the secondary zone, combustion products formed in the primary zone act to lower the local oxygen concentration, resulting in a decrease in NOx formation. Low NOx burners typically achieve NOx emission reductions of 25% - 50%.

LNB are currently used to control NOx emissions from Unit 1. Alone or in combination with additional controls, additional LNB is a technically feasible option to further reduce emissions. Based on the currently achieved emission rates and used in conjunction with OFA, reduction in the range of 15%-30% would be expected depending on operational conditions.

4.2.3 Post Combustion Controls

For post combustion controls, NOx can be reduced to molecular nitrogen (N_2) in add-on systems located downstream of the furnace area of the combustion process. The two main techniques in commercial service include the selective non-catalytic reduction (SNCR) process and the selective catalytic reduction (SCR) process. There are a number of different process systems in each of these categories of control techniques.

In addition to these treatment systems, there are a large number of other processes being developed and tested on the market. These approaches involve innovative techniques of chemically reducing, absorbing, or adsorbing NOx downstream of the combustion chamber. One example of these alternatives is nonselective catalytic reduction (NSCR).

Selective Catalytic Reduction (SCR)

Selective catalytic reduction is a post combustion NOx control technology in which ammonia (NH_3) is injected into the flue gas stream in the presence of a catalyst. SCR control efficiency is typically 70% - 90%. NOx is removed through the following chemical reaction:

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_20 \qquad (1)$$

$$2NO_2 + 4NH_3 + O_2 \rightarrow 3N_2 + 6H_20 \qquad (2)$$

The catalyst bed lowers the activation energy required for NOx decomposition. The catalyst contains an active phase such as vanadium pentoxide on a carrier such as titanium dioxide. These are used for their ability to lower the activation energy required for NOx decomposition. SCR requires an optimum temperature range of 650-800°F. There are two types of SCR.

High-dust SCR occurs upstream of particulate control. Typical applications require soot blowers for catalyst cleaning. Firing Lignite coal results in an exhaust stream heavily laden with particulate matter, which can contain catalyst poisons such as sodium. The catalyst plugging observed at the Lignite-fired boiler at Coyote Station [12] was caused by materials that could not be cleaned by a soot blower system. Because of Coyote's experience and the potential for comparable catalyst surface plugging at Stanton, a high-dust SCR is determined to be technically infeasible on Unit 1 on Lignite. Since Stanton Station is permitted for both Lignite and PRB, SCR cannot be installed as a PRB control option because of the lignite limitations as discussed. Therefore, High Dust SCR on either fuel will not be considered further.

Low-dust SCR occurs downstream of particulate control. For Unit 1, it requires reheat to bring the flue gas temperature back to the effective range after it is cooled for particulate removal. With reheat, it is a technically feasible option for NOx reduction. Based on an engineering assessment[11] and current NOx emissions, a low-dust SCR could provide additional reduction in the range of 80%-90%.

Selective Non-Catalytic Reduction (SNCR)

In the SNCR process, urea or ammonia-based chemicals are injected into the flue gas stream to convert NO to molecular nitrogen, N_2, and water. SNCR control efficiency is typically 25% - 50%. Without a catalyst, the reaction requires a high temperature range to obtain activation energy. The relevant reactions are as follows:

$$NO + NH_3 + \frac{1}{4}O_2 \rightarrow N_2 + 3/2 H_2O \qquad (1)$$

$$NH_3 + \frac{1}{4}O_2 \rightarrow NO + 3/2 H_2O \qquad (2)$$

At temperature ranges of 1470 to 1830°F reaction (1) dominates. At temperatures above 2000°F, reaction (2) will dominate.

NOxOUT®

NOxOUT® is a commercially available, urea based, SNCR process for the reduction of NOx from stationary sources. The process requires injection of stabilized urea liquid into the combustion flue gas in a location where the temperature range is 1,600 - 2,000 °F.

Based on an SNCR engineering assessment[11] that included the temperature, residence time and the current level of NOx control, an emissions reduction of approximately 15-30% would be expected. However, there are many operational effects to consider. Ideally, SNCR operates at steady state reagent addition rates. Due to the swinging of Unit 1 to meet MISO demands, reagent addition, and corresponding NOx emissions, would vary considerably. Variable reagent addition leads to the formation of

---

[12] *SCR catalyst Performance in Flue Gases Derived from Subbituminous and Lignite Coals.* Steven A. Benson; Jason D. Laumb; Charlene R. Crocker; John H. Pavlish. 7/1/2004 (Appendix F)

ammonium sulfate, which can cause plugging and corrosion. Some estimates suggest that the air heaters must be cleaned quarterly for approximately 2-3 days. If unplanned outages were included, it would only increase the average cost effectiveness. Finally, the engineering assessment did not incorporate Unit 1 load changes due to demand requirements, which would further exacerbate air heater fouling. Therefore, percent reductions are simply estimates. It is important to note that the economic analysis does not include unplanned outages to clean the ammonium sulfate from the air heaters because SNCR was already considered well outside the average cost effective ranges in the BART rule (See Appendix B).

Low Temperature Oxidation (LTO)

The LTO system utilizes an oxidizing agent, such as ozone, to oxidize various pollutants including NOx. In the LTO system, NOx in the flue gas is oxidized to form nitrogen pentoxide (equations 1, 2, and 3). The nitrogen pentoxide forms nitric acid vapor as it contacts the water vapor in the flue gas (4). Then the nitric acid vapor is absorbed as dilute nitric acid and is neutralized by the sodium hydroxide or lime in the scrubbing solution, which forms sodium nitrate (5) or calcium nitrate. The nitrates are removed from the scrubbing system and discharged to an appropriate water treatment system.

$$NO + O_3 \rightarrow NO_2 + O_2 \qquad (1)$$

$$NO_2 + O_3 \rightarrow NO_3 + O_2 \qquad (2)$$

$$NO_3 + NO2 \rightarrow N_2O_5 \qquad (3)$$

$$N_2O_5 + H_2O \rightarrow 2HNO_3 \qquad (4)$$

$$HNO_3 + NaOH \rightarrow NaNO_3 + H_2O \qquad (5)$$

LTO systems, including the commercially available Tri-NOx® and LoTOx describer below, generally represent a technically feasible control option for Unit 1, with an expected control efficiency of 80%-90%.

Tri-NOx®

This technology uses an oxidizing agent such as ozone or sodium chlorite to oxidize NO to NO_2 in a primary scrubbing stage. Then NO_2 is removed through caustic scrubbing in a secondary stage. The reactions are as follows:

$$O_3 + NO \rightarrow O_2 + NO_2 \qquad (1)$$

$$2NaOH + 2NO_2 + ½\ O_2 \rightarrow 2NaNO_3 + H_2O \qquad (2)$$

Tri-NOx® is a commercially available multi-staged wet scrubbing process in industrial use. Several process columns, each assigned a separate processing stage, are involved. In the first stage, the incoming material is quenched to reduce its temperature. The second, oxidizing stage, converts NO to NO_2. Subsequent stages reduce NO_2 to nitrogen gas, while the oxygen becomes part of a soluble salt. A major advantage of the Tri-NOx® process is that concurrent scrubbing of SO_2 can be achieved. Tri-NOx is typically applied at small to medium sized sources with high NOx concentration in the exhaust gas (1,000 ppm NOx). Under these conditions control efficiencies of 99% can be achieved.

LoTOx

BOC[13] Gases' Lo-TOx is an example of a commercially available version of an LTO system. LoTOx technology uses ozone to oxidize NO to NO_2 and NO_2 to N_2O_5 in a wet scrubber (absorber). This can be done in the same scrubber used for particulate or sulfur dioxide removal, The N_2O_5 is converted to HNO_3 in a scrubber, and is removed with lime or caustic. Ozone for LoTOx is generated on site with an electrically powered ozone generator. The ozone generation rate is controlled to match the amount needed for NOx control. Ozone is generated from pure oxygen. In order for LoTOx to be economically feasible, a source of low cost oxygen must be available from a pipeline or on site generation. The normal NOx control efficiency range for Lo-TOx is 80% to 95%.

Non-Selective Catalytic Reduction (NSCR)

A non-selective catalytic reduction (NSCR) system is a post combustion add-on exhaust gas treatment system. NSCR is often referred to as a three-way conversion catalyst because it simultaneously reduces NOx, unburned hydrocarbons (UBH), and CO. Typically, NSCR can achieve NOx emission reductions of 90 percent. In order to operate properly, the combustion process must be near stoichiometric conditions. Under these conditions, in the presence of a catalyst, NOx is reduced by CO, resulting in nitrogen (N_2) and carbon dioxide (CO_2). The most important reactions for NOx removal are:

$$2CO + 2NO \rightarrow 2CO_2 + N_2 \qquad (1)$$

$$[UBH] + NO \rightarrow N2 + CO_2 + H_2O \quad (2)$$

NSCR catalyst has been applied primarily in natural gas combustion applications. This is due in large part to the catalyst being very sensitive to poisoning, as could be expected with coal exhaust streams. Based on a cursory industry review, there were no

---

[13] BOC Gases is a part of The BOC Group plc. (www.boc.com)

commercial installations of NSCR on a coal fired boiler. Therefore, NSCR is viewed as technically infeasible as BART for Unit 1.

Novel Multi-Pollutant Controls

Rotating Opposed Fire Air – ROFA®

ROFA technology utilizes the injection of air through nozzles at asymmetrical positions on opposite sides of a boiler to introduce a swirling quality to the combustion gas. The swirling generates turbulence and rotation throughout the furnace. The rotation prevents laminar flow, resulting in greater utilization of the entire volume of the boiler. Efficiency is improved as a resulted of the lowered temperature provided by the swirling combustion gases. Using of ROFA technology results in a reduction of excess air without an increase in CO emissions. Further, the decrease in oxygen as a result of the excess air reduction leads to a decrease in NOx. As mentioned above, Unit 1 has a short fire box, which could limit the effectiveness of the ROFA technology.

Electro-Catalytic Oxidation (ECO)

ECO technology utilizes a reactor in which SO_2 and NOx and mercury are oxidized to nitrogen dioxide (NO_2), sulfuric acid and mercuric oxide, respectively, using non-thermal plasma. The NO_2 and remaining SO_2 are then removed and concentrated in a scrubber with ammonia injection. This technology is intended for use on low-dust streams and must be located downstream of existing particulate controls.

Pahlman Process

The Pahlman process involves the treatment of flue gas with a sorbent containing magnesium oxide. Using the solubility properties of magnesium at different ionization states, SO_2 and NOx are captured and dissolved in a spray dry system. The sorbent is then captured at a downstream baghouse and can be regenerated.

ECO and the Pahlman process technologies are still in the testing and development phase. They are not currently considered commercially available. Therefore, they are not technically feasible as BART for Unit 1. ROFA is a commercially available OFA alternative, but a site specific applicability study has not been performed for Unit 1 at this time to determine the feasibility of installation. Progress on these technologies will be monitored as the BART implementation timeline progresses.

4.3 Evaluate the Effectiveness of Feasible NOx Options

The results of the engineering analysis performed by Alstom Power presented options for the addition of SNCR and OFA in addition to the existing LNB control. Because these technologies are not mutually exclusive, they are also evaluated in combination. The Alstom Report is presented in Appendix D. Alstom projects NOx target emission rates for OFA that are comparable to presumptive limits.

It is important to note that there are several uncertainties associated with Alstom's estimates. First, the Alstom analysis was expedited in an attempt to meet March 1 deadline under NDDH's accelerate BART schedule. The summary results are simply 'targets' as stated in the report. Second, Alstom proposes emission ranges based on specific operational scenarios that are 'representative' of normal operations. These target emission rates represent specific static operational scenarios that may not be reflective of future operation or inclusive of variable load Specifically, GRE may give preference to Unit 1 in the future with the addition of a new scrubber, which would cause heat input to increase over any shorter term averaging period. Third, for the existing low NOx burners that were installed in 1998 Alstom had provided a contractually guaranteed emission rate that was difficult to meet under all boiler operating conditions and burner tuning at that time.

The attached Alstom report estimates that certain 'target' emissions can be met. This is not as certain as a contractual guarantee. Alstom was eventually able to meet their 1998 LNB commitment through significant additional work, but it is an indication of the complexity of predicting NOx emission reductions from Unit 1. Unit 1 has a relatively short fire box, which adds uncertainty to targeted estimates because overfire requires additional space above the burners for ample mixing. Finally, as previously mentioned, carbon monoxide is expected to increase as a result of installing OFA, which may also limit OFA effectiveness for NOx control. For these reasons, a risk factor is appropriate for adjusting the lb/MMBtu equivalents from the Alstom report. Table 4-2 describes the recalculation methodology to adjust the Alstom report to a 30-day rolling BART emission rates.

Table 4-2 Alstom Emissions

Control	Design Emissions for PRB from Alstom Report[14] (BART Annual)	Alstom Design % Reduction from 0.40 lb/MMBtu	Recalculated Lignite Emission Rates at Historic Baseline of 0.44 lb/MMBtu (BART 30-Day)	
			lb/MMBtu	lb/hr based on 1,800 MMBtu/hr
LNB/OFA	0.32 lb/MMBtu	20%	0.35 lb/MMBtu	633.6 lb/hr
SNCR	0.29 lb/MMBtu	27%	0.32 lb/MMBtu	574.2 lb/hr
LNB/OFA +SNCR	0.22 lb/MMBtu	45%	0.24 lb/MMBtu	435.6 lb/hr

---

[14] Design emission rates used as annual estimates for projecting ton per year reductions.

Based on the current utilization and design degree of control being achieved on Unit 1, Table 4-3 describes the expected annual emissions from each of the remaining feasible control options.

Table 4-3 Control Effectiveness of Technically Feasible NOx Control Options

Control Technology	Expected Control Efficiency	Controlled Emissions lb/MMBtu	Controlled Emissions ton/year
SCR with Reheat	90%	0.044	210.2
LTO	90%	0.044	210.2
SNCR + PRB + Alstom LNB + OFA	55%	0.196	946.1
SNCR + PRB	47%	0.230	1111.3
Alstom LNB + OFA + SNCR	45%	0.239	1156.3
SNCR	33%	0.290	1401.2

4.4 Evaluate the Impacts of Feasible NOx Options

As illustrated above in Table 4-3, the technically feasible control options provide varying levels of emission reduction. Therefore, it is necessary to consider the economic and energy/environmental impacts to better differentiate as presented below.

4.4.1 Economic Impacts

Table 4-4 details the expected costs associated with each technology based on pre-BART historical baseline emissions, the EPA cost model and site specific information. Factors affecting the control cost estimates include extensive renovations necessitated by space constraints, extended downtime for installation, and reagent costs. The detailed cost analysis for each technology is provided in Appendix A.

Table 4-4 NOx Control Cost Summary

Control Technology [15]	Installed Capital Cost (MM$)	Annualized Operating Cost (MM$/yr)	Pollution Control Cost ($/ton)	Incremental Control Cost ($/ton)
SCR with Reheat	$56.55	$12.49	$6,478	$10,036
LTO	$43.88	$44.78	$23,217	Inferior
SNCR + PRB + Alstom LNB + OFA	$10.67	$5.31	$4,452	$6,910 (D2)
SNCR + PRB	$8.41	$5.01	$4,877	Inferior
Alstom LNB + OFA + SNCR	$10.66	$3.00	$3,053	$6,927
SNCR	$8.39	$2.70	$3,661	Inferior
Alstom LNB + OFA + PRB	$2.27	$2.30	$3,037	$836 (D2)
Alstom LNB + OFA	$2.27	$0.30	$504	NA-Base
Fuel Switch to PRB	$0.00	$2.00	$5,006	NA-Base PRB (D2)[16]

The incremental control cost listed in Table 4-4 represents the incremental value of each technology as compared to the technology with the next highest level of control. Control technologies listed as “inferior” do not represent cost effective options in comparison to the dominant control technologies on an incremental dollar per ton basis. In this analysis, dominant controls are located on the least cost envelope, as illustrated graphically in Figure 4-2[17].

---

[15] Cost estimates for LNB and OFA controls rely on March 2006 Alstom evaluation. SNCR Cost revised in November 2007 to reflect estimate by WGI.

[16] (D2) = Secondary dominant control. The addition of PRB fuel scenarios creates parallel least cost envelopes as illustrated in Figure 4-2. Secondary dominant controls represent the alternative incremental scenario, incorporating additional fuel switching controls.

[17] The annual emission reduction shown for LNB/OFA represents ‘normal’ annual operation and excludes instances of Unit 10 downtime. Future emission rates may vary from historical as discussed.

To reflect PRB fuel and associated NOx controls, a 'Dominant 2 (D2)' scenario has been added to differentiate between incremental costs associated with Lignite reductions.

Based on the BART final rule and other similar regulatory programs like CAIR and BACT, cost-effective NOx controls are in the range of $300 to $1,300 per ton removed as illustrated in Appendix B. EPA presumptive NOx limits were set based on average cost effectiveness of less than $1300/ton. Accordingly, fuel switching, SNCR alone or in combination with LNB/OFA, SCR with reheat, and LTO can arguably be eliminated from BART consideration on the basis of cost effectiveness. All of these technologies represent capital investments that are not justified on a cost per ton or incremental cost basis. In addition to cost effective arguments, the incremental deciview reductions associated with the various controls further support OFA/LNB for either Lignite or PRB as BART. Please refer to Section 7 for more discussion on projected deciview improvements.

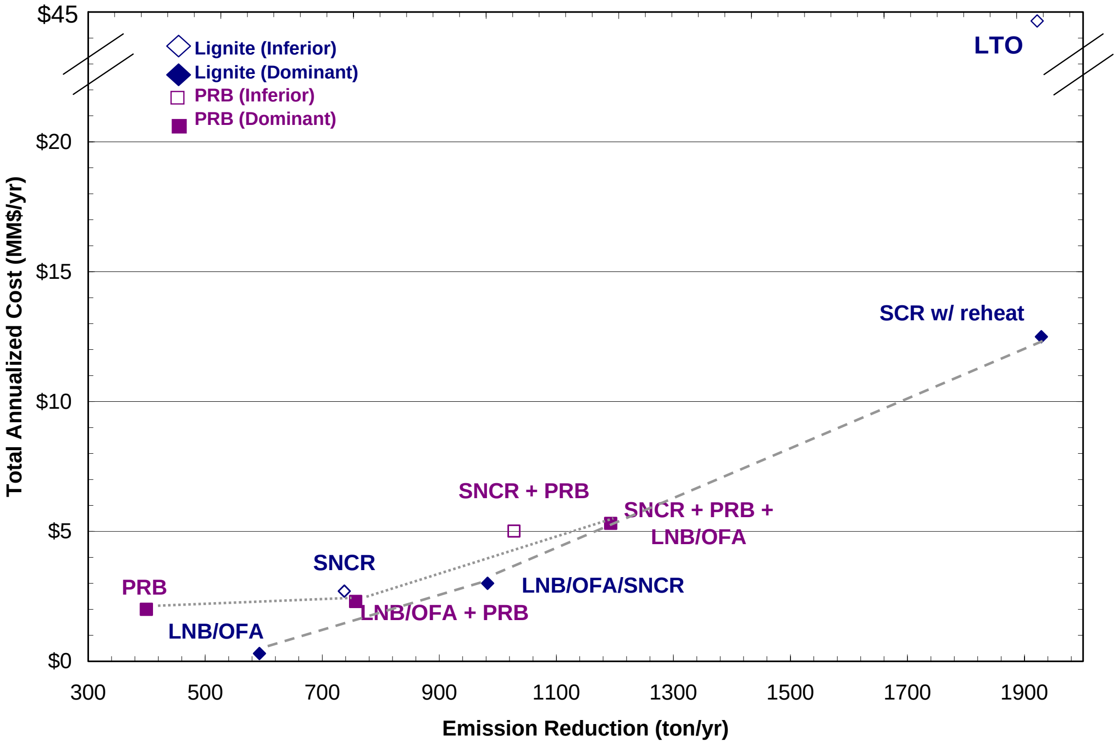

Figure 4-2 Incremental NOx Analysis The remaining feasible technologies are illustrated on the basis of annualized emission reduction in tons per year and total annualized cost in millions of dollars per year. Dominant and inferior controls are represented by darkened or empty diamonds, respectively; secondary dominant controls (PRB scenarios) are shown with darkened or empty squares.

4.4.2 Energy and Environmental Impacts

The energy and non-air quality environmental impacts for OFA/LNB options, SNCR, SCR, and LTO are described in Table 4-5.

Table 4-5 NOx Control Technology Impacts Assessment

Control Option	Energy Impacts	Other Impacts
LTO	- The blower, circulation pump ozone generation and wastewater discharge require additional electrical usage.	- Waste water generated by LTO technologies requires bio-treatment. - Stanton site is limited for additional wastewater controls.
SCR with Reheat	- The reheat required to make SCR technically feasible will result in high energy use and associated costs.	- Reheat would require additional natural gas use, which is not currently available and would require installation of a natural gas line. - Ammonia slip concerns, which contributes to regional haze. - Additional safety and regulatory concerns associated with ammonia storage on site.
SNCR (or SNCR with OFA/LNB)	- Minimal additional energy impacts.	- Ammonia slip concerns, which contributes to regional haze. - Additional safety and regulatory concerns associated with ammonia storage on site. - Variably operating conditions caused by unit swinging will necessitate extensive O&M requirements.[18] - Loss of fly ash re-use. - Potential for an increase in CO emissions as described in Section 2.1 and 2.2 of Appendix D. Any CO increase may require permitting actions and approval from NDDH.
OFA/LNB	- Minimal energy impacts.	- Potential for an increase in CO emissions as described in Section 2.1 of Appendix D. Any CO emissions increase may require permitting actions and approval from NDDH. - Potential for tube wastage.

---

[18] Unit 1 load swings will cause reagent control problems with SNCR or LNB/OFA/SNCR option leading to ammonium sulfate formation and potential corrosion and plugging issues. Since the SNCR technology is not justified economically, these impacts were not more thoroughly assessed, but would be significant. Some estimates predict quarterly outages of 2-3 days to clean fouled air heater. If incorporated into the economic analysis, it would further increase costs beyond EPA's average cost effective levels.

4.5 Proposed BART for NOx

It is important to precede the control determination with an understanding that Stanton Station Unit 1 is a non-presumptive unit at <200MW. As such, economies of scale for pollution control costs are not realized and emission reductions provide relatively less regional visibility improvements. All factors must be weighed in making the BART control determination.

Based on the above analysis, and the visibility impacts found in Section 7.0, GRE establishes OFA with additional LNB adjustments as BART for NOx reduction at Stanton's Unit 1. From a top down analysis, SCR can be ruled out on $/ton basis as not cost effective. The SNCR/OFA/LNB option can be ruled out on several points including economic arguments ($/ton and incremental $/ton cost effectiveness higher than BART presumptive ranges), several qualitative 'Energy and Environmental Impacts' and most significantly, relatively insignificant incremental visibility improvement over LNB/OFA. The OFA/LNB option represents the most cost effective retrofit technology for further controlling NOx emissions from Stanton Station Unit 1.[19]

The proposed BART emissions limit for Unit 1 is 0.35 lb/MMBtu on a 30-day rolling average. This limit will allow the station to maintain compliance while accommodating Unit 1 swinging as a result of MISO requirements as well as to use currently permitted fuels. GRE will use its existing continuous emissions monitoring systems (CEMS) to demonstrate compliance with the proposed BART limit.

BART NOx Emission Limit

Pollutant	Permit Limit	BART Limit
NOx	0.46 lb/MMBtu	0.35 lb/MMBtu

---

[19] It is worth noting that EPA established presumptive NOx emission rates for >750MW units based upon combustion controls including OFA and LNB. Other than cyclone units, EPA did not require post combustion controls for BART compliance for these presumptive units. Many preliminary BART analyses, as well as state efforts including the Colorado BART SIP, are finding that OFA/LNB are BART and that post combustion controls are not warranted given cost effectiveness considerations in conjunction with incremental deciview analyses.

5.0 Sulfur Dioxide (SO_2) BART Analysis

5.1 SO_2 Control Options

Stanton Station is permitted for either Lignite or PRB coal. Accordingly, the analysis must consider SO_2 control options with respect to different sulfur contents associated with permitted fuels. There is a detailed discussion in Appendix E regarding the expected sulfur range for PRB and Lignite. Since the current coal contract for PRB expires in late 2009, there are a range of sulfur contents that must be incorporated into the BART limit. Table 5-1 lists the available SO_2 control options for Stanton Unit 1.

Table 5-1 Available SO_2 Control Technologies

SO_2 Control Options
Pre-Combustion Controls
Flue Gas Desulfurization
Dry Sorbent Injection
Spray Dry Absorber
Wet Lime/Limestone Absorber
Novel Control: TurboSorp®

5.2 Eliminate Infeasible SO_2 Control Options

The pollutant SO_2 is formed when sulfur present in fuels is oxidized by either process conditions or by combustion. Pre-combustion controls utilize methods for improving the physical or chemical properties of the fuel before it is combusted. Existing methods for post-combustion SO_2 control can be categorized as either dry or wet flue gas desulfurization (FGD).

5.2.1 Pre-Combustion Controls

Several options exist for the beneficiation of coal. Coal impurities can be reduced through pretreatment options such as coal washing and coal drying. No information could be located in support of the effectiveness of washing Lignite coal. Coal drying is being explored at GRE’s Coal Creek Station as a potentially viable option for Lignite fired boilers. In this process, raw coal is crushed and screened to remove rocks and other impurities, such as pyretic sulfur. The crushed coal is then thermally processed to remove excess moisture. It is currently under development as a commercial scale, demonstration at the GRE’s Coal Creek Station. Contingent upon the success of this demonstration, it may be evaluated at a later time for Stanton to provide more operational flexibility for SO_2 control. Since it has not been demonstrated commercially at full scale, coal drying will not be further evaluated in this report.

It is worth adding that different boilers have different sulfur removal rates based on the characteristics of the mined coal. The amount of sulfur removed in the boiler at any one time may change. And yet, sulfur removed in the boiler is sulfur being removed from the flue gas stream and not being emitted to the environment.

Reducing the amount of sulfur present in the fuel is another pre-combustion control for SO_2 reductions. It can be achieved by switching to a lower sulfur containing coal. Unit 1 is currently permitted to burn both Lignite and PRB coals. Although Unit 1 could theoretically coal blend as an element of post-BART operational flexibility for added SO_2 control, Stanton Station intends to burn either Lignite or PRB on a long term basis.[20]

5.2.2 Flue Gas Desulfurization (FGD)

The FGD systems commonly used to control SO_2 emissions can be classified as either wet or dry systems. Both systems rely on creating turbulence in the gas stream to increase contact with the absorbing medium. Wet systems are commonly capable of achieving higher removal efficiencies than dry systems because it is easier to mix a gas with a liquid than a solid. FGD requires the use of an alkali slurry powder. Lime (or limestone) is the most widely used compound for acid gas absorption. Sodium based reagents are also available, and while they provide better SO_2 solubility, they are significantly more expensive. Reagent addition at greater than stoichiometric rates is required for dry systems and can improve removal efficiencies in wet systems.

Wet FGD systems may discard all of the waste by-product streams or regenerate and reuse them. Wet systems generally require more extensive networks of pumps and piping than dry systems to recirculate, collect and treat the scrubbing liquid. As implied by the name, dry scrubbers require less water than wet systems but also require higher temperatures to ensure that all moisture has been evaporated before leaving the scrubber. There are many available FGD systems including wet scrubbing, spray dryer absorption, and dry sorbent injection.

Wet Lime/Limestone Scrubbing

Wet lime/limestone scrubbing involves scrubbing the exhaust gas stream with a slurry comprised of lime (CaO) or limestone ($CaCO_3$) in suspension. The process takes place in a wet scrubbing tower located downstream of a PM control device to prevent the plugging of spray nozzles and other problems caused by the presence of particulates in the scrubber. The SO_2 in the gas stream reacts with the lime or limestone slurry to form calcium sulfite ($CaSO_3 \cdot 2H_2O$) and calcium sulfate (CaSO4). As applied to Unit 1, wet scrubbing is capable of achieving approximately 95% control. In addition to 100% wet scrubbing scenario, a 10% flue gas bypass of the scrubber will be evaluated below. Both scenarios of wet scrubbing are technically feasible as BART for Unit 1 on either fuel.

---

[20] For testing or fuel switching, it is possible that a secondary fuel may be brought on site for a short period. In discussions with NDDH, it was proposed that for a limited time, the alternative fuel and associated limit would apply on a daily basis for the purpose of calculating towards a 30-day rolling BART limit. As an example, if Stanton switches back to Lignite or wishes to test dried Lignite, the Lignite limit would apply to each 24 hour period in which Lignite was the primary fuel.

Spray Dry Absorption and Baghouse

Spray dry absorption is a dry scrubbing system that sprays a fine mist of lime slurry into an absorption tower where the SO_2 is absorbed by the droplets. The absorption of the SO_2 leads to the formation of calcium sulfite ($CaSO_3 \cdot 2H_2O$) and calcium sulfate ($CaSO_4$) within the droplets. The liquid-to-gas ratio is such that the heat from the exhaust gas causes the water to evaporate before the droplets reach the bottom of the tower. This leads to the formation of a dry powder, which is carried out with the gas and collected with a fabric filter baghouse. Spray dryer absorption control efficiency is typically in the 70% to 90% range. A spray dry scrubber is technically feasible as BART for Unit 1 on either fuel.

Dry Sorbent Injection (DSI)

Dry sorbent injection involves the injection of a lime or limestone powder into the exhaust gas stream. The stream is then passed through a baghouse or ESP to remove the sorbent and entrained SO_2. The process was developed as a lower cost FGD option because the mixing occurs directly in the exhaust gas stream instead of in a separate tower. Depending on the residence time and gas stream temperature, sorbent injection control efficiency is typically between 50% and 70%. In combination with the existing ESP, DSI is only expected to achieve about 35% removal or less. For Unit 1 on Lignite, the existing ESP could not handle the additional particulate loading without a corresponding increase in particulate emissions. Therefore, it is ‘technically’ feasible, but is not viable as a retrofit due to an increase in PM emissions for Lignite. If the DSI is accompanied with a new baghouse, removal is expected to be 55% for Lignite. On the other hand, given PRB’s lower sulfur content, DSI provides additional cost effective reductions that make it both feasible and viable. ESP performance testing would need to occur in advance of the BART regulatory deadline to confirm ESP control effectiveness as well as to confirm that any increase in PM is within regulatory limits. DSI is therefore technically feasible as BART for Unit 1 on either fuel.

Novel Multi-Pollutant Control: TurboSorp®

TurboSorp® is a dry FGD technology in which the flue gas is pushed through an open chamber reactor. The flue gas enters the reactor through a nozzle with venturi geometry for optimum distribution of gas flow. The fluidized bed of particles circulates above the venturi inlet inside the vessel and water is injected to maintain outlet temperatures in the range of 45ºF to 55ºF above saturation temperature. Recycled particles from the baghouse along with hydrated lime are injected at this location to control outlet SO_2. The stream is then passed through a fabric filter or ESP to remove large particulate before discharge through the stack.

A booster fan would be required at the outlet to control the gas flow rate. The system would also require installation of a hydrator or pug mill to facilitate the lime hydration process. Test plants are currently operating in Europe and the United

States. Though not considered technically feasible due to its lack of commercial availability at this time, TurboSorp® may be considered in future control technology assessments as GRE evaluates BART implementation.

Additional novel controls including ECO and the Pahlman process for NOx and SO_2 are included in Section 4.2.3 for NOx Controls.

5.3 Evaluate the Effectiveness of Feasible SO_2 Options

Table 5-2 describes the expected emissions from each of the remaining feasible control options. Estimated emission rates are based on the control technology's expected reduction, which is then applied to annual emission rates from 2000-2004. (For more information, please refer to the cost analysis spreadsheets in Appendix A.) It is important to note that actual control efficiency will differ from these calculated values based upon the installed control technology's actual performance and the specific fuel characteristics at that time.

Further, these values differ from the emission rates that are used for modeling visibility impact, which are representative of the emission rates that are consistently achievable over any 30-day period. Caution should be used when attempting to derive short term emission rates from calculated annual emission reductions based on general control design values. Finally, this analysis is based only on the sulfur content of the PRB currently used. When Stanton Station's PRB contract expires in 2009, there will no longer be a low sulfur guarantee on the PRB. As presented in Appendix E, there are a range of realistic PRB sulfur contents.

Table 5-2 Control Effectiveness of Technically Feasible SO_2 Control Options

Control Technology	Expected Control Efficiency	Controlled Emissions[21] (lb/MMBtu)	Controlled Emissions (ton/year)
Absorber (Wet Scrubber)	95%	0.091	438.4
Spray Dry Baghouse + PRB	92%[21]	0.150	724.8
Spray Dry Baghouse	90%	0.181	876.9
DSI Baghouse + PRB	86%	0.248	1,195.9
Absorber 10% Bypass	86%	0.263	1,271.4
DSI Existing ESP + PRB	80%	0.358	1,727.4
Fuel Switch to PRB	70%	0.550	2,657.5
DSI Baghouse	55%	0.817	3,945.9
DSI Existing ESP	35%	1.180	5,699.6

5.4 Evaluate the Impacts of Feasible SO_2 Options

The economic and environmental/non-air quality impacts of the remaining controls are illustrated below.

5.4.1 Economic Impacts

Table 5-3 details the expected costs associated with each technology based on pre-BART historical baseline emissions, the EPA cost model and site specific information. The detailed cost analysis for each technology is provided in Appendix A. Based on the BART final rule, EPA set the SO_2 presumptive level for units >750MW based upon an average cost effectiveness of $919 per ton as illustrated in Appendix B.

---

[21] Controlled emission reductions are projected from pre-BART baseline and historical Lignite operating conditions. Future Lignite could potentially include higher sulfur coal than the baseline. Therefore 24-hour max and 30-day rolling emission will be higher.

Table 5-3 SO_2 Control Cost Summary

Control Technology	Installed Capital Cost (MM$)	Annualized Operating Cost (MM$/yr)	Pollution Control Cost ($/ton)	Incremental Control Cost ($/ton)
Absorber (Wet Scrubber)	$88.16	$13.18	$1,617	$4,484
Spray Dry Baghouse + PRB	$79.51	$13.31	$1,692	$8,083 (D2)
Spray Dry Baghouse	$77.84	$11.22	$1,454	$4,385
DSI Baghouse + PRB	$57.20	$10.43	$1,411	Inferior
Absorber 10% Bypass	$65.64	$9.49	$1,296	$1,420
DSI Existing ESP + PRB	$11.52	$5.20	$758	$3,444 (D2)
Fuel Switch to PRB	$0.00	$2.00	$337	NA- Base PRB (D2) [22]
DSI Baghouse	$57.20	$8.43	$1,814	Inferior
DSI Existing ESP	$11.52	$3.20	$1,105	NA-Base

The incremental control costs listed in Table 5-3 represent the incremental value of each technology as compared to the technology with the next highest level of control. Control technologies listed as “inferior” do not represent cost effective options in comparison to the dominant control technologies on an incremental dollar per ton basis. In this analysis, dominant controls are located on the least cost envelope, as illustrated graphically in Figure 5-1.

Figure 5-1 shows two dominant curves depending on fuel. To cover the expected range of PRB sulfur contents discussed in Appendix E, the 92% calculated PRB SO_2 Scenario is used to establish the PRB dominant curve. We did not include a PRB Absorber Scenario for both qualitative and quantitative reasons. Qualitatively, Stanton Station Unit 10 already has a spray dry baghouse, which generally supports selection of this control technology for Unit 1 on lignite due to operator knowledge of the control systems as well as potential ability to share existing systems, such as ash and lime handling. Wet scrubbing has several qualitative limitations listed in Table 5-4 Other Impacts. Quantitatively, wet scrubbing with lignite did not represent a significant visibility improvement over dry scrubbing that when combined with cost per ton and incremental cost per ton analyses generally supports dry scrubbing as BART on lignite.

---

[22] (D2) = Secondary dominant control. The addition of PRB fuel scenarios creates parallel least cost envelopes as illustrated in Figure 5-1. Secondary dominant controls represent the alternative incremental scenario, incorporating additional fuel switching controls.

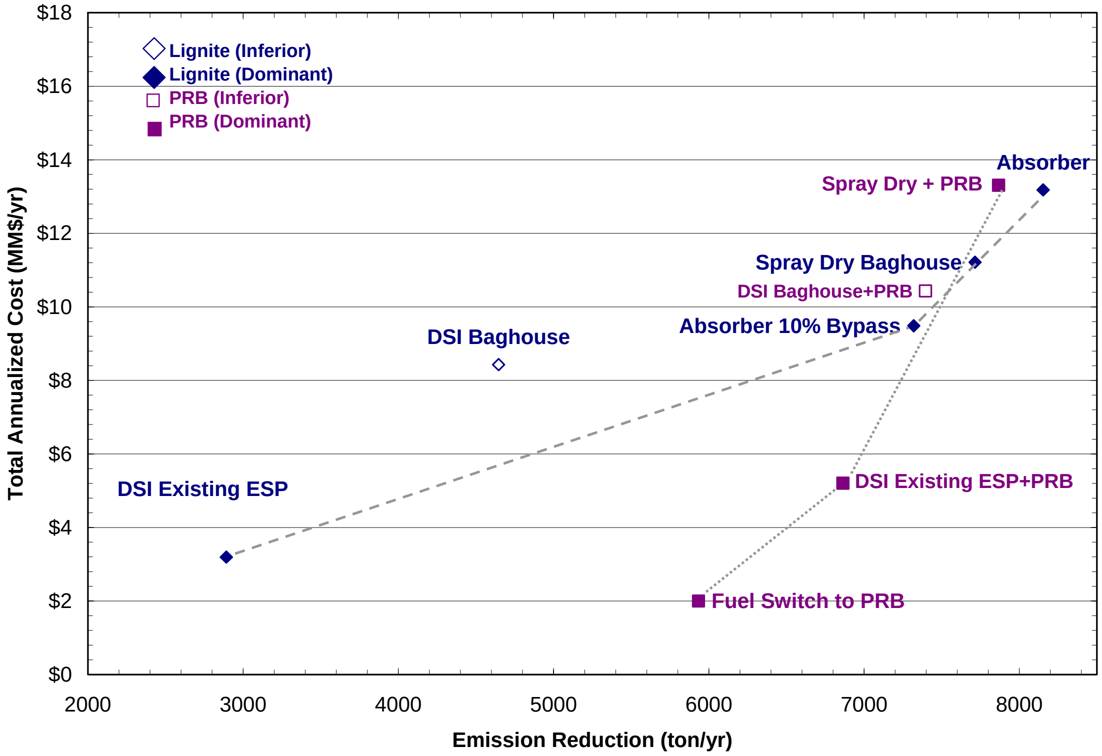

Figure 5-1 Incremental SO$_2$ Analysis The remaining feasible technologies are illustrated on the basis of annualized emission reduction in tons per year and total annualized cost in millions of dollars per year. Dominant and inferior controls are represented by darkened or empty diamonds respectively. Secondary dominant controls (PRB scenarios) are presented as darkened or empty squares.

The DSI baghouse scenarios can be eliminated because they represent inferior controls on an incremental cost basis. All of these technologies represent significant capital investments that are not strictly justified on a cost per ton or incremental cost basis. Most importantly, for final BART determinations, one must evaluate visibility improvements for the various scenarios as discussed in Section 7.0.

5.4.2 Energy and Environmental Impacts

The energy and non-air quality impacts for absorber wet and dry scrubbing options are presented in Table 5-4. No significant environmental impacts are associated with a fuel switch to PRB.

Table 5-4 SO_2 Control Technology Impacts Analysis

Control Option	Energy Impacts	Other Impacts
Wet Scrubbing (0% and 10% bypass)	- Blower requires increased energy use.	- Ponding for scrubber discharge will be limited because of site space constraints. The space that could potentially be used for wet scrubber ponding was formerly an ash pond[23]. Due to geologic instabilities and proximity to river, the ash had to be removed. - Extensive process downtime for installation, requiring replacement power. - Loss of fly ash re-use. EPA Coal Combustion Products Action Plan prefers dry over wet scrubbers. - Wet stack modifications required. - Due to space constraints, the existing storage warehouse must be relocated. - Additional water consumption and wastewater generation. - Waste water discharge will increase mercury loading in the Missouri River.
DSI with Existing ESP	- An ESP upgrade would require additional energy use.	- For Lignite, sorbent injection would result in increase particulate loading, resulting in higher PM emissions. The existing ESP would need to be upgraded to comply with existing PM limits. - Increased particulate loading rules out the possibility of using carbon injection for future mercury control. - For PRB, performance testing with DSI and/or carbon for mercury would need to occur to ensure compliance with PM limit. It is assumed that an ESP upgrade would not be needed for DSI.
DSI Baghouse	- Blower requires increased energy use.	- Requires process downtime and replacement power during installation. - Due to space constraints, the existing storage warehouse must be relocated.
Spray Dry Baghouse	- Blower requires increased energy use.	- Requires process downtime and replacement power during installation. - Due to space constraints, the existing storage warehouse must be relocated.

---

[23] See plot plan in Appendix G.

5.5 Proposed BART for SO_2

It is important to precede the control determination with an understanding that Stanton Station Unit 1 is a non-presumptive unit at <200MW. As such, economies of scale for pollution control costs are not realized and emission reductions provide relatively less regional visibility improvements. All factors must be weighed in making the BART control determination.

From a top down analysis, the wet scrubber on either fuel can arguably be eliminated based on dollar per ton and incremental dollar per ton assessments as well as more qualitative Energy and Environmental Impacts as discussed. This determination is further supported by the incremental dV analysis in Section 7.

The next option is dry scrubber and baghouse technology. For lignite, the cost per ton and incremental cost per ton are well above the EPA average cost effective values. Since the spray dry baghouse is modeled to provide perceptible dV reductions on lignite, Great River Energy has agreed to install a spray dry baghouse for lignite. This determination is further supported by the concerns, as discussed, associated with the next level of control as DSI and ESP on lignite.

Because of PRB's relatively lower sulfur content as compared to lignite, both the dollar per ton and incremental dollar per ton cost effectiveness are higher than comparable lignite control scenarios. More importantly, the lower sulfur PRB provides significant dV reductions unscrubbed. Therefore, scrubbed PRB offers relatively less dV improvements than scrubbed lignite fuels. Given careful consideration of the BART requirements, a spray dry baghouse for PRB can arguably be ruled out on both cost per ton and incremental cost per ton effectiveness. This is supported by the incremental dV analyses in Section 7.

The next PRB control option is DSI using the existing ESP. It is the most effective control option based both on cost per ton and incremental cost per ton. Since it is consistent with EPA's average cost effectiveness threshold, it is considered BART for PRB. This determination is further supported by the incremental dV analyses in Section 7.

In order to encompass future operating scenarios, maintain fuel flexibility and ensure SO_2 emission reductions, GRE is therefore proposing a split permit limit reflective of the BART control determinations associated with each fuel. For Lignite, based on installation of a spray dry baghouse, the BART emission is 0.24 lb/MMBtu on a 30-day rolling average period. This value is derived from maximum sulfur concentrations, illustrated in Appendix E, as found in North Dakota Lignite. For PRB, based on installation of DSI with existing ESP, the BART emission limit is 0.36 lb/mmbtu on a 30-day rolling average basis.

BART SO_2 Emission Limits

Pollutant	Permit Limit	BART Limit
SO_2 Lignite	3.0 lb/MMBtu	0.24 lb/MMBtu
SO_2 PRB	3.0 lb/MMBtu	0.36 lb/MMBtu[24]

GRE will use its existing continuous emissions monitoring systems (CEMS) to demonstrate compliance with the proposed lb/MMBtu BART limit.

---

[24] Please refer to the Executive Summary section entitled Additional Considerations.

6.0 Condensable Particulate Matter (CPM) BART Analysis

Based on EPA's interpretation that 'total particulate' includes condensable particulate matter (CPM) and at NDDH's request, GRE provides an estimate of CPM from Stanton Station's Unit 1. It is important to note that ND utilities are not required to test for CPM. They are only required to test for particulate using Methods 5 or 17, depending on plant permit requirements. Stanton's Title V permit for Unit 1 includes a particulate limit and compliance is demonstrated based on a correlation curve with opacity that was developed using EPA Method 17.

Since GRE does not have stack test data for CPM, a literature review was conducted to estimate CPM emissions based on a correlation to tested filterable values. Unfortunately, there is wide variability in CPM emissions when correlated to filterable emissions, regardless of the methodology selected. Some of the variability it associated with Method 202 and sulfate interference. Since CPM exists in several forms such as ammonia salts and sulfur containing particles, Method 202 cannot compensate for sulfate levels, and consequently overestimates CPM emissions. AP-42 is another methodology that provides a linear relationship between sulfur content and CPM emissions, which is arguably inaccurate, especially at higher sulfur concentrations. Nevertheless, for the purpose of this BART analysis, CPM emissions are approximated and assessed according to BART requirements.

6.1 Identify CPM Control Options

It is generally accepted that CPM is largely formed by ammonia salts and sulfur containing particles. In the absence of ammonia from NO_X controls, no ammonium salts are expected in Unit 1 indicating that the majority of CPM is in the form of sulfuric acid mist (SAM). In general, the inorganic portion of CPM far exceeds the organic portion and is composed primarily of sulfates, which emanate from SO_2. Sulfuric acid mist is formed from sulfur trioxide (SO_3) reacting with water in exhaust streams. SO_3 (and SO_2) is formed when sulfur present in the coal is oxidized by either process conditions or by combustion. Accordingly, the majority of control options for CPM are the SO_2 control technologies described previously in Section 5.0 and listed in Table 6-1 below.

Table 6-1 Available CPM Control Technologies.

CPM Control Options
Wet Electrostatic Precipitator
Dry Sorbent Injection
Spray Dry Absorber
Wet Lime/Limestone Absorber

6.2 Eliminate Infeasible CPM Control Options

Wet Electrostatic Precipitator

In applications where a wet electrostatic precipitator (WESP) is used for particulate removal, it may also be used for SAM removal. A WESP uses a water spray to remove particulate matter from the ESP collection plates. For SAM removal, caustic is added to the water spray system, allowing the spray system to function as an SAM absorber. As indicated in Section 3.0, WESP control is a technically feasible but economically infeasible control option. CPM emissions do not significantly change the economic analysis. As such, WESP is economically infeasible for CPM control. If added to the particulate analysis in Section 3, CPM emissions do not significantly change the economic impacts. No additional PM controls are necessary.

Dry Sorbent Injection (DSI)

Dry sorbent (pulverized lime or limestone) is directly injected into the duct upstream of the fabric filter. SAM reacts with sorbent and the solid particles are collected with a fabric filter. This process was developed as a lower cost option to conventional spray dry absorption (SDA) technology. DSI is technically feasible for controlling CPM. However, as indicated in Section 5.0, DSI represents a lower degree of control than will be achieved by the proposed SO_2 BART controls for Stanton Station.

Spray Dry Absorption

Spray dryer absorption is a dry scrubbing system that sprays a fine mist of lime slurry into an absorption tower where the pollutants (SO_2 and SAM) are absorbed by the droplets. The absorption of the SO_2 and SAM leads to the formation of calcium sulfite ($CaSO_3 \bullet 2H_2O$) and calcium sulfate ($CaSO_4$) within the droplets. The liquid-to-gas ratio is such that the heat from the exhaust gas causes the water to evaporate before the droplets reach the bottom of the tower. This leads to the formation of a dry powder, which is carried out with the gas and collected with a fabric filter. Dry scrubbing is the proposed SO_2 BART control technology for Stanton Station Unit 1. It is technically feasible for controlling CPM and is expected to provide a corresponding decrease in SAM as the primary component of CPM.

Wet Lime/Limestone Scrubbing

Wet lime/limestone scrubbing involves scrubbing flue gas stream with a slurry comprised of lime (CaO) or limestone ($CaCO_3$) in suspension. The process takes place in a wet scrubbing tower located downstream of a PM control device to prevent the plugging of spray nozzles and other problems caused by the presence of particulates in the scrubber. The SO_2 and SAM in the gas stream reacts with the lime or limestone slurry to form calcium sulfite ($CaSO_3 \bullet 2H_2O$) and calcium sulfate ($CaSO_4$). Based on the visibility impacts presented in Section 7.0 and the economic and environmental impacts presented in Section 5.4, wet scrubbing is eliminated as a BART control option.

6.3 Evaluate the Effectiveness of Feasible CPM Options

A number of methods exist with which to estimate CPM emissions. However, consistent and accurate CPM estimates vary widely due in large part to the uncertainties currently associated with CPM emissions measurements as presented below.

EPA's AP-42 emission factor uses a linear relationship between CPM and the sulfur content of coal. Historical coal sulfur contents have ranged from 0.40% to 1.56% for Stanton Station with an average of 1.30%. There are two issues relevant to the uncertainty associated with using AP-42 emission factors: how well they represent the results of Method 202 measurements and the known artifacts in the inorganic portion of Method 202. (Namely, condensable sulfates are formed in the aqueous measurement process that would not otherwise form CPM in the atmosphere. These sulfates are generally termed "pseudo particulates" and their formation results in inflated CPM values when using Method 202[25].)

Five tests from coal-burning boilers in various locations provide some indication of the relationship between Method 202 measurements and AP-42 calculations. These sites all used wall fired boilers and pulverized coal and were equipped with a particulate control (ESP or fabric filter) but had no NO_X or SO_2 controls.

In the AP-42 calculations, CPM varies linearly with sulfur content. However, Method 202 measurements do not yield such a linear relationship. This suggests that the AP-42 correlation with coal sulfur is not appropriate. There is not sufficient data to assess if CPM measurements corrected for pseudo particulates would have a linear relationship with coal sulfur content. At higher sulfur contents, AP-42 calculations appear to overestimate CPM compared to Method 202, which already overestimates CPM. For very low sulfur content coal Method 202 may provide the more conservative estimate.

Since GRE does not have Method 202 test data from its boilers, CPM emissions are estimated by using a ratio of 4:1 for CPM to filterable PM (Method 5) based on the literature data presented in both Figure 6-1 and Table 6-2 below. The bar graph and table below summarizes the sulfur content, Method 202 CPM and AP-42 CPM, as well as the ratio of condensable to filterable PM using these two techniques from these five sites. The tests give a range of condensable to filterable PM ratios of 1.44-6.69 using Method 202, with an average ratio of 3.61.

---

[25] A comparison of Method 202 with a modified version to correct for pseudo particulates was performed at the Xcel Energy (previously Northern States Power) Black Dog Station, which at the time of the test fired pulverized coal at 0.25% sulfur content with wall-fired burners. The boilers were equipped with electrostatic precipitators for particulate control, but did not have ammonia-based NOX controls or SO2 controls. The comparison was accomplished by measuring CPM with standard Method 5 and Method 202 techniques and then repeating the measurements using a cold filter in the Method 5 train to simulate conditions for formation of CPM in the atmosphere. At Method 5 temperatures, sulfate based CPM can pass through the collection filter. A cold filter will capture these sulfate and sulfuric acid particulates so that any sulfate measured in the impingers of Method 202 may be considered pseudo particulates. This comparison indicates as much as an 83% overestimation of CPM using Method 202.

Table 6-2 Filterable and Condensable PM Comparison[26,27].

Source	Average Coal Sulfur Content	AP-42 CPM (lb/MMBtu)	Method (M) 202 CPM (lb/MMBtu)	Ratio of Condensable (M 202) to Filterable, (M 5) PM	Ratio of Condensable (AP-42) to Filterable, (M 5) PM
Logan Generating Company, L.P. Cogen Facility	1.13	0.083	0.0208	4.56	18.20
PSE & G - Mercer Station Unit 1	0.75	0.045	0.0373	3.00	3.61
PSE & G- Mercer Station Unit 2	0.75	0.045	0.0563	6.69	5.34
Deseret Generation and Trans. Coop.- Bonanza Power Plant	0.47	0.017	0.0096	1.44	2.55
Xcel Energy Black Dog Station	0.25	0.01	0.0437	2.36	0.54
Xcel Energy Black Dog Station – corrected for pseudo particulates (Modified M 202)	*0.25*	*0.01*	*0.0076*	*0.41*	*0.05*
Average Ratio CPM: Filterable				**3.61**	**6.05**

As described above, the existing methodologies for approximating CPM emissions all have their limitations. The Electric Power Research Institute (EPRI) is currently working with the EPA to revise Method 202 in an effort to produce more accurate CPM emission estimates. For the sole purpose of approximating CPM from its Lignite-fired boilers for this BART analysis, GRE has chosen to multiply its filterable particulate matter (PM), as determined using EPA Method 5 test data, by a factor of 4. This ratio is based on literature data comparing the results of CPM measured by EPA Method 202[28] to filterable particulates as measured by EPA Method 5. It is also reflective of recent BACT permit limits[29], which show a range of CPM ratios from roughly 2 to 4 times the corresponding PM limit. Accordingly, the proposed CPM emission factor will conservatively estimate CPM emissions for the purposes of this BART evaluation.

As shown in Figure 6-1, a modified Method 202 can correct for pseudo-particulates. It is shown that Method 202 alone can overestimate CPM by as much as 83%, on a relatively low sulfur coal.

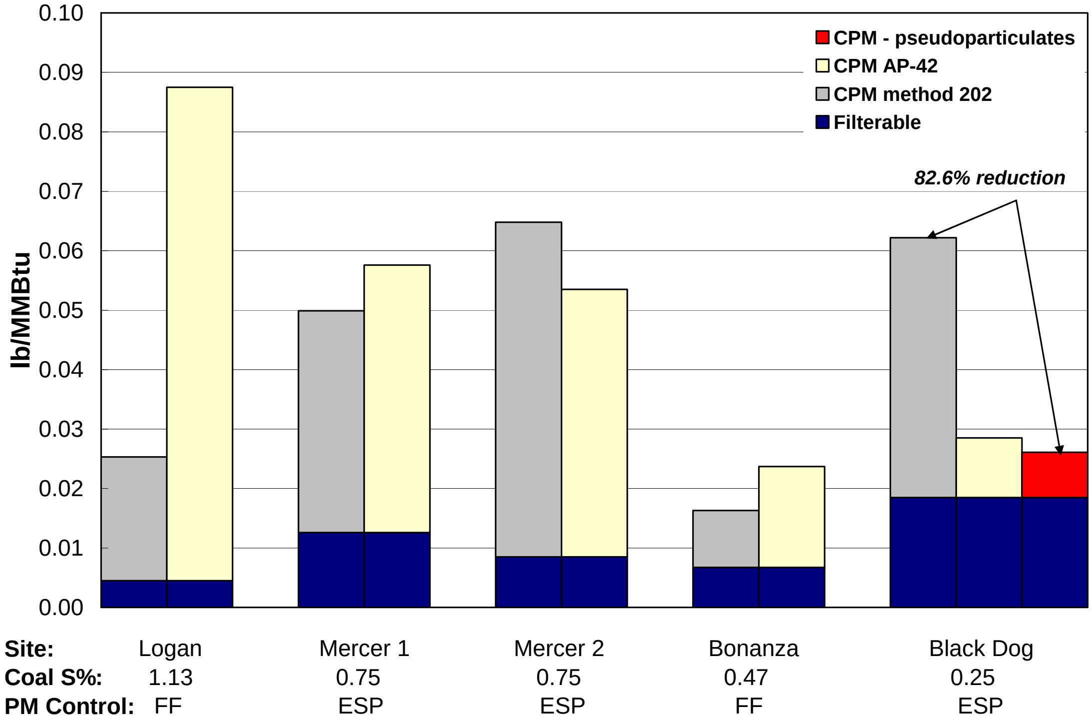

Figure 6-1. Comparison of Method 202 and AP-42. Breakdown of particulate matter is illustrated for 5 power plants[30,31].

Table 6-3 provides CPM estimates using Method 202 and also attempts to correct for pseudo-particulate.

Table 6-3 Annual CPM Emissions Estimate Based on Method 202 Approximation

Unit 1 Method 5 Result (lb/MMBtu)	PM (filterable) Emissions	CPM w/ pseudo-particulates (lb/MMBtu)	CPM w/o pseudo-particulate (lb/MMBtu)	CPM w/ pseudo-particulates (ton/yr)	CPM w/o pseudo-particulate (ton/yr)
0.02	97.3 tpy[32]	0.08	0.014	389.2	67.7

---

[30] "In Stack Condensible Particulate Matter Measurements and Issues" by Louis A. Corio and John Sherwell in the Journal of Air & Waste Management Association: 50:207-218.

[31] “Measurement of Condensible Particulate Matter: A Review of Alternatives to EPA Method 202, EPRI, Palo Alto, CA: 1998. Report TR-111327.

[32] Annual emissions are based on past actual operations for Stanton Station Unit 1. 7,947 annual operating hours with a utilization rate of 68%. (0.02 lb/MMBtu x 1224 MMBtu/hr x 7947 hr/yr/2000 = 97.27 tpy)

6.4 Evaluate the Impacts of Feasible CPM Options

Baseline SO_2 emissions for Unit 1 are calculated to be 8,592 tons per year. As illustrated in Table 6-3, CPM emissions are estimated at approximately 389.2 tons per year, or only 4.5% of the SO_2 emissions. If corrected for pseudo-particulates, CPM emissions may be as low as 67.7 tons per year, or only 0.8% of the SO_2 emissions. Detailed economic and environmental impacts for the available SO_2 control technologies have been presented in Section 5.4. With either the corrected or uncorrected value, the incorporation of CPM emissions will not significantly change the SO_2 economic evaluation. Further, as discussed in Section 3 and as modeled in Section 7, existing PM controls at the permit limit of 0.1 lb/MMBtu are considered BART. With an uncorrected CPM emission rate (0.08 lb/MMBtu) estimated at 4 times filterable PM (0.02 lb/MMBtu), Unit 1 is still conservatively operating below the filterable emission rate (0.1 lb/MMBtu), which has been modeled and contributes a maximum 0.02 Δ-dV to regional haze (see Section 7.5). Therefore, comparable to the SO_2 determination, CPM emissions do not significantly change the PM determination in Section 3.

6.5 CPM Visibility Impacts

As illustrated in Section 3.5, visibility impairment due to particulate matter is negligible in comparison to the contributions attributed to sulfates and nitrates. For Stanton Station, the modeled comparison of the current Method 5 PM results (0.02 lb/MMBtu) and the existing PM permit limit (0.1 lb/MMBtu) yielded an additional visibility impairment of only 0.02 Δ-dV on the 98th percentile for the fivefold increase in emissions. As stated above, it is assumed that total particulate emissions (uncorrected condensable + filterable) will be 5 times the filterable contribution, or in this case, slightly less than 0.1 lb/MMBtu, given the uncertainties with the methodologies. Consequently, the total visibility impairment attributed to uncorrected CPM is estimated to be less than 0.02 Δ-dV. These results indicate that total particulate emissions (uncorrected condensable + filterable) will have a negligible influence on overall visibility impacts. Therefore, even if CPM emissions are as high 4 times filterable PM, the modeled visibility impairment would not be significant and additional SO_2 and PM controls are not economically justifiable.

6.6 Proposed BART for CPM

GRE has reviewed, summarized and discussed the limitations of various methodologies for estimating CPM emissions. GRE proposes no additional control for CPM as supported by the visibility analysis in Section 6.5. It is recognized that proposed BART SO_2 controls will reduce CPM, or specifically sulfuric acid mist (SAM) as the major component of CPM, by as much as 90% with a dry scrubber technology, or a slightly lower amount with PRB dry sorbent injection. .

7.0 Visibility Impacts Analysis

The degree of visibility improvement is arguably the most critical component of the BART determination process. As indicated in EPA's final BART guidance[33], states are required to consider the degree of visibility improvement resulting from the retrofit technologies in combination with other factors, such as economic, energy and other non-air quality, when determining BART for an individual source. By incorporating visibility improvements, the BART analysis is distinctly different than a traditional Best Available Control Technology (BACT) analysis, which relies more heavily on cost considerations.

The CALPUFF program models how a pollutant contributes to visibility impairment with consideration for the background atmospheric ammonia, ozone and meteorological data. Additionally, the interactions between the visibility impairing pollutants NOx, SO_2 and PM_{10} can play a large part in predicting impairment. It is therefore important to take a multi-pollutant approach when assessing visibility impacts.

7.1 Assessing Visibility Impairment

The CALPUFF program models how a pollutant contributes to visibility impairment with consideration for the background atmospheric ammonia, ozone and meteorological data. Additionally, the interactions between the visibility impairing pollutants NOx, SO_2 and PM_{10} can play a large part in predicting impairment. It is therefore important to take a multi-pollutant approach when assessing visibility impacts.

The visibility impairment contribution for different emission rate scenarios can be determined using the CALMET, CALPUFF, POSTUTIL, and CALBART modeling templates provided by the North Dakota Department of Health (NDDH). The North Dakota BART modeling protocol[34] describes the CALPUFF model inputs including the meteorological data set and background atmospheric ammonia and ozone concentrations along with the functions of the POSTUTIL and CALBART post processing elements. The CALBART output files provide three methods with which to assess the expected post-BART visibility improvement: the 98th percentile, 90th percentile, and the number of days on which a source exceeds an impairment threshold.

As defined by federal guidance and Section 33-15-25-01 of the North Dakota Air Pollution Control Rules, [35] a source "contributes to visibility impairment" if the 98th percentile of any year's modeling results meets or exceeds the threshold of five-tenths of a deciview (dV) at a Federally protected Class I area receptor. The pre-BART evaluation of this criterion conducted by the North Dakota Department of Health identified Stanton Station Unit 1 as subject to BART[36] because it 'causes or contributes' to visibility impairment at the four North Dakota Class I areas.

---

[33] Federal Register / Vol. 70, No. 128 / Wednesday, July 6, 2005 / Rules and Regulations p. 39106.

[34] *Protocol for BART-Related Visibility Modeling Analyses in North Dakota,* Final Version, November, 2005.

[35] Chapter 33-15-25 is a new rule on public notice through May 15, 2006.

[36] Subject to BART notification from NDDH is included in Appendix C.

In addition to establishing whether or not a source contributes to impairment on the 98th percentile, the severity of the visibility impairment contribution, or reasonably attributed visibility impairment, can be gauged by assessing the number of days on which a source exceeds 0.5 Δ-dV.

As a worst case, pre-BART modeling of Stanton Station indicated a maximum of 29 days above 0.5 Δ-dV occurred at TRNP South Unit in 2002. There were fewer days above 0.5 Δ-dV for 2000 and 2001. Finally, the determination of reasonable progress along the predicted glide path can be assessed using the 90th percentile prediction.

7.2 Predicting 24-Hour Maximum Emission Rates

Pursuant to verbal guidance from NDDH staff and consistent with use of the highest daily emissions for pre-BART visibility impacts, the post-BART emissions to be used for the visibility impacts analysis should reflect a maximum 24-hour average projected emission rate. The projected 24-hour maximum emission rate was estimated for each control technology considered in this analysis. These predictions were based on a 30-day expected emission rate for each technology, taking into consideration some potential for operational and fuel-based variability for that technology.[37] Table 7-1 and Table 7-2 provide a summary of the modeled 24-hour emission rates and their computational basis for the evaluated NOx and SO_2 control technologies, respectively.[38] For modeling simplification, other stack parameters such as exit temperature and velocity, height, elevation and diameter were not changed and can be found in the protocol[39].

As discussed in Section 4.0, NOx emission rates are highly dependent on Unit 1 load swings due to MISO demands, which can result in a wide range of lb/MMBtu emission rates. For this reason, the 24-hour maximum NOx emissions are presented as lb/hr rates, which is consistent with visibility modeling inputs. Although the 24-hour maximum emission rate for the proposed BART of LNB with OFA shows negligible improvement from pre-BART on either fuel, LNB/OFA will provide more significant reductions with respect to 30-day and annual time periods.

Table 7-1 NOx Predicted 24-hour Maximum Emission Rates

---

[37] Since the PRB scenario was added after completion of modeling, Barr developed a correlation curve based on existing modeling and used it to extrapolate PRB dV improvements. This information is included in Appendix C.

[38] As noted in the Executive Summary, under Additional Considerations and Associated Potential Reductions, Great River Energy is committing to either installation of a dry scrubbing technology with baghouse or converting Unit 1 to a clean coal technology, such as IGCC. For determining appropriate 24-hr modeling values, it is therefore appropriate to use the lignite SO_2 emission rates in Table 7-2 as worse case. The NOx values are essentially the same between lignite and PRB in Table 7-1. For Particulate, a value of 0.07 lb/mmbtu can be used consistent with worse case fuel assumptions and installation of a baghouse as noted in the Executive Summary.

[39] *Protocol for BART-Related Visibility Modeling Analyses in North Dakota*, Final Version, November, 2005.

Control Strategy	30-day Rolling Emission Rate	24-hour Max. Emission Rate	Basis[40]
Pre-BART Baseline	--	669 lb/hr	Actual emissions data from 2000 – 2002. Represents the highest NOx emission rate per calendar day.
LNB/OFA	633.6 lb/hr	665.3 lb/hr	20% design control efficiency and 5% variability.
SNCR	574.2 lb/hr	631.6 lb/hr	27.5% design control efficiency and 10% variability.
LNB/OFA + SNCR	435.6 lb/hr	479.2 lb/hr	45% design control efficiency and 10% variability.
Low-Dust SCR	79.2 lb/hr	87.1 lb/hr	90% design control efficiency and 10% variability.

With respect to projected maximum SO_2 emission rates, it is important to recall that Stanton Station is currently permitted for both lignite and PRB. Since the current PRB fuel contract expires in 2009, there are a range of possible sulfur contents for either lignite or PRB that must be considered. As discussed in Appendix E, SO_2 maximum emission rates are based on a projected worst case fuel, which is lignite comparable to Milton R. Young. (It is lignite that is located on the same side of Missouri River as Stanton Station and is the closest operating lignite mine.) Past SO_2 emissions from MRY Unit 1 and historical Stanton Station data were used to establish 1.56% as the worst case coal sulfur content. Emission rates were then calculated in Table 7-2 using the expected control efficiencies and AP-42 conversion factor. Please refer to Appendix E for more specific information on projected sulfur values associated with lignite and PRB fuels.

---

[40] Design rates are based on normal operating conditions and are subject to the conditions described in the Alstom engineering assessment (Appendix D).

Table 7-2 SO_2 Predicted 24-hour Maximum Emission Rates

Control Strategy	30-day Rolling Emission Rate	Control Efficiency	24-hour Maximum Emission Rate	Basis
Pre-BART Baseline	--	--	3,418.0 lb/hr 1.90 lb/MMBtu	Actual emissions data from 2000 – 2002. Represents the highest SO_2 emission rate per calendar day.
Wet Scrubber	216.0 lb/hr 0.12 lb/MMBtu	95%	263.3 lb/hr 0.15 lb/MMBtu	Projected Lignite Values [41]
Spray Dry Baghouse	432.0 lb/hr 0.24 lb/MMBtu	90%	526.5 lb/hr 0.29 lb/MMBtu	Projected Lignite Values [40]
DSI Baghouse	1,944.0 lb/hr 1.08 lb/MMBtu	55%	2,369.3 lb/hr 1.32 lb/MMBtu	Projected Lignite Values [40]
DSI and ESP w/PRB	0.36 lb/MMBtu	80%	778 lb/hr 0.43 lb/MMBtu	Projected PRB Values[42]
Fuel Switch to PRB	0.55 lb/MMBtu	70%	0.66 lb/MMBtu	Projected PRB Values[41]

SO_2 emission rate is based on the control efficiency with 0% variability and the average maximum coal sulfur content for Stanton Unit 1 and Milton R. Young Unit 2 as determined by past coal data or EDR[43] emission calculations.

7.3 Modeled Results

Visibility impairment is modeled using the meteorological data for the years 2000, 2001 and 2002 for the scenarios described below. In addition to the 15 combinations of SO_2 and NOx controls, results for the baseline pre-BART emissions and for the post-BART PM control visibility contribution scenarios, which were presented in Section 3.5, are also included. Results for the 90th, 98th and number of days above 0.5 dV at

---

[41] Values are derived from maximum sulfur concentrations as found in North Dakota Lignite reserves as could be expected over any 30-day rolling period and are different than the predictions based on past actual operations presented in Section 5.0.

[42] See Appendix E for more information.

[43] Historical (1998 through 2004) Lignite emissions inventories for Stanton Station show a maximum coal sulfur content of 1.55% and EDRs for Milton R. Young Station years 2004 and 2005 show a maximum coal sulfur content of 1.57%. (EDRs available at http://www.epa.gov/airmarkets/emissions/raw/index.html.) See also Appendix E.

each of the Class I areas are included in Table 7-4 through Table 7-6. Additionally, Figure 7-1 illustrates scenarios 1 through 15 on a dollar per dV basis. The figure focuses on year 2002 modeling results because it is the year that showed the most severe pre-BART visibility impairment.

13	Wet Scrubber	SNCR	
14	Wet Scrubber	OFA + SNCR	
15	Wet Scrubber	SCR	
16	PRB	PRB	0.759
17	PRB	LNB/OFA + PRB	0.836
18	DSI/ESP + PRB	LNB/OFA + PRB	0.946
19	DSI BH + PRB	LNB/OFA + PRB	1.009
20	Dry Scrubber + PRB	LNB/OFA + PRB	1.065

As illustrated by the dollar per deciview analysis in Figure 7-1, there are a range of potential BART control combinations and associated visibility improvements. It is important to note that the range of potential deciview improvements spans from a low of 0.3 dV to a maximum of 1.3 dV. With respect to determining the cost effectiveness of the various scenarios, the annualized cost for each scenario was plotted against the average visibility improvement in Figure 7-1. There are two curves representing control options for Lignite and PRB. The inherently lower sulfur PRB causes the curve to shift significantly to the right, providing more deciview reductions for comparable control costs.

---

[44] See addendum to Appendix C on modeling correlation based on previously modeled scenarios.

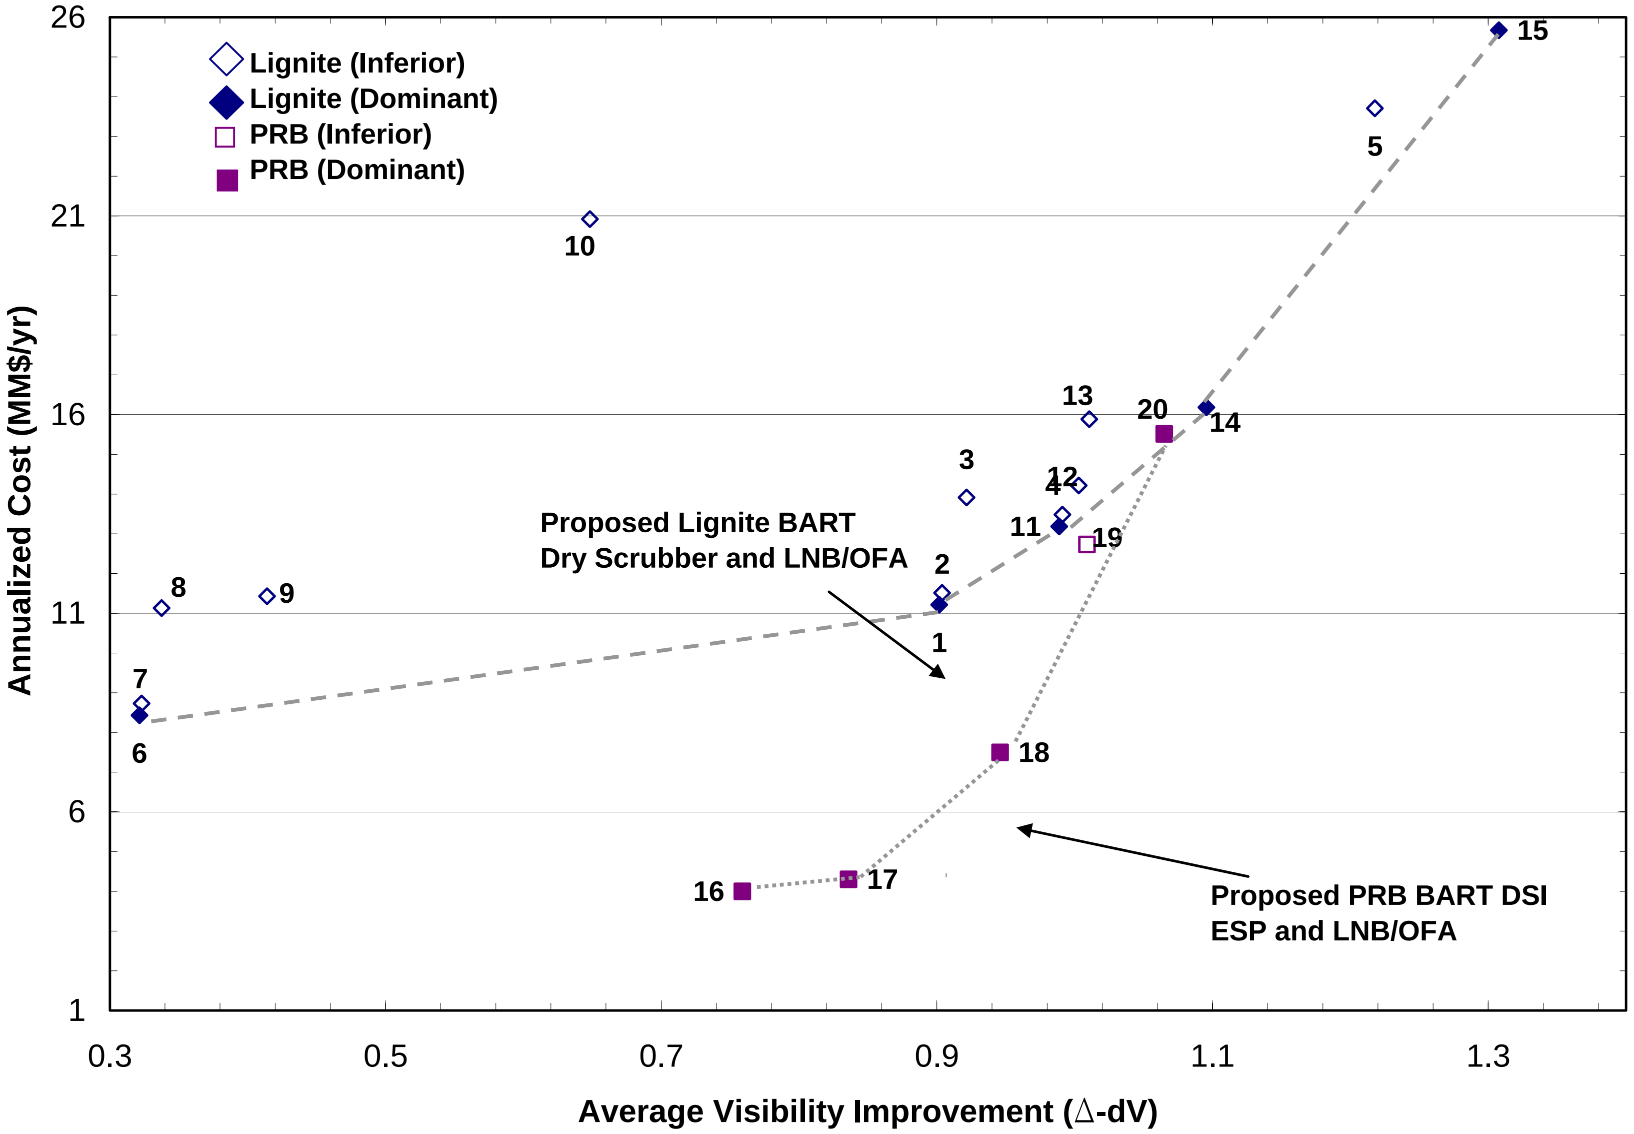

Figure 7-1 Dollar per Deciview Analysis. Scenarios 1 through 15 are plotted for the 98th percentile of 2002 based on the total annualized cost and the average visibility improvement for the 4 Class 1 areas. Dominant controls are presented as filled diamonds and inferior controls are represented as empty diamonds and secondary dominant controls (PRB scenarios) are represented with filled or empty squares. See Table 7-7 for additional scenario description.

The first cluster of Scenarios 6, 7, 8 and 9 represent roughly 0.3 to 0.4 dV improvement from the baseline. Scenario 6 represents the most cost effective Scenario in this cluster and is the start of the least cost envelope curve. The next scenario cluster occurs at an average visibility improvement of 0.9 to 1.0 dV. This second cluster includes Scenario 1, and 2 as part of the least cost envelope curve.

The slope of the least cost envelope increases significantly after Scenario 2. The SNCR addition (Scenarios 4 and 14) causes the curve to rise sharply, which is a graphical representation of the relative significance of additional costs combined with limited dV improvements. After Scenario 2, the graph demonstrates that for an additional 0.1 to 0.2 dV improvement, there will be annualized cost increase from $12.4MM to $15.1MM annualized cost.

Finally, Scenario 2 OFA/LNB did not provide significant modeled deciview improvements from Scenario 1 LNB, which would generally support Scenario 1 as BART from a strictly visibility perspective. Nevertheless, Great River Energy recognizes that the Scenario 2 OFA/LNB will provide 30-day and annual NOx reduction benefits that are supportive of visibility improvements even though the 24-hr modeled effects are not readily apparent.

For the secondary curve based upon PRB control scenarios 16-20, the curve demonstrates that PRB unscrubbed Scenarios 16 and 17 provides approximately the same absolute dV improvement as the Lignite Scenario 2 determined to be BART. The secondary curve climbs to DSI and ESP as the next control. Since it was viewed as cost effective based on dollar per ton and incremental dollar per ton assessments, it is established as BART for PRB. Scenario 20 only provides an additional ~0.1 dV improvement. Therefore, from a visibility perspective in conjunction with cost effectiveness arguments, it is not considered BART on PRB. Since Scenario 2 provides a lesser dV improvement over Scenario 18, Scenario 2 will be used as a conservative basis for further discussion.

7.4 Visibility Impacts of the Proposed BART

Scenario 2 represents a significant reduction in modeled visibility impairment from the baseline in the four North Dakota Class 1 Areas. For example, on average, for the 2002 98th percentile, over a 0.9 Δ-dV improvement is expected from the average baseline of 1.45 dV. Interestingly, the Scenario 2, 0.9 Δ-dV BART average reduction places Stanton Unit 1 only slightly above (at 0.55 dV) EPA’s 0.5 dV ‘cause or contribute’ threshold, which is considered imperceptible to the human eye.

Table 7-8 provides the expected percent visibility improvement for the proposed BART Scenario 2 along with pre-BART and post-BART days above the 0.5 dV contribution threshold. With the 98th percentile correction[45], the eighth highest daily visibility impairment is less than 0.5 Δ-dV at all but one station[46] for the modeled years 2000 and 2001.

Table 7-8 Proposed BART Scenario 2 - Average Improvement Over Baseline

Year	Average Percentile Improvement		Average Days Above 0.5 Δ-dV		
	90th	98th	Pre-BART	Improvement	Post-BART
2000	68%	64%	17	14	3
2001	69%	65%	20	16	4
2002	70%	63%	23	14	9

Additional reductions associated with Scenarios 4, 14, and 15 in Table 7-6, as the worst case year, will not reduce the number of days above the contribution threshold from Scenario 2 without significant additional costs as demonstrate in Figure 7-1. The most significant incremental reductions occur in 2002 in TRNP South Unit. For these reasons, the visibility impacts analysis support Scenario 2 as BART for Stanton Station Unit 1.

---

[45] As stated in the modeling protocol, the 98th percentile is roughly the eighth-highest daily prediction. By this estimation, any modeled scenario with fewer than 7 days above 0.5 Δ-dV has a 98th percentile below 0.5Δ-dV.

[46] The eighth highest daily impairment for Lostwood NWA in 2001 is only 0.524 Δ-dV

8.0 Summary of Proposed BART

Based on careful consideration of all factors included in this BART analysis, Scenario 2 (Dry Scrubber/Baghouse and OFA/LNB) is considered BART for Stanton Station Unit 1. In order to arrive at this determination, one must first quantitatively assess the average and incremental cost effectiveness of individual pollutant controls as well as qualitatively assess energy and other environmental impacts. As discussed in Sections 3 thru 6, these individual pollutant assessments are then viewed in conjunction with combined control scenarios as part of the visibility assessment in Section 7 to ultimately determine BART.

With respect to particulate controls (PM), as a single pollutant, GRE will maintain the current PM performance standard of 0.1 lb/MMBtu. Section 3.0 PM analysis confirms that additional PM controls are not economically justified on a dollar per ton basis. More importantly, the modeled benefits associated with potential PM reductions are less than 0.02 dV, which is considered an insignificant deciview reduction for North Dakota's Class 1 areas. Therefore, the combined assessment of cost and insignificant deciview improvements support maintaining a PM emission limit of 0.1 lb/MMBtu.

For NOx controls, GRE establishes LNB with OFA as BART as described in Section 4.0. A low dust SCR with reheat can be ruled out on cost per ton and incremental cost effectiveness arguments. SNCR, by itself, and LTO are also arguably above the average cost effective thresholds used by EPA to set presumptive BART limits. EPA clearly did not intend for larger emission units >750MW to install post combustion NOx controls by setting presumptive emission rates consistent with LNB/OFA technologies. Large cyclone units are the only emission units required to install post combustion NOx controls. Figure 7-1 shows that LTO and SNCR without LNB/OFA, are inferior controls since they are not on the dominant curve. The combination of SNCR with OFA can be ruled out on cost per ton and incremental cost per ton along with other operational, energy, environmental impacts as noted in Table 4-4. Further, the operational limitations of SNCR (Scenarios 4 and 14), also support the selection of Scenario 2 as BART. This determination, is most importantly, supported by the visibility analysis, which demonstrates only a 0.1 Δ-dV associated with SNCR (Figure 7-1 – Scenario 2 to Scenario 4). While LNB with OFA shows little modeled improvement with respect to the 24-hour projected maximum emission rate, this control will provide approximately 20-25% reduction on a 30-day and annual basis from the baseline. Potential changes in load variability for Unit 1 as well as visibility modeling support a BART limit of 0.35 lb/MMBtu on a 30-day rolling average rather than a lb/hr limit.

For SO_2 control, GRE proposes to install a dry scrubber technology with 90% design removal efficiency and a 0.24 lb/MMBtu 30-day rolling average BART limit on lignite. Alternatively, a fuel switch to PRB coal in addition to DSI technology utilizing the existing ESP controls is considered BART and would establish a 30-day rolling limit of 0.36 lb/MMBtu.

From a top down analysis, Scenario 15 (Wet FGD & SCR) is considered above the EPA average cost effective thresholds that were used to set presumptive BART limits. More importantly, the incremental deciview improvements from Scenario 2 (Dry scrubber & SCR) are only 0.1 dV, which is viewed as insignificant. There are other qualitative non-air quality, environmental impacts and site limitations, which would preclude wet scrubber from consideration.

In continuing the top down analysis, as discussed in Sections 4 and 5, Scenario 14 (wet FGD & LNB/OFA/SNCR) can arguably be considered above the EPA average cost effective thresholds for SO2 and NOx. Further, the incremental dV improvement from Scenario 2 to Scenario 14 is <0.1dV. Therefore, the combined effective of cost per/ton, incremental cost per ton and incremental deciview improvement strongly supports Scenario 2 as BART.

Scenario 4, which includes SNCR as the only difference with Scenario 2, can be ruled out because the LNB/OFA/SNCR cost per ton reductions are outside of the cost effective range according to BART guidelines. Further, the incremental dollar per ton for SNCR is extremely high and there are other energy and environmental impacts that would preclude it from consideration. In terms of incremental visibility improvement, there would be approximately 0.1 dV improvement from Scenario 2 to Scenario 4.

Arguably, between Scenario 1 and 2, there is not much of a modeled visibility improvement. Because LNB/OFA provides monthly and annual reductions and because the technology is a cost effective retrofit, it is established as BART.

BART Emission Limits

Pollutant	Permit Limit	BART Limit
PM_{10}	0.10 lb/MMBtu	0.10 lb/MMBtu
NOx	0.46 lb/MMBtu	0.35 lb/MMBtu
SO_2 Lignite	3.0 lb/MMBtu	0.24 lb/MMBtu
SO_2 PRB	3.0 lb/MMBtu	0.36 lb/MMBtu

In combination, the Scenario 2 BART controls will provide an average visibility improvement of over 0.9 Δ-dV compared to the pre-BART baseline that will significantly contribute to the state’s effort in meeting its reasonable progress goals under the Regional Haze Rule. From a visibility standpoint, other BART control scenarios do not provide significant incremental improvements and are not justified on cost per ton and incremental cost per ton effectiveness arguments at this time.

SO2	7,871	8,084	8,548	9,046	7,660

Uncontrolled PM Emission Rate Using AP-42 - For SW Disposal Rates

	Total	Filterable	Condensable
T/yr	32,844	32,659	185
lb/Hr	8266	8219	47

Filterable PM Emission Factor	84.2	lb/ton coal
Condensable PM Emission Factor - Lignite	0.039	lb/MMBtu

BART Baseline Emissions [1]
2 Year Averages

	T/yr	**lb/hr**	**lb/MMBtu**	**Period**
PM10	**90**	**33.3**	**0.019**	2000, 2001
PM	**91**	**33.7**	**0.019**	2000, 2001
NOx	**2,139**	**783.2**	**0.44**	2002, 2003
SO2	**8,592**	**3266.5**	**1.81**	2001, 2003

[1] SO2 and NOx lb/MMBtu is the average of the two highest years (excluding 2004 because both types of coal were used) plus one standard deviation of the years 2000-2003

[2] PRB calculations:
SO2 PRB lb/MMBtu = lb/MMBtu on Lignite * PRB % S / Lignite % S
SO2 PRB lb/hr calculated using lb/MMBtu SO2 * design duty
lb/hr = average emission rate adjusted to 100% utilization

[3] lb/MMBtu in 2004 includes PRB and Lignite

Sulfur Dioxide (SO_2)	8,591.6	-		8591.6	-	NA

Notes & Assumptions

1 Total Direct Capital Cost Cost Estimated using GRE cost estimate from Coal Creek, 19% as compared to dry ESP cost.
2 Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 3
3 ESP Maintenance costs Eq 3.45 EPA Cont Cost Manual Section 6 Chapter 3
4 ESP Maintenance Materials Eq 3.45 EPA Cont Cost Manual Section 6 Chapter 3
5 Used an ESP SCA grid factor of 553 ft^2/1000 acfm per GRE, D. Stockdill.
6 High control cost is due to the small additional decrease in emissions as compared to existing controls.
7 Assumed WESP size is 20% of IAPCS model calculated size for electricity and spray water use.
8 Per GRE 3/22/02 cost estimate $35/MW-hr, 140 MW

Notes & Assumptions

1 Total Direct Capital Cost Cost Estimated using the Integrated Air Pollution Control Sytem Program Version 5a, EPA May 1999
Model input scaled to 312 MW (=192 MW * 801500 ACFM / 493400 ACFM) to account for high stack flow rates at Stanton

2 Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 3

3 ESP Maintenance costs Eq 3.45 EPA Cont Cost Manual Section 6 Chapter 3
4 ESP Maintenance Materials Eq 3.45 EPA Cont Cost Manual Section 6 Chapter 3
5 Used an ESP SCA grid factor of 553 ft^2/1000 acfm per GRE, D. Stockdill.
6 High control cost is due to the small additional decrease in emissions as compared to existing controls.
7 Per GRE 3/22/02 cost estimate $35/MW-hr, 140 MW

Notes & Assumptions

1 WGI total direct installed cost estimate adjusted for inflation 10/2/2007
2 Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1
3 Compressed air for baghouse assumed to be 2 scfm / 1000 acfm EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1.5.1.8
4 Bag replacement at 10 min/bag EPA Cost Cont Manual 6th ed Section 6 Chapter 1.5.1.4 lists replacement times from 5 - 20 min per bag.
5 Bag replacement costs for baghouse need to be updated. Bag costs from EPA example calculations were used. Bags for Stanton would be larger and more expensive.
6 Dry scrubbing SO2 costs include addition of a baghouse. Assumed that the existing ESP could not handle additional loading.
7 Per GRE 3/22/02 cost estimate $35/MW-hr, 140 MW

Notes & Assumptions

1 WGI total direct installed cost estimate adjusted for inflation 10/2/2007
2 Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1
3 Compressed air for baghouse assumed to be 2 scfm / 1000 acfm EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1.5.1.8
4 Bag replacement at 10 min/bag EPA Cost Cont Manual 6th ed Section 6 Chapter 1.5.1.4 lists replacement times from 5 - 20 min per bag.
5 Bag replacement costs for baghouse need to be updated. Bag costs from EPA example calculations were used. Bags for Stanton would be larger and more expensive.
6 Dry scrubbing SO2 costs include addition of a baghouse. Assumed that the existing ESP could not handle additional loading.
7 Per GRE 3/22/02 cost estimate $35/MW-hr, 140 MW

Notes & Assumptions

1. Total Direct Capital Cost Cost Estimated using the Integrated Air Pollution Control Sytem Program Version 5a, EPA May 1999
Model input scaled to 312 MW (=192 MW * 801500 ACFM / 493400 ACFM) to account for high stack flow rates at Stanton
2. Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1
3. Compressed air for baghouse assumed to be 2 scfm / 1000 acfm EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1.5.1.8
4. Bag replacement at 10 min/bag EPA Cost Cont Manual 6th ed Section 6 Chapter 1.5.1.4 lists replacement times from 5 - 20 min per bag.
5. Dry scrubbing SO2 costs include addition of a baghouse. Assumed that the existing ESP could not handle additional loading.
6. WGI total direct installed cost estimate for baghouse adjusted for inflation 10/2/2007
7. Per GRE 3/22/02 cost estimate $35/MW-hr, 140 MW

Notes & Assumptions

1 Total Direct Capital Cost Cost Estimated using the Integrated Air Pollution Control Sytem Program Version 5a, EPA May 1999
Model input scaled to 312 MW (=192 MW * 801500 ACFM / 493400 ACFM) to account for high stack flow rates at Stanton

2 Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1

3 Compressed air for baghouse assumed to be 2 scfm / 1000 acfm EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1.5.1.8

4 Bag replacement at 10 min/bag EPA Cost Cont Manual 6th ed Section 6 Chapter 1.5.1.4 lists replacement times from 5 - 20 min per bag.

5 Dry scrubbing SO2 costs include addition of a baghouse. Assumed that the existing ESP could not handle additional loading.

6 JXK Revised 1/11 controlled emission rate to account for reduced control effectiveness due to short residence time in available ductwork

7 Stone and Webster 2002 total direct installed cost estimate adjusted for inflation

8 Operation cost is presented on a per pollutant basis, total annual operating cost for a PRB fuel switch is $4,000,000. This cost is divided in half to represent the total cost attributed to each of the pollutant that will show emission reductions as the result of the fuel switch (SO2, NOx).

Notes & Assumptions

1. Total Direct Capital Cost Cost Estimated using the Integrated Air Pollution Control Sytem Program Version 5a, EPA May 1999
   Model input scaled to 312 MW (=192 MW * 801500 ACFM / 493400 ACFM) to account for high stack flow rates at Stanton
2. Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1
3. Compressed air for baghouse assumed to be 2 scfm / 1000 acfm EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 6 Chapter 1.5.1.8
4. Bag replacement at 10 min/bag EPA Cost Cont Manual 6th ed Section 6 Chapter 1.5.1.4 lists replacement times from 5 - 20 min per bag.
5. Dry scrubbing SO2 costs include addition of a baghouse. Assumed that the existing ESP could not handle additional loading.
6. JXK Revised 1/11 controlled emission rate to account for reduced control effectiveness due to short residence time in available ductwork
7. Stone and Webster 2002 total direct installed cost estimate adjusted for inflation

Notes & Assumptions

1 Estimated Equipment Cost per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2. Scaled to reflect Alstom March 2006 cost estimate for SCR without reheat.
2 For Calculation purposes, duty reflects increased flow rate, not actual duty.
3 Calculations per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2
4 Capital Cost per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.36 -2.43
5 Reagent Use per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.32 - 2.35
6 SCR Catalyst Volume per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.18 - 2.24
7 SCR Reactor Size per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.25 - 2.31
8 SCR Catalyst Replacement per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.50 - 2.53
9 SCR Electrical Demand per EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.48
10 SCR Maintenance Costs EPA Air Pollution Control Cost Manual 6th Ed 2002, Section 4.2 Chapter 2 Eq 2.46
11 Control Efficiency = 90% reduction which is typically the upper range of normal SCR control efficiency
12 Adusted cost for high flow from excess are by ratio of Stanton F Factor to Method 19 Lignite F Factor 15,476 dscf/MMBtu Stanton vs 9,860 dscf/MMBtu for Lignite
13 Per GRE 3/22/02 cost estimate $35/MW-hr, 140 MW
14 Per March 2006 Alstom report, catalyst replacement every 8000 hours. This requires an additional 2 week outage per 3 year outage cycle, annualized to 4.7 days.

Bowers vs. SWAPCA	Bowers vs. SWAPCA	300	300	1000	1000	954-1134 was ruled too much, in favor of 256-310 for SO2. This did consider incremental value. Sections XVII to XIX
WRAP Trading Program Methodology	WRAP			3000		
	EPA - Referenced by Wrap					References EPA-600S\7-90-018. Low is <$500/ton, Moderate is $500-3000/ton, High is over $3000/ton

The dollars per ton estimates cited above were obtained from BART guidance, documentation of similar regulatory programs such as CAIR, and relevant court decisions. These materials indicate that most EPA sanctioned documents, including the final BART ruling, concretely support an average expected reasonable cost range of $1,300 to $1,800 per ton of NOx removed and a range of $1,000 to $1,300 per ton of SO_2 removed. The BART presumptive limits were set based on cost effective controls that were on average less than these ranges. As an example, the presumptive SO_2 limit was established based on an average cost effectiveness of less than $1,000/ton. As the cost analysis extends into RPO, WRAP and other regional planning documentation, the cost ranges become more variable and difficult to predict. For ease of comparison, the federally established ranges for NOx and SO_2 were used as a BART cost threshold basis.

RE: Great River Energy – Coal Creek and Stanton Stations
Supplemental Information for Cost Effectiveness under BART

Dear Mr O'Clair:

As follow-up to our June 4, 2007, meeting with you and Mr. David Glatt, this document serves to outline information relevant to determining an appropriate cost effectiveness threshold for evaluations under Best Available Retrofit Technology (BART). Great River Energy (GRE) submits this information as an addendum to the BART analyses and proposal documents that have been submitted to the North Dakota Department of Health (NDDH) for GRE's Coal Creek and Stanton stations. This information and proposal is for your consideration, and we look forward to continuing our dialogue with you on this matter.

Cost effectiveness is one of several important factors evaluated to determine BART in accordance with U.S. Environmental Protection Agency (EPA) rules and guidance. The EPA is specific in its assignment of presumptive BART emission rates and cost effectiveness expectations.[1] Alternative cost effectiveness values referenced through Section 309 of the Clean Air Act are of interest, but are not as specifically tailored to the goals of the BART rules.

The NDDH has suggested a value deemed cost effective for purposes of economic impacts under BART. This value stems from a reference in the 2004 proposed rule for BART determinations.[2] Specifically, the proposed BART Rule references a draft technical support document[3] (TSD) for

---

[1] Technical Support Document for the Best Available Retrofit Technology (BART) Notice of Final Rulemaking – Setting BART SO_2 Limits for Electric Generating Units: Control Technology and Cost Effectiveness, April 2005. Note that scatter plot evaluations for NOx and SO_2 illustrate that presumptive levels are established from large electricity generating units (EGUs) to ensure the highest visibility reduction.

[2] Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations; Proposed Rule; F.R. Vol. 69, No. 87, May 5, 2004, p. 25198

[3] Western Regional Air Partnership Regional Haze BART (Trading Program Option) TSD 6A, Draft: July 16, 1999

the Western Regional Air Partnership's (WRAP) Annex[4] to a report submitted to the EPA by the Grand Canyon Visibility Transport Commission (GCVTC) in 1996.[5]

The cost effectiveness ranges stated in this WRAP TSD reference an EPA assessment of NOx and SO_2 controls for coal-fired boilers that was published in 1990.[6,7] While the information presented is of interest to BART, a straight inflation adjustment from an analysis performed in the late 1980s and published in 1990 does not provide an accurate reflection of current pollution control technologies and associated capital and operating cost effectiveness

The 1990 EPA document presents a range of control costs that vary by coal sulfur content, boiler type, and generating capacity. It further states that cost estimates rely heavily on site-specific parameters and that both cost and pollutant removal efficiency should be balanced when selecting a control technology for a given boiler. At the time of the report, many technologies considered for BART, including selective non-catalytic reduction (SNCR) for NOx, were not commercially available and are therefore not reflected in the analysis. With the wide variety of specific control costs presented in the document, the range of \$500 to \$3,000 presented as moderate in the WRAP TSD is a subjective number that broadly incorporated all NOx and SO_2 costs for every type and size of utility.

The document states that \$3,000 was used as an approximation to exclude controls that meet BACT level emissions. While BACT controls have been accepted as BART in many cases, the opposite is not necessarily true. Therefore, while BACT average and incremental cost effectiveness thresholds may be reviewed while determining BART cost effectiveness, the EPA's BART Rule and TSDs as well as associated visibility improvements should ultimately be the determinative guidance.

The WRAP TSD was produced under the assumption that BART may not be required for EGUs, which is the premise of the WRAP trading program. Further, in the executive summary to the WRAP annex, it is explained that the goal of WRAP is to employ reductions that are "better than BART" to achieve greater reductions than dictated by reasonable progress goals

For these reasons, WRAP cost estimates include more than just "BART-eligible sources." As a final WRAP comment, note that the WRAP Annex explicitly sets program penalties at \$5,000/ton of excess emissions.[8] This penalty is established at "three to four times greater than the expected market trading price," which is, by definition, an expected cost effectiveness of approximately \$1,200/ton to \$1,600/ton.

[8] Voluntary Emissions Reduction Program for Major Industrial Sources of Sulfur Dioxide in Nine Western States and A Backstop Market Trading Program, September 29, 2000, p. 47

Given the outdated nature of the EPA control assessment that is at the root of WRAP's $500 to $3,000/ton range, it is critically important to rely on more recent cost documentation as provided by the EPA in the BART Rule and associated technical support documents and as provided in GRE's BART analyses reports to the NDDH.

With respect to cost effectiveness as defined in the BART Final Rule,[9] the expected control costs range from $900/ton to $2,400/ton for SO_2 removal and from $300/ton to $1,300/ton for NOx, with most NOx estimates at less than $1,000/ton. Again, these estimates rely heavily on boiler type, capacity, and the fuel burned. The following two excerpted figures illustrate not only the EPA's intent to evaluate BART cost effectiveness on the type and size of boiler, but also confirms that average cost effectiveness is established at a much lower level than that suggested by the NDDH. As an example, highlighted in the two excerpted figures are the rows that would apply to Stanton Station.

FIGURE 1

Unit capacity (MW)	Tons (K) of SO_2 emitted in 2001	Percent of BART eligible coal-fired unit's 2001 emissions	Calculated average cost effectiveness for MW grouping ($/ton SO_2 removed)	Percent of estimated removable BART SO_2 emissions from coal-fired units*
<50 MW	26	0.4	1962	0.9
50–100 MW	93	1.4	2399	1.6
100–150 MW	171	2.5	1796	2.2
150–200 MW	235	3.5	1324	3.4
200–250 MW	253	3.8	1282	3.1
250–300 MW	281	3.2	1128	4.0
>300 MW	5712	85.2	......	84.8

BART Units (>200MW)	6246	92.2	919	91.9

TABLE 3.—AVERAGE COST-EFFECTIVENESS OF NOx CONTROLS FOR BART-ELIGIBLE COAL-FIRED UNITS

Unit type	Coal type	Number units nation-wide	National average ($/ton)
Dry-bottom wall-fired	Bituminous	114	1229
	Sub-bituminous	66	576
	Lignite	3	1296
Tangential-fired	Bituminous	105	567
	Sub-bituminous	72	281
	Lignite	9	614
Cell Burners	Bituminous	32	1287
	Sub-bituminous	3	1021
Dry-turbo-fired	Bituminous	7	775
	Sub-bituminous	7	599
Wet-bottom	Bituminous	6	378
Cyclones (with SCR)	All	56	900

In the determination of NOx control cost effectiveness the NDDH should also be cognizant of determinations made by other states in EPA Region 8. As an example, in Colorado's final BART guidance[10] it has been stated that no post-combustion NOx controls will be required, precluding the need to consider SNCR and selective catalytic reduction (SCR) as potential control options.

---

[9] Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations; Final Rule; F.R. Vol. 70, No. 128, July 6, 2005, p. 39133-39135

[10] Colorado BART, March 16, 2006

In the proposed BART Rule[11] the EPA also states that post-combustion NOx controls should not be necessary, other than on cyclone units.

The BART Final Rule further supports that visibility impacts are a key component of the BART determination. If one control technology provides a significant improvement in visibility over another, the State may and should consider this information in its BART determination. Under this assumption, one cost effectiveness threshold would not be appropriate for all units because there would be varying degrees of visibility improvements.

In terms of visibility improvement, a 0.5 deciview (dV) level has already been determined by the EPA to be a "contribution threshold" for states in determining BART-eligible sources that cause or contribute to visibility impairment and thus become "subject to BART." It can be asserted that any change in impairment from an individual facility with BART-eligible sources less than 0.5 dV can and should be deemed insignificant by a state. In the 2005 document from the NDDH addressing regional haze status[12] the NDDH determined that a newly permitted coal-fired ethanol production facility and a new 175-MW power plant that will be located closer to Class I areas than GRE's facilities would not adversely affect visibility in the North Dakota Class I areas. The fact that these two projects have already been deemed insignificant supports a *de minimis* contribution threshold.

We understand that regional-scale dispersion modeling for BART is pending. Until this analysis is completed it is unknown whether North Dakota will meet its reasonable further progress goals. Accordingly, before requiring emission controls beyond BART, the regional-scale dispersion modeling analysis should be completed with source attribution assessments including those from North Dakota, other contributing states and Canadian sources with their projected reductions. If it can be shown that sources outside the United States are preventing North Dakota Class I areas from meeting their glide path goals, consideration should be given to revising the natural background goal to account for sources that cannot be controlled under the EPA regional haze rules.

Cost effectiveness thresholds have been determined for many other regulatory programs similar to BART. However, BART has the distinct goal of improving/reducing regional haze and is unique in its consideration of visibility impacts. Regardless of the references used to determine cost effectiveness thresholds, it is obvious that pollutant specific thresholds are supported by the EPA. GRE maintains that based on the EPA BART Rule with ranges of $900/ton to $2,400/ton for SO_2 removal and $300/ton to $1,300/ton for NOx removal, and associated references presented in this document, a value of $1,500/ton or less is appropriate for determining cost effectiveness for both NOx and SO_2 control technologies under BART.

November 30, 2005

Mr. Steve Smokey
Environmental Coordinator
Great River Energy
4001 Highway 200A
Stanton, ND 58571

Dear Mr. Smokey:

As specified in the June 15, 2005 final amendments to the EPA July, 1999 regional haze rule, the Department has completed visibility modeling to determine which North Dakota BART-eligible (Best Available Retrofit Technology) sources are subject to BART. The Department's visibility analysis for this BART screening followed the protocol outlined in "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota" (North Dakota Department of Health, November, 2005).

As you are aware, the Great River Energy Stanton Generating Station Unit 1 is a BART-eligible source. Completed visibility modeling for Stanton Station Unit 1 indicates that the maximum 98th percentile delta-deciview prediction for the facility exceeds the BART screening threshold of 0.5 deciviews. Therefore, Stanton Unit 1 is subject to BART.

Two summaries of modeling results are enclosed. Attachment A provides a summary of 98th percentile predictions for the worst-case meteorological year for all BART-eligible facilities. Attachment B provides more detailed results specific to the Stanton Station Unit 1. Included in Attachment B are results for all delta-deciview metrics recommended in the North Dakota protocol, for each year of meteorological data. Also provided are worst-case day and receptor, and the percent contribution for each species.

If you have any questions regarding these results, please contact Steve Weber or Rob White of my staff at (701)328-5188. We look forward to working with you to develop an appropriate BART control strategy for Stanton Station Unit 1.

Sincerely,

Steve Weber for

Terry L. O'Clair, P.E.

Previously Modeled Emission Rate Correlations

Additional modeling runs were not performed to determine the visibility impacts of the PRB fuel scenarios added in the November 2007 report revisions. Instead, previous modeling data (from presentations to NDDH in 2006 and 2007) as well as the modeling results presented in the original report were used to develop a correlation between dV reductions and changes in SO2 and NOx emission rates. The correlations assume that one of the pollutants (either SO2 or NOx) is varried while all other modeled pollutant emission rates remain constant. These correlations are then used to calculate the impacts of control scenarios incorporating the use of fuel switching to PRB coal. (Basis for Scenarios 16-20 in report Section 7)

Executive Summary

The Boiler Retrofits Group of ALSTOM Power Inc. (ALSTOM) is pleased to submit this report to Great River Energy (GRE) Stanton Generating Station. This report details the results of a Phase 1 review of the current PRB and previous Lignite fuels and the available technologies that would reduce NOx emissions to less than 0.29#/mmBtu when firing lignite coal and 0.23 #/mmBtu firing Power Powder River Basin coal, in boiler 1. This study work was authorized by GRE under GRE Contract No. 6072846, dated 01/12/06, and executed under ALSTOM's Engineering Study Contract No. 011070606. Report technical input are from ALSTOM's Firing Systems Engineering – Windsor, CT, and Environmental Controls Systems, Knoxville, TN, and Fuel Tech of Stamford, CT.

A recent Spring Creek, PRB, coal analysis is the base coal for this study, as is lignite coal fired during the original ALSTOM Low NOx burner retrofit contract guarantee tests. The chemical analysis of these fuels can be found in Appendix 5.1. The following table is a summary of the costs and predicted NOx reductions for each technology evaluated specifically for Stanton 1 boiler, firing PRB coal, bottom 2 mills in service at 800k lb/hr feedwater flow: The predicted reductions are based on separate technology capabilities and not the predicted reductions of any combination of technologies:

NOx Reduction Method	**COST ESTIMATE ($m)**						
	Material	**Install**	**Operating**	**Total**	**NOx Reduction**	**Outage**	**Cost/NOx Red.**
RSFC Burner Mods	**0.664**	**0.8**	**0**	**1.46**	**15% - 25%**	**3 wks**	**5.8 to 9.7**
SNCR (Fuel Tech)	**0.8**	**1.8**	**0.1**	**2.7**	**15%**	**4 wks**	**18.0**
SCR (ALSTOM)	**15***	**23**	**2****	**38**	**90%**	**14 wks**	**42.2**

* Indicative pricing does NOT include: new trisector air preheater, SCR gas inlet temperature control device(s), ID Fan alterations, furnace/flue path NFPA Code reinforcements.

** Operating cost includes: 1 yr catalyst replacement + ammonia consumption ~ 340 lb/hr @ full load, $500/ton

1.0 INTRODUCTION

GRE requested a detailed feasibility engineering evaluation of the predicted emissions impacts and the resultant project budgetary estimates of available “in-furnace” and “gas treatment technologies” to further reduce the NOx emissions rate. GRE indicated that the target NOx emissions rate to be considered in this proposed feasibility study is 0.23 lb/mmBtu with 2 mill operation firing PRB and 0.29 lb/mmBtu with 3 mill operation firing lignite. GRE’s emission rate targets are based on a 30 day rolling average. The evaluation considers only ALSTOM designed products or new design technologies that are within ALSTOM’s experience/expertise. The evaluation also considers NOx reduction improvements that may be applied to the RSFC™ burners in combination with “back-end” gas treatment technologies on boiler 1 at Great River Energy’s Stanton Generating Station, located in Stanton, ND.

A. Inquiry Background

In Spring, 2004, GRE began an extended test-burn of the Powder River Basin (PRB) coal from Kennecott Energy Company’s, Spring Creek Mine, located in Montana. ALSTOM Power’s, Technical Services assisted GRE with boiler and burner performance consultation, and with collecting boiler operating data under various loads and furnace conditions on both boiler 1 and 10. Subsequently, GRE converted the Stanton Station to sustained PRB coal firing in November, 2004 marking the start of a five-year coal purchase contract with Kennecott.

Spring Creek Mine coal was test-fired in both boilers 1 & 10 in November, 1996. GRE’s operational results of the PRB test-burn experiences, furnace and mill impacts, and lessons learned during the 1 month test burn were documented and submitted to ALSTOM. The main problem encountered was coal pulverizers running too hot, and causing pulverizer internal fires. The firing of PRB then, presented many coal and ash handling related problems, as well. ALSTOM is also in receipt of overall plant emissions and proximate coal analysis of the PRB fired during the November, 1996 test-burn. In 1997, boiler 1 originally equipped round burners were removed and retrofitted with new Low NOx technology RSFC™ round burners, designed by ABB C-E Services, Inc. (ABB C-E Services Inc., a predecessor to ALSTOM Power).

GRE’s December 7, 2005 request letter specifies that the primary focus of the study will be the available “in-furnace” NOx reduction burner technologies with less emphasis on “back-end” gas treatment technologies. GRE cautions that due to the furnace volume and furnace retention duration, use of over-fire air (OFA) to reduce NOx, may not be a practical solution. ALSTOM agrees that further detailed studies would be required to carefully assess the furnace conditions and dynamics to arrive at confident NOx reduction strategies. GRE requested that this feasibility study include recommendations to address firing of either the current PRB coal or the former Lignite coal from Dakota Coal Company. GRE requests that the ultimate outcome of the study include a set of feasible NOx reduction alternatives identifying the predicted NOx emissions and their correlating recommended equipment budgetary estimates for both “in-furnace” and “back-end” technologies. A site visit by key members of the ALSTOM Study team was conducted on January 17 and 18, 2006 as the initial study activity.

B. Intent and Objective of Study

The intent of this study is to provide Great River Energy a feasibility engineering evaluation of the potential equipment retrofit alternatives that would allow further NOx emissions reductions by implementing "in-furnace" or "back-end" technologies. Budgetary material estimates (+/-25% accuracy) are developed of the recommended modifications resulting from this proposed study. GRE has also requested that the recommendations should consider the flexibility to revert to either North Dakota Lignite or PRB coal types.

C. Unit Description

Boiler 1, designed and supplied by Foster Wheeler, under FW Contract # 2-79-2009, as a lignite, pulverized coal, front wall fired unit. The boiler was designed for balanced draft furnace operation, natural boilerwater circulation, with a split backpass and attemporator spray flow for SH and RH outlet temperature control, radiant superheat division walls, platen superheater and convective reheater surface The original design maximum continuous rating (MCR) is 1,200,000 lb/hr at 1875 psig and 1005°F superheat outlet steam conditions with 463°F economizer feedwater temperature. There are 2 secondary air and 1 primary air regenerative air preheaters for flue gas heat recovery. Furnace dimensions are 27'- 1-1/4" in depth and 48' – 11-3/4" in width, by 80'-9" in height.

Boiler 1 was originally equipped with 3 – MB 23 Foster Wheeler mills which were later replaced with 3 – 943 RP Combustion Engineering Pulverizers, in 1979. These three mills presently connect to 12 **RSFC™** round burners in a four burner – 3 row arrangement. The originally supplied 20 inch diameter coal pipes were changed to 22 inch coal pipes, in 1979. Each of the 943 RP mills is designed to process 115,900 lbs/hr raw coal feed at 1-1/4 x 0 size, 40 HGI, @ 656°F mill inlet temperature to 65% fineness through the 200 mesh screen.

D. Study Deliverables

ALSTOM deliverables under this study contract are:

1. Provide commentary on coal pipe sizing as it relates to the impact of firing of PRB fuel vs lignite and what, if any, compromise may be expected with NOx emissions between a system that is designed specifically for one fuel vs. a system designed to fire either fuel.
2. Provide commentary on predicted changes in unit NOx, CO, and unburned carbon emissions
3. Provide input on additional changes to the firing system design that may be implemented to address detrimental impacts of PRB firing
4. Provide a list of at least two NOx reduction alternatives categorized by both "in furnace" and "back end" technologies, with budgetary estimates for materials .
5. Where necessary to illustrate a potential modification recommended in the report, ALSTOM will provide conceptual sketches of the suggested modification.
6. Budgetary pricing estimates (+/- 25%) will be provided on a final engineering and material supply basis for suggested modifications to the firing system and back end gas treatment system on boiler #1
7. Preparation of a draft report (for GRE comment) prior to final report release.
8. Study kick off meeting and engineering data gathering on site

E. Study Assumptions

While preparing this study , ALSTOM has made numerous assumptions regarding our analysis ,in conjunction with information gathered during and subsequent to the site scoping trip and kick off meeting. Should GRE desire that ALSTOM revise our assumptions or exceptions, ALSTOM would be pleased to discuss these changes with GRE . The items currently identified as assumptions are as follows:

1. ALSTOM's engineering study estimated NOx based on ten(10) different operating conditions , based on feedwater flow, coal type, and number of mills in service. The specific cases were agreed to between GRE and ALSTOM during the site meeting January 17 & 18, 2006.
2. The PRB analysis used for the study was identified as Sample # 05069253-Sa (Dakota Gasification Company Great Plains Synfuels plant) dated 12/16/2005 ,9:46 am . The complete analysis is shown in Appendix 5.1.
3. The Lignite coal analysis used in the study is that fired during the Alstom Low Nox burner retrofit contract (76797) .The complete analysis of this coal is shown in Appendix 5.1.
4. Alstom has evaluated application of overfire air technology to the unit, assuming current best practice approach to the design, installation, and operation of the overfire system.
5. ALSTOM's study scope does not include the detailed assessment of boiler thermal performance or steam flow capacity, tubing metal temperatures in any section of SH or RH, slagging or fouling or the capability of any boiler equipment such as fans, mills, etc., in achieving the operating conditions used for the basis of the NOx emission predictions.
6. ALSTOM's emission modeling assumes firing 100% of each candidate coal at indicated feedwater flow and conditions assuming the burner /overfire air system optimized for the specific fuel. Additional modeling was performed to predict NOx emissions at all ten(10) different operating conditions, assuming the firing system (burner and overfire air system) is modified to accommodate firing either fuel interchangeably. The study has not included any consideration for blended fuels.
7. ALSTOM's assessment of the current Low NOx system is limited to the equipment originally supplied by C-E (C-E, a predecessor to ALSTOM Power).
8. ALSTOM has assumed that all of the boiler firing and pulverizer equipment and the pressure parts are in good working condition. The assessment offered in this proposal is not intended to serve as a condition assessment of pressure parts or other boiler equipment.

2.0 CONCLUSIONS

2.1 Firing Systems Performance and Emissions Predictions

1. The target NOx level of 0.23 lb/mmBtu appears achievable on the PRB with burner modifications and the addition of an overfire air system, with mill #13 (top mill) out of service, at the "normal, current" feedwater flow of 800 k lb/hr. ALSTOM would predict NOx in the range of 0.18-0.23 lb/mmBtu under these conditions, depending upon final operating excess air and the amount of overfire air used.

2. The target NOx level of 0.29 lb/mmBtu appears achievable on the lignite coal with burner modifications and the addition of an overfire air system, with all mills in service, at the "normal, current" feedwater flow of 870 k lb/hr. ALSTOM would predict NOx in the range of 0.27-0.31 lb/mmBtu under these conditions, depending upon final operating excess air and the amount of overfire air used.

3. Generally, NOx will be reduced at feedwater flows below the above conditions, and, conversely, NOx will increase as feedwater flow increases above those conditions cited above. This is due to the relative contribution from Zeldovitch mechanism NOx, commonly referred to as thermal NOx. Thermal NOx is formed by the atmospheric fixation of nitrogen and oxygen at high (> 2600ºF) temperatures. Higher feedwater (steam) flows require greater coal feed rates, which contribute to higher furnace gas temperatures. A detailed breakdown of predicted NOx for the seven(7) PRB coal firing cases and the three (3) Lignite coal firing cases is given in Appendix 5.2 of this report.

4. Based on prior testing at GRE Stanton Unit 1, as well as ALSTOM field experience elsewhere, lowest NOx will be achieved with Mill 13 (top mill) out of service, as compared with having Mill 12 (bottom mill) out of service. The unit operates in a "simulated overfire air mode" with the top mill out of service, which tends to reduce overall NOx emissions. ALSTOM would predict similar result given the assumption of future modifications to the firing system to add overfire air technology.

5. Operation of Unit 1 above the current feedwater (steam) flow levels of 800k lb/hr on PRB coal (i.e. with all mills in service) would reduce the potential for meeting the 0.23 lb/mmBtu NOx target for this fuel. ALSTOM would anticipate NOx in the overall range of 0.36-0.40 lb/mmBtu with the current low NOx burner only arrangement with all mills in service at feedwater flows in the 900-1100 k lb/hr range. With low NOx burner modifications and an overfire air system retrofits implemented, ALSTOM would estimate NOx in the range of 0.25 –0.32 lb/mmBtu, at feedwater flows in the 900-1100 k lb/hr range with all mills in service on the PRB fuel. The study did not consider operation of the unit on lignite at feedwater flows in excess of 870 k lb/hr per agreement with GRE.

6. CO emissions are a strong function of the efficiency of combustion, which is dependent on a multitude of system design and operating parameters. Operating excess air (O2) levels in the furnace, fuel reactivity, furnace residence time, and fuel/air mixing effectiveness all have a first order effect on CO emission levels. Based on historical CO emission data from prior unit testing with the PRB fuel, using the multipoint grid in the flue gas stream, the current CO levels on PRB can be less than 10 ppm, but appear to be more typically on the order of 100ppm average(corrected to 3% O2). Measured CO level during the low NOx burner retrofit guarantee tests was 32 ppm (corrected to 3% O2), but can be higher based on operational variables. From ALSTOM field experience with firing both PRB and lignite coals in utility boilers, the CO would be expected to increase somewhat post retrofit to an overfire air system, as staged

combustion slightly delays the fuel/air mixing (to lower thermal and fuel NOx) necessary to minimize CO. ALSTOM would therefore anticipate CO emissions on the order of 100 to 300 ppm post retrofit to a low NOx system using overfire air on PRB coal. CO emissions on the order of 100 to 300ppm would be likely on the lignite coal. These values are very sensitive to firing system and boiler controls tuning and operation, and may vary substantially based on unit condition and operation variations. CO can increase exponentially as excess O2 is lowered or allowed to vary below nominal threshold levels .

7. Unburned carbon in flyash (UBC) levels are typically less than 1% by weight with the current low NOx burner system. Both the PRB and lignite coals fired are reactive coals, in terms of both ignitability and carbon burnout characteristics. One measure of a coal's relative reactivity is its fixed carbon to volatile matter ratio. The specified PRB coal has a FC/VM ratio of 1.22, and the lignite ratio is 0.99, these ratio values are indicative of very reactive coals with low unburned carbon in flyash levels expected. Some increase in UBC may be expected with the addition of an overfire system, due to the inherent fuel/air staging as well as limited upper furnace residence time in Unit #1. It is expected that UBC levels would remain below 2% post retrofit to an overfire air low NOx system.

8. A review was conducted of current coal pipe size (diameter) vs. coal /mill transport air velocity at measured transport air/fuel ratios on the PRB coal. The standard maximum airflow thru a 943 RP mill is 3300 lb/min. For PRB, the expected transport air/coal (A/F) ratio should be 3.55 at the "typical" feedwater flow of 800k lb/hr, with two (2) mills in service. This is generally consistent with the measured values of A/F ratio in ALSTOM test report dated Dec, 2005. Under these conditions, coal velocities of 93.5 ft/sec can be expected firing PRB, calculated for a 21" I.D. coal pipe. This velocity slightly exceeds the ALSTOM design standard velocity of 70-90 ft/sec. ALSTOM would expect negligible negative impact on firing system performance at the calculated velocity. ALSTOM would also expect negligible impact on erosive wear in the coal pipes and/or coal nozzle at the calculated velocity.

9. A review was conducted of current coal pipe size (diameter) vs. coal /mill transport air velocity at measured transport air/fuel ratios on the lignite coal . The standard maximum airflow thru a 943 RP mill is 3300 lb/min. For lignite, the expected transport air/coal (A/F) ratio should be 3.62 at the "typical" feedwater flow of 870k lb/hr, with three (3) mills in service. Under these conditions, coal velocities of 94.7 ft/sec can be expected firing lignite, calculated for a 21" I.D. coal pipe. This velocity slightly exceeds the ALSTOM design standard velocity of 70-90 ft/sec. ALSTOM would expect negligible negative impact on firing system performance at the calculated velocity. ALSTOM would also expect negligible impact on erosive wear in the coal pipes and/or coal nozzle at the calculated velocity.

10. ALSTOM has reviewed the current coal piping and future low NOx burner/overfire air system in terms of flexibility of operation on either PRB coal or lignite coal, and has determined that either fuel could be fired interchangeably, in terms of coal pipe/ and burner coal nozzle velocity within ALSTOM design limits. This conclusion is valid with two (2) mills in service firing PRB @ feedwater flow of 800k lb/hr, and with three (3) mills in service firing lignite @ feedwater flow of 870 k lb/hr. It should be noted that ALSTOM expects NOx emissions to vary dependent on the fuel fired, as above.

11. For reference, ALSTOM has calculated expected coal (pipe) velocities when firing PRB with all three mills in service at a feedwater flow of 900k, 1000k, and 1100 k lb/hr (consistant with Case's 5, 6 and 7). Although the boiler cannot currently sustain these feedwater flow levels, it is noted that the coal (pipe) and burner coal nozzle tip velocity will be on the order of 93.3,

93.4, 93.5 ft/sec, respectively, which slightly exceeds the ALSTOM design standard velocity of 70-90 ft/sec. ALSTOM would expect negligible negative impact on firing system performance at the calculated velocity. ALSTOM would also expect negligible impact on erosive wear in the coal pipes and/or coal nozzle at the calculated velocity.

12. 12. ALSTOM has reviewed how long term operation with PRB may affect firing system performance. Beyond the emissions impacts cited above, it is suggested that refractory throat modifications be made along with air register modifications. These modifications would be required in conjunction with installation of an overfire air system. The modifications would serve two purposes. First, they would account for the percentage of secondary air flow diverted from the burner air registers to the overfire air ports, required to optimize secondary air velocity thru the burner register with overfire air in operation (consistant with Company design standards) and to achieve best burner performance in terms of emissions, turn down, flame shaping, and flame stability. Secondly, the refractory throat modifications would reflect latest ALSTOM field experience to minimize or avoid slagging or “burner eyebrows”.

13. Based on preliminary firing system design of a Low NOx system incorporating burner modifications with overfire air, the current burner air register should be modified for a target heat input consistent with a realistically achievable steam flow target. In general, the current air registers are oversized for the “typical”, current day, feedwater flows in the 800-870 k lb/hr range. <u>IF</u> GRE plans to continue operation at these feedwater flows, and add overfire air to further reduce NOx in the future (with either 2 mill operation on PRB or 3 mill operation on lignite), ALSTOM would recommend modifications to downsize the burner air registers.

14. If GRE intends to operate with three mills in service with PRB coal at feedwater flow rates in excess of the current 870 k lb/hr “typical“ MCR condition, it is suggested that a comprehensive boiler thermal performance study would also be recommended to access feasibility of same and equipment modifications that may be required to achieve same.

15. ALSTOM has completed a preliminary design for an overfire air system based on target NOx reduction requirements, boiler physical layout, equipment interferences and obstructions as determined in the site scoping trip, and current day “typical “ operating feedwater flows. The preliminary design is comprised of four (4) each overfire air ports, located directly above each column of burners on the front wall of the boiler. The centerline of the overfire air ports would be located at approx elevation of 1754’. The main burner windbox would be the source of (secondary) air for the overfire air ports, four (4) each simple ducts (with flexible joint) would be installed at the top of the windbox to divert a portion of the main windbox secondary air to the overfire air assemblies. This location has proven successful in several Company installations of RSFC burners with overfire air. Side wall overfire air was considered, but optimum performance would not be expected with this configuration. Side wall overfire air would also require more extensive (and expensive) ductwork installation, with takeoffs from each side of the main burner windbox. A schematic of the proposed overfire air arrangement is shown in the attached conceptual drawing.

16. The estimated budgetary cost (engineering and materials) for the proposed overfire air system and associated RSFC burner modifications is $644,000.00. More detail of the cost estimate and scope of material supply is shown in section 3.0.

2.2 SNCR Conclusions

The following table summarizes the SNCR conclusions. See Appendix 5.4 at the rear of this report for more detailed material information.

DESIGN CRITERIA	**Case 1**	**Case 2**	**Case 3**
Type of Furnace	FW PC		
Fuel Fired	PRB	PRB	Lignite
Mills in Operation	3	2	3
Maximum Heat Input (mmBtu/hr)	1489	1191	1295
Uncontrolled NOx; (lb/mmBtu)	0.38	0.27	0.40
lb/hr	566	322	518
Percent NOx Reduction	20%	15%	27.5%
Controlled NOx (lb/mmBtu)	0.304	0.23	0.29
lb/hr	453	274	378
NOx Removed lb/hr	113	48	142
Expected NOxOUT® A Flow (gph)	84	38	94
Furnace CO, (ppm)	<200	<200	<200
Expected Ammonia Slip (ppm,as measured)	5	5	10
Flue Gas Temp (°F)	2150 to	2000 to	2050 to
	2250	2100	2150
Injectors – Level 1 Wall Injectors	9	9	9

2.3 SCR Conclusions

The following table summarizes the SCR conclusions. See Appendix 5.5 at the rear of this report for more detailed material information.

NO_x removal	90% minimum 24 hour average
Draft Loss	Not to exceed 4 inches of WG, from the economizer outlet to the air heater inlet.
Ammonia Slip	Not to exceed 2 ppm
Catalyst life	8000 hr. of operation, or 12 months from initial operation, whichever occurs first.
SO_3 Oxidation.	Less than 1.2% as measured during the first month of operation.
Ammonia consumption as NH3	Not to exceed 370 lb./hr

3.0 RECOMMENDATIONS

3.1 Modifications to Radially Stratified Flame Core (RSFC™) Burners

Item	Quantity	Description
1.	Twelve (12)	RSFC™ burner air register modifications ,comprised of a cylindrical sleeve in teriary air zone .and revised inserts in primary and secondary zone swirler assemblies .
2.	One (1) Set	Drawings for revised burner throat refractory profile to meet RSFC™ requirements
3.	One (1) Lot	SAMA control diagrams which illustrate proposed function of burner /SOFA dampers
4.	One (1) Lot	General arrangement drawings illustrating burner modification installation instructions and weights

Equipment Required for Separated Overfire Air (SOFA) Installation

5.	Four (4) each	SOFA registers with two (2) compartments, top and bottom crotch cooling air; complete with manual adjustable yaw and tilt nozzle tips, partition plates, dampers and necessary linkages
6.	Four(4) each	Seal boxes for above SOFA registers(tube sheet to SOFA register seal
6.	Four(4) each	Shop optimized tube panel assemblies (26” wide, 2.5” OD fined tubes on 3.25” centerlines)
7.	Four(4) each	OFA ductwork to connect SOFA registers to takeoff at top of existing burner windboxes (with flexible joint)
8.	Eight (8)	Electric rotary drive mechanisms for the OFA register damper control – [Two (2) per register](modulation with steam flow rate)
9.	As Required	SOFA guides, windbox structural modifications, Insulation and lagging
10.	One (1) Lot	General arrangement drawings illustrating SOFA and SOFA ductwork installation instructions and weights
11.	One(1) Lot	Commissioning staff for a three week period to observe final burner/SOFA installation, make initial burner adjustments prior to post outage boiler startup, support demonstration of design heat input operation, tuning to make final adjustments to firing system to meet predicted levels of performance, and observation and support during final guarantee tests. Includes supply of temporary economizer outlet gas sampling test probes grid (O2/CO/NOx) and instrumentation to support initial burner /SOFA commissioning and tuning

3.2 SNCR Recommendations

The proposed NOxOUT® SNCR system for all three design cases would consist of a 20,000 gallon FRP heated and insulated Reagent Storage Tank that would feed into a Circulation Module (SLP3-C) installed in a heated enclosure located near the tank. This would provide reagent feed to a Redundant Pump Metering Module (SPL3-RP) that will automatically meter the reagent into a dilution water stream based on the demands of the system.

The diluted reagent is then pumped to a distribution module that will then control the flow of diluted reagent and atomizing air to one level of 9 wall injectors installed through the waterwalls in the upper furnace. The flow to the injectors is automatically controlled based on the operation of the unit and is determined during start-up and optimization of the system. See Appendix 5.4 for greater detail of recommended system components

3.3 SCR Recommendations

The following equipment is recommended to achieve 90% NOx reduction

QUAN.	ITEM	DESCRIPTION
SCR Reactor and Accessories		
1 Only	**SCR Reactor**	SCR Reactor, carbon steel
4 Only	**Soot Blowers**	Sonic type soot blowers
60 Only	**SCR Catalyst Modules**	High dust type catalyst.
1 Lot	**Access**	Access at each catalyst level
1 Lot	**Catalyst Handling Equipment**	catalyst handling and hoisting equipment,.
1 Lot	**Ductwork**	1/4” carbon steel ductwork.

Mechanical Equipment, Ammonia System

QUANTITY	ITEM	DESCRIPTION
2 Only	**Dilution Fans**	One (1) operating, one (1) spare unit.
1 Lot	**Ammonia Vapor Piping**	from ammonia storage tank to injectors
1 Only	**Ammonia Injection Grid and mixer**	Ammonia injection grid inlet of SCR

ELECTRICAL Equipment

QUANTITY	ITEM	DESCRIPTION
SCR, Ammonia and Ash Systems		
1 Only	**Field Instruments**	Instrumentation and controls
1 Only	**PLC and Control Logic**	PLC controller with I/O
1 Only	**SCR Inlet Gas Analyzer & Monitoring System**	Complete with microprocessor based NOx, and oxygen analyzers

4.0 Discussion/Study Methodology

4.1 Discussion

During the site visit, GRE raised a question concerning the reasons and logistics of constructing a single cell SCR versus construction of three (3) separate SCRs for each of the three air preheaters.

ALSTOM responds to this question with the following: The current temperatures at the economizer outlet are too high for SCR operation at some load conditions and too low at other load conditions. This is made more extreme if one considers the three air heaters separately. The existing economizer needs to be reworked with either a water or gas bypass or some alternate form of SCR gas inlet temperature control and the existing three small airheaters replaced with one or two modern design trisector air heaters. ALSTOM ECS is basing the design at Stanton on the use of a single SCR reactor.

The ALSTOM ECS conceptual drawings of the SCR includes work termination points (ductwork points) in correlation to the material estimate.

The SCR gas inlet conditions of 0.5 lb/mmBtu is the basis upon which the 0.05 lb/mmBtu controlled outlet NOx is predicted (90% reduction). The output NOx predictions is based on an inlet NOx and an bulk inlet gas temperature between 600°F and 800°F.

After review of the operating data and plant GA drawings, ALSTOM ECS has the following comment to the SCR design:

> The flue gas temperatures leaving the economizer often vary outside the normal range of operation for the SCR. This will require modification to the economizer and air heaters in order to bring the temperature within an acceptable range. The three air heater design is typically unsuitable for use with an SCR system. We would recommend that they be replaced with a trisector design. The SCR reactor is best located above the air heater section of the building. In order to properly route the ductwork from the economizer to the air heater, extensive modification to the building will be necessary. After completion of these modifications, NOx emissions of .05 lb/MBtu should be achievable.

4.2 Methodology

To address the impact of firing 100% Spring Creek, lignite, or a combination of the two, ALSTOM's methodology was to:

- Review the laboratory coal analysis of coals provided by GRE.
- Using test data from PRB testing (supported by ALSTOM field staff) during April and May of 2004, and Sept/Oct 2005, as well as the final low NOx burner guarantee tests (on lignite) as a baseline, ALSTOM's Firing Systems Engineering (FSE) assessed potential impacts that may occur in the firing system with the current low NOx burner arrangement and with future overfire air installation.

4.3 NOx Predictions at Specified Conditions

ALSTOM completed a detailed series of NOx predictions under several operating conditions. These results can be found in Appendix 5.2

APPENDIX 5.1 PRB and Lignite FUEL ANALYSIS

Table 6

Unit #1	PRB* As received % by wt	Lignite** As received % by wt
Moisture	25.08	35.47
Ash	3.75	8.17
Sulfur	0.35	0.68
Gross Calorific value (Btu/lb)	9350	6896
Sodium oxide total in ash	5.57	n/a
Volatiles	32.1	28.35
Fixed carbon	39.1	28.01
Carbon	55.2	41.43
Hydrogen	6.55	2.63
Nitrogen	0.648	0.65
Oxygen	33.5	10.97

** Ref: 1996 Low NOx burner guarantee tests

Table 6 Coal Analysis Comparisons

The Spring Creek coal analysis presents a typical analysis for a Sub. Bit "C" Powder River Basin coal. This coal is highly reactive with a low FC/VM ratio of 1.22 and is conducive to low NOx emissions, low sulfur emissions and low flyash unburned carbon levels. The Spring Creek coal has a heating value approximately 25% higher than the lignite coal. The Lignite coal, which is also very reactive, has a lower FC/VM ratio of 0.99 compared to the PRB. As received coal sulfur levels for the lignite coal is approximately twice the level of the PRB coal (0.68 % by weight vs 0.35 % by weight), but on a corrected lb/mmBtu basis , lignite is approximately 1.0 lb/mmBtu sulfur, vs, approximately 0.4 lb/mmBtu sulfur for PRB.

APPENDIX 5.4 SNCR Proposal Letter

For this application, the following cases have been evaluated:

Case 1: For 3 mill operation burning PRB, the SNCR System will provide a 20% NOx reduction from a baseline of 0.38lbs/mmBTU with 5 ppm ammonia slip.

Case 2: For 2 mill operation burning PRB, the SNCR System will provide the requested 15% NOx reduction from a baseline of 0.27lbs/mmBTU with 5 ppm ammonia slip.

Case 3: For 3 mill operation burning Lignite, the SNCR System will provide the requested 27.5% NOx reduction from a baseline of 0.40lbs/mmBTU with 10 ppm ammonia slip..

The proposed NOxOUT® SNCR system for all the cases would consist of a 20,000 gallon FRP heated and insulated Reagent Storage Tank that would feed into a Circulation Module (SLP3-C) installed in a heated enclosure located near the tank. This would provide reagent feed to a Redundant Pump Metering Module (SPL3-RP) that will automatically meter the reagent into a dilution water stream based on the demands of the system.

The diluted reagent is then pumped to a distribution module that will then control the flow of diluted reagent and atomizing air to one level of 9 wall injectors installed through the water walls in the upper furnace. The flow to the injectors is automatically controlled based on the operation of the unit and is determined during start-up and optimization of the system.

The NOxOUT® Process incorporates the controlled injection of a 50% urea based reagent in to the furnace at gas temperatures of 1600 to 2200 ^{0}F to reduce NOx to N_2, CO_2 and H_20. The Process has been successfully applied to nearly 350 units worldwide include more than 30 utility boilers up 700MW.

The NOxOUT® A reagent, a 50% urea based solution, would be supplied by tank truck from licensed suppliers.

The budgetary proposal for the NOxOUT® SNCR system is as follows:

PROCESS DESIGN TABLE

	Case 1	**Case 2**	**Case 3**
Type of Furnace	FW PC		
Fuel Fired	PRB	PRB	Lignite
Mills in Operation	3	2	3
Maximum Heat Input (mmBtu/hr)	1489	1191	1295

APPENDIX 5.5 *SCR Assessment*

1.0 DESIGN INFORMATION

1.1. GENERAL

The following description applies to the SCR systems for the Stanton plant.

Selective Catalytic Reduction (SCR) is a method of reducing the amount of nitrogen oxides (NO and NO_2) in the flue gas of fossil-fired industrial and electric utility equipment. The SCR system is comprised of various components, with the central component being the catalytic reactor that contains the catalyst. This catalyst is typically an active phase of vanadium pentoxide on a carrier of titanium dioxide, formed into elements of a parallel flow configuration. Plates or extruded ceramics (honeycomb design) are used as the substrate for the elements onto which the active material is deposited. Elements are then assembled into larger blocks called modules, which are combined into layers in the reactor. The reactor has one layers of catalyst modules, and operating temperature for the catalyst/reactor is normally 650° to 800°F.

The SCR technique uses a reducing agent, ammonia, to convert the NO_x to nitrogen (N_2) and water vapor on the catalyst surface. The ammonia is introduced into the flue gas duct ahead of the SCR reactor and catalyst, and is diluted with air before injection to aid in distribution. On the catalyst surface, the primary chemical reactions that occur are:

$$4\ NO + 4\ NH_3 + O_2 \Rightarrow 4\ N_2 + 6\ H_2O$$

$$NO + NO_2 + 2\ NH_3 \Rightarrow 2\ N_2 + 3\ H_2O$$

Other reactions between NO_x and ammonia will also take place but to a minor extent. The main components produced are nitrogen and water, which both are harmless compounds. One mole of ammonia reacts with one mole of NO_x. Some ammonia will leave the catalyst unreacted, and is referred to as ammonia slip.

ALSTOM has endeavored to provide a system that matches the plant requirements as closely as possible. ALSTOM would be pleased to discuss the design premises in detail to clarify any assumptions and provide GRE with the most economical and reliable system possible.

BASE BID:

For the Base Bid, ALSTOM offers to provide an SCR Reactor system to reduce the NO_x emissions by 90%. The scope will generally include:

- SCR reactor and catalyst
- static mixers
- sonic sootblowers
- analyzer system
- anhydrous ammonia injection system
- controls and instrumentation for the equipment and processes offered
- cold flow modeling

SCR System for GRE Stanton

ALSTOM is proposing the use of one (1) SCR reactor to treat the flue gas at the Stanton Plant. Flue gas from the boiler after the economizer sections will pass through the SCR and then through the air heaters. The ammonia injection system will employ anhydrous ammonia from an existing storage facility.

Plate type catalyst will be used in the reactor, with a 6.4 mm pitch spacing to meet a 90% NOx reduction.

The reactor is designed with a superficial velocity of about 12 feet per second. Each catalyst layer will be comprised of modules, with the installed module size being approximately 1 meter x 2 meter x 1.5 meter high.

The reactor is designed to accommodate one layer of catalyst. A second layer is provided as a warehouse spare. These layers will be exchanged when necessary to maintain continued performance. The used layer will be washed and stored for reuse at the next scheduled exchange point.

1.2 Operating and Design Conditions

1.2.1 Economizer Outlet Conditions

Alstom is using the customer specified design conditions for the SCR system.

2.0 ADDITIONAL TECHNICAL INFORMATION

EQUIPMENT DESCRIPTIONS

SCR System

The SCR System offered consists of catalyst modules, framework, pedal protection (grating), and sonic sootblowers. The catalyst modules are located in one, high dust, vertical downflow reactor. The reactor is located between the boiler economizer outlet and the air heater inlet. The SCR reactors are of outdoors design, operating under negative pressure conditions.

Catalyst System

The operating life of the catalyst is 8,000 hours of operation between washings.

To minimize the catalyst cost over the plant lifetime, the catalyst activity must be monitored. The objective is to maximize the useful life of the catalyst with minimum investment cost. Accumulation of Vanaduim containing flyash will over time cause the SO2 to SO3 oxidation rate to increase. When this reaches an unacceptable level the catalyst should be removed and washed. Tests have shown that after washing the catalyst performance will return to its original level. A second warehouse spare layer of catalyst has been provided to allow for expeditious exchange of the installed catalyst layer followed by washing on a more relaxed schedule.

To gauge the deactivation of the catalyst, a number of coupons may be installed with the initial catalyst in the reactor. These pieces are periodically removed and tested for their remaining activity in a laboratory. ALSTOM proposes that testing be carried out by removing several plates from an installed module. Annual activity testing on a total of 3 coupons is included for the estimate period.

Catalyst Handling System

The catalyst handling system is designed allow the removal and replacement of the catalyst layer when necessary. Replacement of a catalyst layer is considered to be an outage activity and generally can be accomplished within approximately one (1) work week with the removal system offered.

The catalyst is supplied in modules, approximately 1m x 2m in plan area and 1.5m high. (3’-3” x 6’-6” x 5’ high). Each module weighs approximately 3000 lb. The modules consist of a steel box filled with catalyst and with top lifting attachment points. The modules are base supported on beams with sealing strips when installed.

Lifting equipment supplied by ALSTOM includes carts for transport of the modules inside the reactor, special lifting beams for attachment of hoists to the module attachment points, air powered chain hoists for transport of the modules into and out of the reactor.

The handling procedure for addition of new catalyst to the empty layer is as follows: The new catalyst modules are delivered to the plant and stored at grade. A plant forklift is used to bring the catalyst modules to the lifting points under the electric cable lift. The special lifting beam is attached to the module. The cable lift is used to bring the module up from grade to the installation level. The cable lift is mounted on a beam or jib crane that can move under power and set the module on a work platform at the catalyst entrance door to the reactor. After the cable hoist is unhooked, the air powered chain hoist is used to lift the module a few inches off the platform for transport into the reactor. The chain hoist also has an air powered trolley. Inside the reactor, the module is lowered onto the cart for final transport between support beams to its final installed position. Sealing strips are attached to the top of the support beams before the module is lowered onto them. The workers push the cart into position, lower the module onto the strips and pull the cart back to receive the next module. The air-powered hoist can be used to move the cart from track to track. The only manual moving of the module is rolling the cart a maximum of 20 ft. All other operations are powered.

Removal of spent modules is accomplished in reverse of the above procedure.

Replacement Program/Design Margins

Based upon results from catalyst coupon tests at the Stanton plant, a deactivation rate of 10% per operating year is expected. To cover these ranges, a safety margin has been included in the catalyst design. Certain additional margin has been included for uneven distribution of flue gas parameters such as velocity, temperature, NO_x concentrations and stoichiometric ratios. Also based on coupon tests, the SO2 to SO3 oxidation is expected to increase significantly over time due to Vanadium contamination from the fly ash.

Catalyst Sealing System

To avoid flue gas leakage, the modules are placed on seals between the support structure and the modules. On top of the modules there will be baffle plates installed between adjacent modules to avoid dust deposits in that area.

Ammonia Injection / Mixing

The purpose of the ammonia injection system is to expose the entire catalyst section with an even distribution of ammonia upstream of the first catalyst layer. ALSTOM typically designs to a specific gas flow variation coefficient upstream of the injection grid. This is achieved by means of proper duct design, utilizing ALSTOM's experience with gas modeling, duct bends and vaning. The process uses ammonia gas from the existing storage tanks and meters it, as required by boiler load, into a constant flow of hot dilution air. This 20:1 dilution avoids any risk of handling an explosive mixture of ammonia in air. A static mixer is located in the dilution air pipe downstream of the ammonia line to ensure proper mixing of the ammonia in the dilution air. Ammonia concentration is kept below the lower flammability limit. The ammonia/air mixture is injected into the flue gas duct, through a specially designed injection grid, upstream of the catalyst. This grid has been designed to work together with a sophisticated flue gas mixer to assure uniform distribution of the ammonia and NOx. The flue gas mixer allows the design of the grid to be greatly simplified. Only 28 injection points are required for this application. This design does not require tuning the AIG, thus eliminating all the balancing valves and flow meters on the grid. Use of a nonadjustable grid reduces the time needed to commission the system and also reduces the annual maintenance required.

ALSTOM proposes to use the patented Sulzer type SMV flue gas mixer as illustrated above. A static SMV gas mixer is made up of one or more mixing elements. These consist of corrugated plates which form intersecting channels. The mixing effect takes place between two neighboring plates by a relative displacement of part of each flow, as well as due to the increased turbulence at the open channel intersections. Two mixing elements, oriented 90 degrees from each other, are required to produce a homogenous mixture across both the x and y axes of the duct. Two additional stages of mixing take place in the open duct immediately downstream of each mixing element. This is due to the segmented flow streams that exit the SMV element at various angles to the main axis of the duct and intersect with each other in free space.

Sulzer Chemtech is the worlds leading supplier of static mixers, mixer-heat exchangers and plug-flow reactors. More than 25 years of experience in static mixing results in unique technology, proven design, economical solutions and competent support.

Anhydrous ammonia, per the specification, is being employed as the ammonia type. This ammonia gas is extracted from existing connections on the top of the existing ammonia storage tanks. A new pipeline will run along the existing piperack to transport this gas from the ammonia tanks to the boiler building. Flow from the tanks to the dilution air duct is regulated by a control valve, which receives its signal from the overall SCR control logic.

Fans located near the ammonia injection grid supply dilution air. This dilution airflow is fixed and is set to maintain approximately a 20:1 air/ammonia ratio at maximum ammonia flow to the system. This air/ammonia mixture will be directed to the ammonia feed duct at the nozzle grid.

The preliminary design of the ammonia injection grid calls for 28 injection pipes entering the gas duct ahead of the SCR reactor. Each pipe is about 3 inches in diameter. The location of these 28 injection points is coordinated with the design of the mixer. Duct penetrations are staggered to reduce flue gas pressure drop but, at the same time, provide good mixing of ammonia with the flue gas.

Sootblowers

Sonic Sootblowers are being included to aid in the prevention of the accumulation of deposits. They have proven themselves effective in high dust plants with both coal and oil firing. All reactor levels should be cleaned from reactor top to reactor bottom. An initial cleaning frequency of at least once per hour is recommended, with adjustments made as required.

NO_x Control System

General Control Principles

The most common way of controlling the ammonia injection is to use a set point for the outlet NOx concentration, thus keeping the NOx emission at a constant level across the entire load range of the SCR reactor. The objective is to maintain the emission just below the design point in order to reduce ammonia consumption at lower boiler loads, and lowest achievable ammonia slip.

Alternatively, NOx removal efficiency can be fixed and the control system will calculate a required outlet NOx concentration at any operating condition. The operator would select the choice of control method.

Operation

The required outlet NOx emission initiates process control. As described, the outlet will either be fixed directly or calculated based on the inlet concentration and the desired removal efficiency. Measured NOx concentrations at the SCR inlet, provided by Alstom, and outlet, using the existing CEM, are corrected to standard O_2 levels.

The inlet NOx concentration is used in conjunction with the fixed or calculated NOx outlet value and the flue gas flow rate to determine the mass flow of NOx to be removed. This mass flow is used by the control logic in conjunction with the required mole ratio (NH3/NOx) to determine the mass flow of ammonia needed for the reduction. The controller increases or decreases the ammonia flow, depending on the difference between the NOx outlet set point and the actual NOx outlet value measured downstream of the SCR reactor.

Electrical Controls and Instrumentation

ALSTOM will provide all field instrumentation, PLC hardware, and control logic for the SCR system described herein, including engineering design, drafting and documentation for ALSTOM supplied equipment.

ALSTOM will also provide training and assistance to the customer during the installation of the control equipment for the entire SCR system and its associated processes.

SCR/Ammonia Start up And Shut down Procedures

To start up and shut down the SCR system, the following general procedures and sequences shall be followed. Depending upon the overall system design and layout, certain modifications to the procedure may be necessary and, if so, will be provided by ALSTOM.

Start Up Procedure

1. Prepare the unit for purge by positioning boiler gas path dampers according to manufacturers recommendations, starting fans and airheaters.
2. Purge the boiler, SCR reactor, airheater, and duct.
3. Verify ammonia tank level and pressure. Verify that all isolation valves from the ammonia tank to the flow control valve are open. However do not open the ammonia flow control valve to the dilution air duct.
4. Verify that the sootblowing sequence is activated and that correct airflow and pressure is available to the soot blowers..
5. Place auxiliary fuel firing equipment in service as required for boiler warm-up.
6. Wait until the SCR reactor has passed the established acid dew point temperature, and the flue gas temperature leaving the reactor is above 300 °F.
7. Begin firing solid fuel.
8. Heat the SCR reactor with flue gas until the temperature in the SCR reactor is above the minimum catalyst operating temperature.
9. Start the ammonia injection system control loop and slowly open the ammonia control valve.

Shut Down Procedure

1. Shut off the ammonia supply valve and stop the ammonia injection system control loop.
2. Stop fuel feed to the boiler and continue operation of fans until flue gas has been purged from the entire gas path.

Air Heater Washing

It has been our experience that properly operated plants using SCR units designed for less than 3 ppm of ammonia slip require minimal (once or twice per year) washing of the air heater to control bisulfate formation. Operation outside of the design conditions for the system can easily result in excessive slip and high air heater pressure drop. It is important that the system be both properly designed and operated for satisfactory performance.

Flue Gas Flow Modeling

Gas flow design and modeling is one of ALSTOM Power's primary areas of expertise. We maintain two in house laboratories for gas flow modeling and an extensive staff of people experienced in building, testing, and interpreting the results of gas flow models. The proper design and operation of most of our pollution control equipment, low NOx burners, and large fans are dependent on well-controlled gas flow distribution in the equipment and surrounding ductwork.

ALSTOM has been designing SCR equipment for large boilers since 1985. Every plant is unique and requires a custom solution to achieving proper gas distribution. We have included a gas flow model for Stanton in our proposal to assure optimum performance of the SCR.

3.0 CONSTRUCTION/DESIGN FEATURES

Reactor Vessel

The SCR Reactor will be fabricated from carbon steel plate and will be externally stiffened. The Reactor is configured to hold one layer of catalyst. A second layer will be also be supplied and stored by Haldor Topsoe for future installation when needed. Flow turning, straightening, and mixing vanes are provided in the reactor to optimize the removal of NO_x and maintain minimum flue gas pressure loss.

Catalyst Modules

Catalyst modules, completely assembled and ready for installation into each reactor chamber, will be provided. The catalyst material will be titanium dioxide with tungsten and molybdenum oxides and vanadium pentoxide as the active components. Molybdenum oxide provides protection against poisoning by trace elements. Lifting lugs are provided on each catalyst module for ease of installation and maintenance into and out of the reactor chamber. To avoid flue gas leakage, the modules are placed on sealing strips between the support structure and the modules. On the tops of the modules baffle plates are installed between the modules to avoid dust deposits.

Framework for Modules

The framework for the catalyst modules will be fabricated from steel. Hot-rolled steel shapes and plates will be ASTM-A36. High strength bolts will be ASTM-A307 and/or ASTM-A490. Machine bolts will be ASTM-A307. Structural welding will conform to the Structural Welding Code AWS D1.1. All framework materials will be compatible with the catalytic material. Proper internal module sealing between the plate catalyst and module frame will be provided, where applicable. To facilitate placement and removal of the individual modules, spacing will be provided along two (2) adjacent sides of each reactor, with flashing installed once the modules are in place.

Grating

Grating (pedal protection) on each module face will be furnished. The grating is provided for ease of internal maintenance and inspection. Grating material is of stainless steel, providing corrosion and erosion resistance. Both grating and structural detail drawings will be provided to GRE, and will be compatible with the process and operating requirements.

Special Tools

All special tools required for the installation and normal maintenance of the modules will be provided. A cart will be provided within the reactor chamber for individual module positioning. An overhead electric crane will be positioned to allow for the removal and replacement of the modules.

4.0 SCOPE OF SUPPLY - Typical each boiler.

4.1 Mechanical Equipment, SCR System

QUAN.	ITEM	DESCRIPTION
SCR Reactor and Accessories		
1 Only	**SCR Reactor**	SCR Reactor, fabricated from carbon steel plate, externally stiffened. The Reactor is configured to hold one layer of catalyst. Flow turning, straightening, and mixing vanes are provided to optimize the removal of NO_x and maintain minimum flue gas pressure loss.
4 Only	**Soot Blowers**	Sonic type soot blowers to maintain gas passages through the SCR catalyst system.
60 Only	**SCR Catalyst Modules**	High dust type catalyst. The catalyst material is furnished installed in a steel framework with a nominal size of 1m x 2m plan area and a height of approximately 1.5m. The catalyst pitch is nominally 6.4mm (including 1 wall at 0.8 mm).
1 Lot	**Access**	Access will be provided at each catalyst level, including 2’ x 3’ quick opening doors for internal inspection and larger doors for catalyst removal and replacement.

1	Lot	**Catalyst Handling Equipment**	The SCR Reactor is equipped with a complete set of catalyst handling and hoisting equipment, including carts, air powered hoist, electric hoist, and crane beams that provide a permanently installed method of removing and replacing catalyst blocks. This handling equipment is further described in section 5.
1	Lot	**Ductwork**	1/4” carbon steel ductwork with appropriate stiffening and supports. Ductwork extends from the economizer outlet to the SCR and from the SCR to the air heater.

4.2 Mechanical Equipment, Ammonia System

QUANTITY		**ITEM**	**DESCRIPTION**
Ammonia Injection System and Accessories			
2	Only	**Dilution Fans**	One (1) operating, one (1) spare unit. Dilution air fans taking suction from the air heater hot air discharge and diluting the ammonia vapor 20:1 before injection into the duct.
1	Lot	**Ammonia Vapor Piping**	Ammonia vapor / air mixture piping and distribution from the ammonia storage tank to the duct injection grids. Dilution air duct from the existing hot combustion air duct to the dilution air fans and from the fans to the AIG.
1	Only	**Ammonia Injection Grid and mixer**	Ammonia injection grid in the SCR inlet flue gas duct followed by a flue gas mixer.

4.3 ELECTRICAL Equipment

QUANTITY		ITEM	DESCRIPTION
SCR, Ammonia and Ash Systems			
1	Only	**Field Instruments**	Instrumentation and other related accessories for the operation of the SCR by the Alstom provided PLC system.
1	Only	**PLC and Control Logic**	PLC controller with I/O as needed to control the operation of the SCR. A data highway port will be provided for communication with the owners DCS. PLC cabinet to be located in the owners DCS room. PLC will be provided with Engineering design, drafting, documentation, configuration of controls, and logic diagrams, factory testing of logic, supply of display and control graphics displays for the ALSTOM supplied equipment.
1	Only	**SCR Inlet Gas Analyzer & Monitoring System**	Complete with microprocessor based NO_x, and oxygen analyzers, flow monitors, sampling system, to be housed in the owner's DCS room.

SCOPE BY OTHERS

The following items are not included in the ALSTOM scope and are to be furnished, as required, by others.

1. Existing DCS system (ALSTOM to provide SCR PLC with interface card for communication with DCS)
2. 460V Power feed to Alstom MCC
3. Existing stack CEM to provide SCR with NOx emission value for control of ammonia feed.
4. Existing ammonia storage and unloading facility (ALSTOM to tie in new pipeline to SCR)
5. Subgrade electrical grounding grid.
6. Performance testing
7. Operating personnel and consumables for commissioning and start up.

4.4 List of Major Equipment Suppliers and Subcontractors

MAJOR VENDOR LIST	
PRODUCT	VENDORS
SCR SYSTEM	
Chamber Fabrication	PSP, or equal
Catalyst	Haldor Topsoe or equal
Duct Fabrication	PSP, or equal
Expansion Joints	Effox, or equal
Sootblowing System	Drayton, or equal
AMMONIA SYSTEM	
Storage Tanks	By Others
Vaporizer System	By Others
CONTROLS	
NOx Analyzer	Thermo Electron, or equal

5.0 PERFORMANCE ESTIMATES-SCR SYSTEM

Following the completion of the installation of the proposed equipment and subject to the performance conditions contained in Section 7.1 of this Proposal, ALSTOM estimates the following under steady state conditions as defined in this proposal section 3.2.1:

NO_x removal	90% minimum 24 hour average
Draft Loss	Not to exceed 4 inches of WG, from the economizer outlet to the air heater inlet.
Ammonia Slip	Not to exceed 2 ppm
Catalyst life	8000 hr. of operation, or 12 months from initial operation, whichever occurs first.
SO_3 Oxidation.	Less than 1.2% as measured during the first month of operation.
Ammonia consumption as NH3	Not to exceed 370 lb./hr

5.1 PERFORMANCE CONDITIONS

1. A mutually acceptable test program will determine the estimate testing performance values.
2. Installation of the proposed equipment will be in accordance with ALSTOM's drawings and instructions.
3. Operation and maintenance of the equipment will be in accordance with ALSTOM's instructions and good engineering and operating principles.
4. Performance testing will be conducted with no unusual circumstances. For example, feedwater heaters out of service, no hindrances due to incapacitated FD fans, convection pass dampers, flue gas cleaning equipment, ash handling system, sootblowers, wall blowers, and boiler controls.
5. The fuel fired will fall within the range of the fuel as listed in the specification.
6. Recording devices for operating parameters will be maintained by the Customer and made available to ALSTOM.
7. All replacement parts will be of ALSTOM's manufacture or supply or approved equal.
8. The equipment will be started up in the presence of appropriate ALSTOM personnel.

Documentation

A records system shall be established and maintained to provide documentary evidence of the quality of items and activities affecting quality. ALSTOM will ensure that the following documents, as appropriate, are furnished to GRE:

a) Certificate of Compliance, stating that all equipment and materials furnished comply with the Purchaser's specification.

b) Material Test Reports

c) Material Certifications

d) Foundation Design Drawings

e) Performance Test Results

f) Electrical Test Results and Instrumentation Specifications

g) Documents identifying deviations and their acceptance.

h) Structural Loading Data

SNCR Feasibility with LNB/OFA

An excerpt from an April 13, 2006 email from Alstom is included below. It describes the technical feasibility of using SNCR in combination with LNB/OFA on Stanton’s Unit 1, and includes expected emissions reductions.

Regarding the NOx reduction using both SOFA and SNCR technologies as a combined/cascade system (SOFA + SNCR):
The general consensus between ALSTOM and Fuel Tech is that for the most part, yes, the two systems should work and should reduce NOx ALMOST to the aggregate of each system capability separately however, with the following exceptions:

1. SNCR technology will work slightly less effectively than it would as a sole NOx reduction system.
2. The combined SOFA and SNCR technologies assumes the upper furnace combustion zone, with SOFA modifications implemented, does not exceed 500ppm CO.
3. ALSTOM has not performed any CFD modeling that would otherwise allow more confident predictions on the effectiveness of SOFA + SNCR cascaded technologies.

	Baseline NOx	Case 1 (w/SOFA + mods)/% red.	Case 1(w/SNCR only)/% red	Case 1 (w/SOFA & mods + SNCR) - % red.
Case 1 (1.1m lb/hr fw 3mills, PRB)	0.38 - 0.40	0.27 - 0.32/20%-29%	0.304/20%	20% - 29% + **18% - 20%** = **38% - 49%** Total
Ammonia slip		5 ppm	5ppm	
Case 2 (.80m lb/hr fw #13 off, PRB)	0.27	0.18 - 0.23/15-33%	**0.23/15%	15 - 33% + 17.5% - 20% = 32.5% - 53% Total
Ammonia slip		5 ppm	5ppm	

** Note: the original evaluation had a target NOx of 0.23, which provided the targeted reduction of 15%. The SNCR process is capable of approx. 20% NOx reduction from the baseline.

Case 3 (.9m lb/hr fw Lignite)	0.40	0.27 - 0.32/20 - 33%	0.29/27.5%	20% - 33% + 25% to 27%(20% - 25%)=45% - 60% Total
Ammonia Slip		10 ppm	10 ppm(5ppm)	

Appendix E

Sulfur Content Statistical Analysis

Coal Sulfur Content Statistical Analysis

Lignite Coal

For the purpose of establishing SO_2 emission rates for Lignite, two sources of data were considered.

1) Historical Stanton coal from the Freedom Mine- For Freedom Mine, the maximum daily sulfur content was 1.55% as reported in the 2001 emission inventory.

,

2) MR Young coal from the Center Mine - Milton R. Young's Unit 1 is a lignite fired boiler that does not currently have a scrubber installed for SO_2 control. Emissions from MR Young Unit 1 indicate that the lignite sulfur content has been higher in recent years (2004 through 2005) than historically recorded at Stanton Station. Based on SO_2 emissions[1] from M.R. Young Unit 1, the daily percent sulfur content for lignite was calculated and is presented in Table 3. The top 10 highest daily coal sulfur contents, as listed in Table 3, confirm that the highest daily sulfur content of 1.57% is not a statistical outlier.

Table 1. Sulfur Content Statistical Analysis

	Date	**% Sulfur in Lignite[2]**
Average 2004-2005		1.01
Minimum Daily	4/10/2005	0.04
Maximum Daily	7/2/2005	1.57
Average + 2 Standard Deviations		1.31

These data are consistent with North Dakota lignite reserves as could be used by Stanton over the expected life of the plant. Given that the MR Young data is slightly higher than Stanton, it was chosen as a representative daily maximum sulfur percentage for future Stanton lignite combustion. Using the statistical analysis of this data presented in Tables 1 and 2, 1.31% sulfur (2.44 lb/MMBtu) and 1.57% sulfur (2.94 lb/MMBtu) were determined to be representative for a future predicted 30-day rolling average and a 24-hour maximum sulfur content, respectively.

---

[1] Daily SO_2 emissions data for M. R. Young's Unit 1, years 2004 and 2005 from electronic data records located at <http://www.epa.gov/airmarkets/emissions/raw/index.html> (attached)

[2] % Sulfur in Lignite is calculated based on the SOx emission factor from AP-42 Chapter 1-7, Table 1.7-1. The emission factor is given as 30S lb/ton where S is the weight % sulfur content of wet lignite. To convert to lb/MMBtu the emission factor is multiplied by 0.0625. Therefore, S = lb/MMBtu SO_2/0.0625/30

Table 2. Predicted Emissions Calculations

	30-Day Rolling	24-Hour Maximum
Sulfur %	1.30	1.57
lb/MMBtu	2.44	2.94
Dry Scrubber Control Efficiency	90%	90%
Predicted Emissions	0.24 lb/MMBtu	0.29 lb/MMBtu
	432.0 lb/hr	526.5 lb/hr

Table 3. Top 10 Highest Daily Sulfur Contents

PRB Coal

Stanton Station is currently permitted to burn both lignite and PRB coals. Currently, Stanton receives coal from the Spring Creek Mine located in eastern Montana. The mine uses a sulfur reject value of 1.2 lb/MMBtu with a contractual guarantee of 0.8 lb/MMBtu. According to the contract, the financial penalty is only the incremental value of SO_2 allowances for any overage from the 0.8 lb/mmbtu value. Although most shipments conform to the 0.8 lb/MMBtu requirement, it is not uncommon to receive shipments with a sulfur content of 1.0 lb/MMBtu as could be expected during a 30-day rolling period. Consequently, for the purpose of establishing a regulatory limit, it is prudent to use the mine's reject value at 1.2 lb/MMBtu.

Given that the existing PRB contract expires in 2009, it is necessary to incorporate sulfur contents from other potential Montana PRB mines. Table 4 presents 3 realistic examples of Montana PRB mines and their average sulfur characteristics.

Table 4. Montana PRB Mine Characteristics[3]

Montana Coal Mine	Average Sulfur Content (%)	HHV (Btu/lb)	SO_2 Emissions (lb/MMBtu)[4]
Spring Creek	0.34	9,350	0.64
Absaloka	0.64	8,750	1.28
Rosebud	0.80	8,750	1.60

Assuming a 90% SO_2 control scenario, an SO_2 limit of 0.15 to 0.16 lb/MMBtu is justified to cover the range of expected PRB fuels as well as possible sulfur variability within a mine. Based on this information, it is clear that a compliance limit set at or slightly above 0.15lb/mmbtu is justified for the life-of-plant.

---

[3] Coal specification data from BNSF information, included in attachments.

[4] Calculation method in EPA AP-42, Chapter 1: External Combustion Sources.
SO_2 Emissions (lb/MMBtu) = (35 x sulfur content (%)) / HHV (Btu/lb) / 2000 (lb/ton) x 1E6 (Btu/MMBtu)

Date	SO_2 Emission Rate (lb/hr)	SO_2 Emission Rate (lb/MMBtu)	% Sulfur in Lignite

Abstract

Lignite and subbituminous coals from the United States of America have characteristics that impact the performance of catalysts used in selective catalytic reduction (SCR) for nitrogen oxide removal and mercury oxidation. Typically, these coals contain ash-forming components that consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. The alkali and alkaline-earth elements are partitioned between reactions with minerals and reactions to form alkali and alkaline-earth-rich oxides during combustion. The particles resulting from the reaction with minerals produce low-melting-point phases that cause a wide range of fireside deposition problems. The alkali and alkaline-earth-rich oxides consist mainly of very small particles (<5 μm) that are carried into the backpasses of the combustion system and react with flue gas to form sulfates, and possibly carbonates. These particles cause low-temperature deposition, blinding, and plugging problems in SCR systems. These coals also contain the very low levels of chlorine that are necessary for mercury oxidation. Slipstream testing was conducted at two selected subbituminous-fired power plants and one lignite-fired power plant to determine the impacts of ash on SCR plugging, blinding, and mercury oxidation. The results indicated a high potential for

blinding and plugging due to the formation of sulfate-bonded deposits and no evidence for mercury oxidation.

Keywords: Coal; Selective catalytic reduction (SCR); Blinding; NO_x; Mercury; Oxidation

---

1. Introduction

Selective catalytic reduction (SCR) for NO_x control and mercury oxidation was investigated using a slipstream reactor at power plants firing subbituminous and lignite coals to determine the potential for ash plugging, catalyst blinding, and mercury oxidation. SCR units lower NO_x emissions by reducing NO_x to N_2 and H_2O. Ammonia (NH_3) is the most common reducing agent used for the SCR of NO_x. The SCR process involves the use of a metal oxide catalyst such as titanium dioxide-supported vanadium pentoxide catalyst (V_2O_5). These units are operated at about 340–370 °C (650–700 °F). Subbituminous and lignitic coals are known for their ability to produce alkali and alkaline-earth sulfate-bonded deposits at low temperature (<1000 °C) in utility boilers. The mechanisms of the formation of low-temperature sulfates have been extensively examined and modeled by the Energy and Environmental Research Center (EERC) in work termed Project Sodium and Project Calcium in the early 1990s [1,2]. Deposit buildup of this type blinds or masks the catalyst, diminishing its reactivity for converting NO_x to N_2 and water and potentially creating increased ammonia slip [3]. Elemental mercury oxidation has been observed in laboratory-, pilot-, and full-scale testing using SCR catalysts [4–6]. In these studies, the metal oxides, V_2O_5 and TiO_2, have been shown to promote the conversion of elemental mercury to oxidized and/or particulate-bound mercury. Full-scale tests in Europe [7] and the United States [8] have indicated that the V_2O_5 and TiO_2 catalyst may promote the formation of oxidized mercury. The ability to oxidize mercury is largely dependent on the composition of the coal [8].

Lignite and subbituminous coals produce ash that plug and blind catalysts [9–12]. The problems currently being experienced on SCR catalysts include the formation of sulfate- and phosphate-based blinding materials on the surface of catalysts and the carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing them on top of the SCR catalysts [3]. The most significant problem that limits the successful application of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates, phosphates, and possibly carbonates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency [3,11–14]. The degree of the ash-related impacts on SCR catalyst performance depends upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design [11–15].

Cichanowicz and Broske [13] conducted tests on a South African and a German Ruhr Valley coal and found that the German Ruhr Valley coal significantly increased the pressure drop across the catalyst because of the accumulation of ash. They found that the German coal produced a highly adhesive ash consisting of alkali (K and Na) sulfates. In addition, they reported that the alkali elements are in a water-soluble form and highly

Table 1

mobile and will migrate throughout the catalyst material, reducing active sites. The water-soluble form is typical of organically associated alkali elements in coals. The German Ruhr Valley coal has about 9.5% ash and 0.9% S on an as-received basis, and the ash consists mainly of Si (38.9%), Al (23.2%), Fe (11.6%), and Ca (9.7%), with lower levels of K (1.85%) and Na (0.85%) [13]. Cichanowicz and Muzio [14] summarized the experience in Japan and Germany and indicated that the alkali elements (K and Na) reduced the acidity of the catalyst sites for total alkali content (K+Na+Ca+Mg) of 8–15% of the ash in European power plants. Licata et al. also found that alkaline-earth elements such as calcium react with SO_3 on the catalyst, resulting in plugging of pores and a decrease in the ability of NH_3 to bond to catalyst sites. The levels of calcium in the coals that caused blinding ranged from 3% to 5% of the ash. Studies conducted on the impact of alkali elements associated with biomass found that, when biomass is fired, poisoning and blinding of SCR catalysts occurred [16,17].

The slipstream reactors were installed at three power plants. Two of the plants were cyclone fired: one with lignite and one with subbituminous coal. The third plant was a pulverized-coal, tangentially fired unit with subbituminous coal. The slipstream reactors were designed to expose SCR catalysts to flue gas and particulate matter under conditions that simulate gas velocities, temperatures, and ammonia injection of a full-scale plant. The control system maintains catalyst temperature, pulse air to remove accumulated deposits, constant gas flow across the catalyst, and records pressure drops and temperatures. The reactor was operated in an automated mode and can be controlled via modem connection. Testing at each power plant was conducted over a 6-month period. The reactor was inspected and cleaned at 2-month intervals, and a catalyst section was removed for analysis. The

Table 2
Key selection criteria

Field test 1—Columbia Station
Tangentially fired boiler to show differences in ash partitioning as compared to cyclone-fired systems. High-potential-blinding coal in Caballo, which can be burned nearly 100% for the entire test.
Field test 2—Baldwin Station
Plant is cyclone fired. Units are already equipped to do slipstream testing. Plant currently fires a blend of Antelope and tires; plant is willing to fire 100% Antelope. High potential blinding coal in Antelope.
Field test 3—Coyote Station
Cyclone-fired with lignite. High potential blinding with high alkali and alkaline-earth elements. Coal can have very high sodium contents and is known to cause significant low-temperature deposition.

Oxygen (by difference)	16.61	18.96	20.35

catalysts and associated ash deposits were analyzed to determine the characteristics of the ash on the surface and in the pores. In addition, the mercury speciation in the flue gas upstream and downstream of the catalyst was conducted at 2-month intervals during the testing at the lignite-fired plant. The ability of the SCR catalyst materials to catalyze gaseous elemental mercury ($Hg^0[g]$) to a more soluble and chemically reactive $Hg^{2+}X(g)$ forms was evaluated, along with the potential increase in particle-associated mercury, Hg(p). Increasing the oxidized and particulate fractions of mercury has the potential to increase the capture efficiency of mercury by conventional control devices such as wet flue gas desulfurization (FGD) scrubbers and electrostatic precipitators (ESPs).

This paper summarizes pressure drop, formation of deposits that blind the surface of the catalyst, and the ability of SCR catalysts to oxidize mercury.

2. Experimental

2.1. Overview of test program and fuel characteristics

A portable SCR slipstream reactor system was designed and constructed to conduct full-scale evaluation of the SCR catalyst ash plugging and blinding and mercury oxidation. A particle-laden flue gas slipstream was isokinetically extracted from the flue gas duct ahead of the air heater at full-scale utilities using an induced-draft fan. Two systems were constructed

so that data may be collected simultaneously from two full-scale sites. Testing was conducted at three boilers, including tests on a cyclone boiler firing Powder River Basin (PRB) coal, a lignite-fired cyclone boiler, and a pulverized coal boiler burning PRB. SCR catalysts were exposed to flue gases and combustion-derived fly ash particles for 6-month time periods to study the blinding effect of fly ash and ash deposits on catalyst performance.

The electric utility units selected for testing are shown in **Table 1**. The plants where the SCR slipstream system was installed included Alliant Energy's Columbia Station, Dynegy's Baldwin Station, and Otter Tail Power Company's Coyote Station. **Table 1** describes the plants, and **Table 2** summarizes the characteristics and selection criteria.

The units tested were selected based on the fuels fired, boiler type, and availability of the unit for sampling. The average composition of the coals fired during the testing is

listed in **Tables 3 and 4**. The subbituminous coals were typically low ash, nominally 4.5% to 5.5% with very high levels of calcium in the ash. In comparison, the lignite contains higher levels of ash and lower calcium but higher levels of sodium. The alkali and alkaline-earth elements are primarily associated with the organic matrix of the coal as salts of carboxylic acid groups [18]. The portion of the ash-forming components that are associated with the organic matrix of the coal for subbituminous coal ranges from 30% to 60% [18]; for the lignite coal, the portion is about 20% to 40%. The remaining ash-forming components consist of mineral grains. For these coals, the percent organically associated is 29% for the Antelope, 36% for Caballo, and 19% for Beulah. The minerals present in the coals determined by computer-controlled scanning electron microscopy (CCSEM) analyses are listed in **Table 5**. The primary minerals present in the subbituminous coals include quartz and various clay minerals with some pyrite and a mineral that is rich in Ca, Al, and P. This mineral has been identified in some coals as crandalite. The primary minerals found in the Beulah coal include clay minerals (kaolinite), pyrite, and quartz.

2.2. SCR slipstream system

The SCR slipstream system consists of two primary components: the control room and the SCR reactor. The reactor section consists of a catalyst section, an ammonia injection system, and sampling ports for NO_x at the inlet and exit of the catalyst section. The control

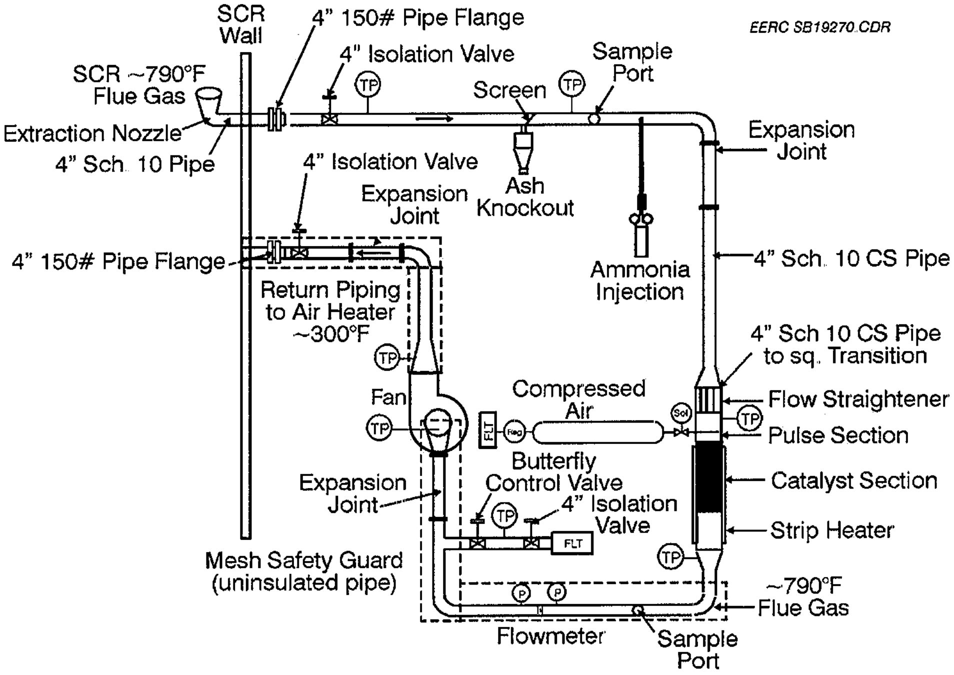

Fig. 1. Schematic diagram of SCR slipstream system.

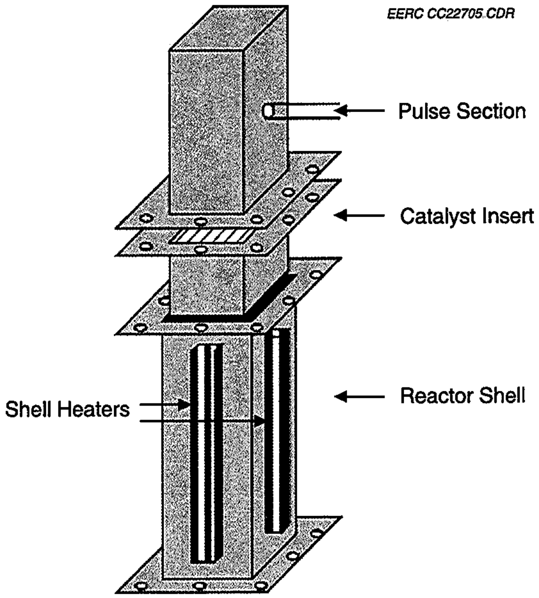

Fig. 2. Diagram of reactor section SCR slipstream system.

room houses a computer system that logs data and controls the gas flow rates, temperatures, pressure drop across the catalyst, and sootblowing cycles. The computer was programmed to maintain constant temperature of the catalyst, gas flow rates, sootblowing cycles, and ammonia injection. The computer is equipped with a modem that

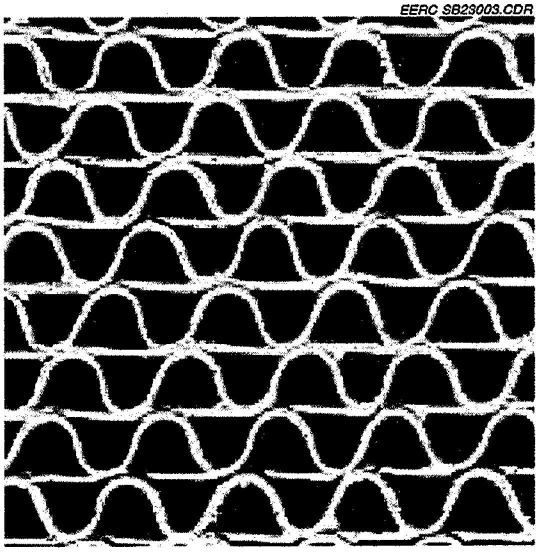

Fig. 3. Haldor Topsoe SCR catalyst showing the gas flow passages.

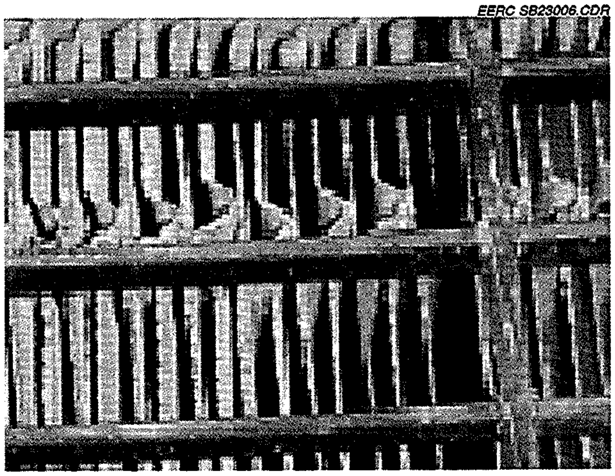

Fig. 4. Babcock Hitachi SCR catalyst showing the gas flow passages.

allowed for downloading of data and modification of the operation of the reactor from a remote computer located at the EERC.

A schematic diagram of the SCR slipstream system is shown in Fig. 1. Flue gas is isokinetically extracted from the convective pass of the boiler upstream of the air heater. The temperature is typically about 790 °F. The flue gases pass through a 4-in. pipe equipped with sampling, thermocouple, and pressure ports. Ammonia is injected into the piping upstream of the reactor section. The reactor consists of a steel housing that is approximately 8.5 in. square and 8 ft long. The reactor section illustrated in Fig. 2 has three components, including a flow straightener, a pulse section or sootblower, and a catalyst test section. A metal honeycomb is used as a flow straightener upstream of the catalyst section and is about 6 in. long. A purge section was installed ahead of the catalyst test section to remove accumulated dust and deposits. The catalyst test section is located downstream of the purge section. The entire catalyst section is insulated and equipped with strip heaters for temperature control. The catalyst test section is 3.28 ft (1 m) in length and houses three catalyst sections. Thermocouple and pressure taps are located in the purge sections for measurements before and after each section.

The induced-draft fan is used to extract approximately 400 acfm (200 scfm) of flue gas from the convective pass of the utility boiler to achieve an approach velocity of 5.2 m/s

Table 6
Selected operating conditions of the SCR catalysts

- Catalyst dP: 0.5–1.0 in. water column
- Fan sized for up to 30 in. water column.

2.2.1. SCR catalyst

The catalyst installed at the Baldwin and Coyote Stations was the Haldor Topsoe catalyst. Topsoe's DNX-series of catalysts comprises SCR DENOX catalysts tailored to suit a comprehensive range of process requirements. DNX-series catalysts are based on a corrugated, fiber-reinforced titanium dioxide (TiO_2) carrier impregnated with the active components vanadium pentoxide (V_2O_5) and tungsten trioxide (WO_3). The catalyst is shaped to a monolithic structure with a large number of parallel channels. The unique catalyst design provides a highly porous structure with a large surface area and an ensuing

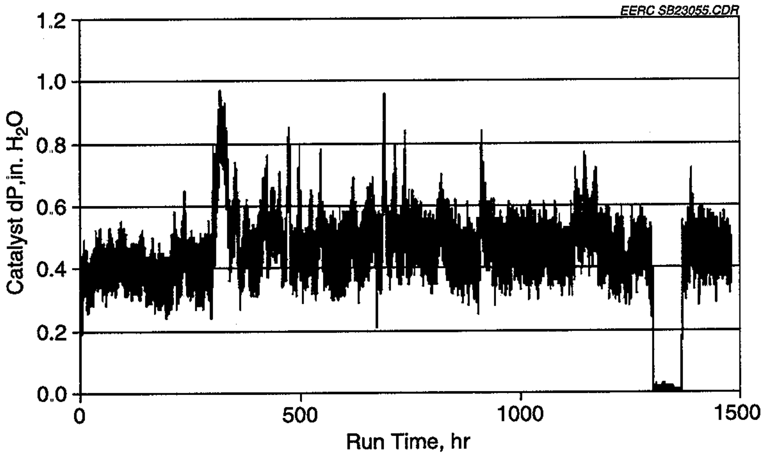

Fig. 8. Catalyst pressure drop at Columbia Station at 0 to 2 months of operation.

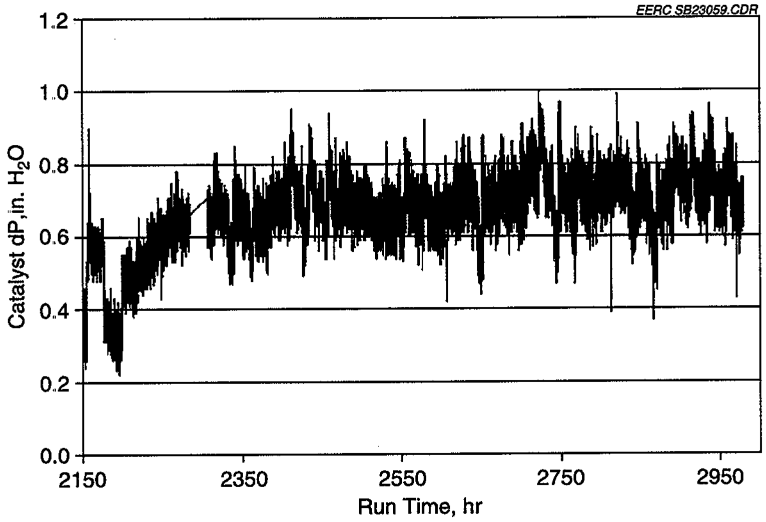

Fig. 9. Catalyst pressure drop at Columbia Station at 2 to 4 months of operation.

large number of active sites. Fig. 3 is an image of the Haldor Topsoe SCR catalyst. The pitch of the catalyst was approximately 6 mm.

The catalyst installed at the Columbia Station was a Babcock Hitachi plate-type catalyst. This catalyst is a TiO_2-based plate catalyst, developed and manufactured by Hitachi. Fig. 4 shows the design of the catalyst. The pitch of the catalyst was approximately 10 mm.

2.2.2. System performance measurement

Upon installation at each utility boiler unit, flue gas temperature, composition, and velocity measurements were obtained using portable equipment. Shakedown testing of the

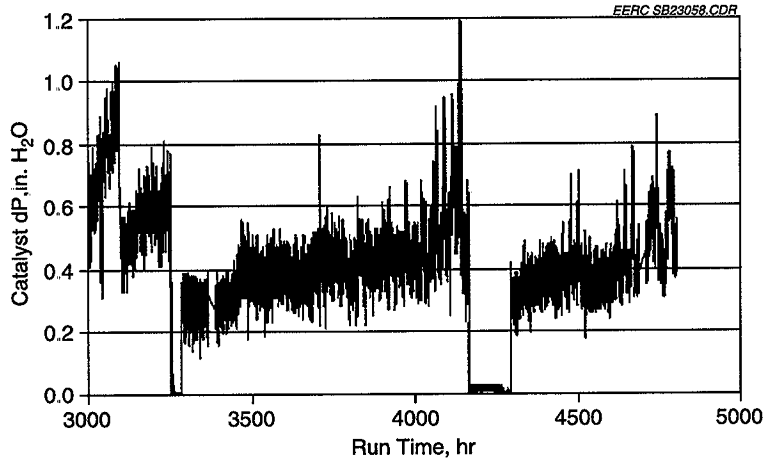

Fig. 10. Catalyst pressure drop at Columbia Station at 4 to 6 months of operation.

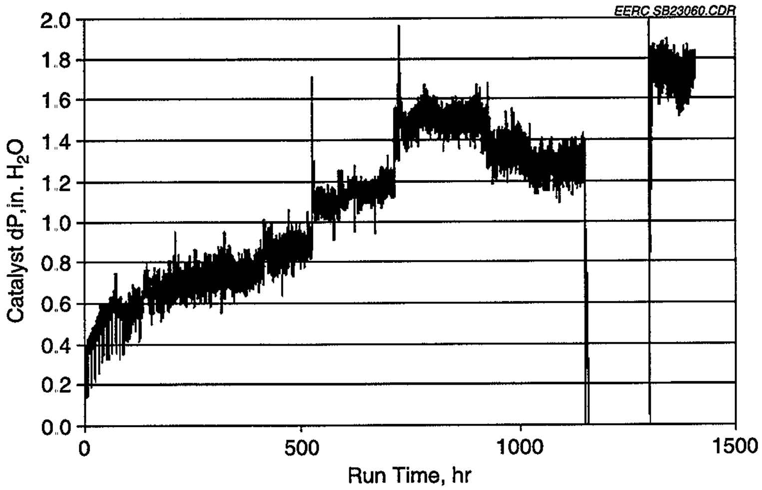

Fig. 11. Catalyst pressure drop at Coyote Station at 0 to 2 months of operation.

unit was conducted to ensure that all components were operating properly and that data were being logged and could be retrieved. After installation and shakedown were completed, the reactor was operated in a computer-controlled, automated mode and monitored on a daily basis to ensure proper operation and data quality. During operation of the SCR slipstream system, catalyst temperature, sootblowing frequency, and pressure drop across the catalyst were monitored and logged. Samples of the exposed SCR catalyst and associated deposits were obtained after exposure to flue gas and particulate for 2, 4, and 6 months. The samples of the catalyst were analyzed to determine the components that were bonding and filling pores, resulting in decreased reactivity.

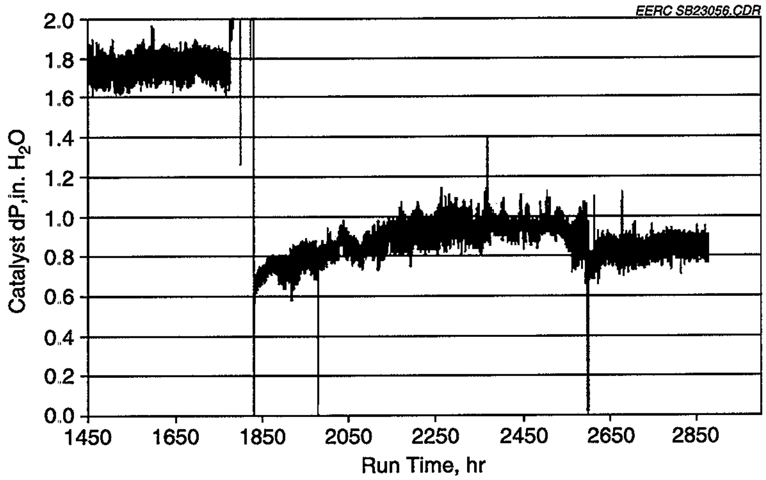

Fig. 12. Catalyst pressure drop at Coyote Station 2 to 4 months of operation.

The characteristics of ash that accumulated on the catalyst were examined using SEM–X-ray microanalysis and X-ray diffraction (XRD) [18]. Correlations between the physical and chemical characteristics of any ash deposits on the SCR test section and entrained-ash sample collected at the chamber inlet and the coal inorganic composition will be made to

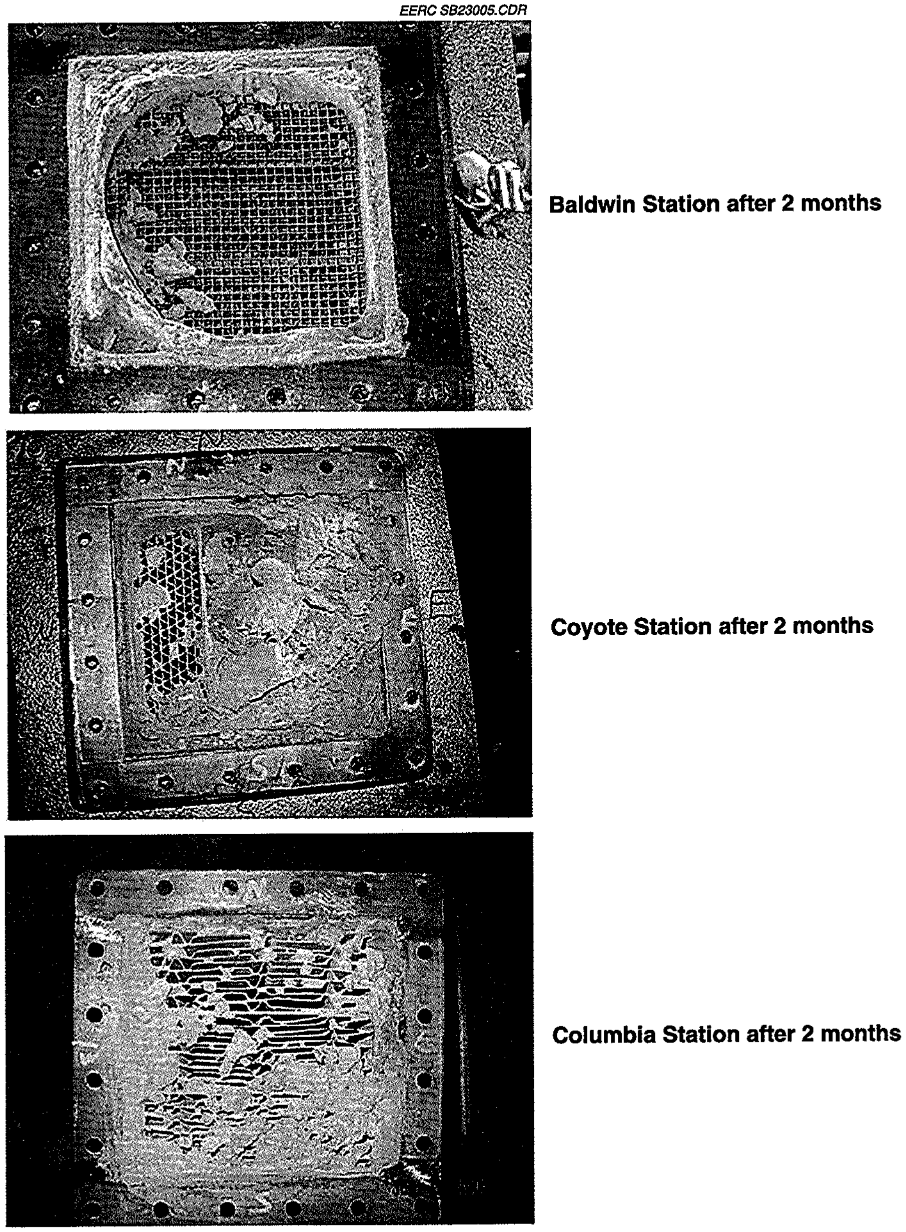

Fig. 13. Pictures of catalyst inlet after about 2 months of testing at each plant.

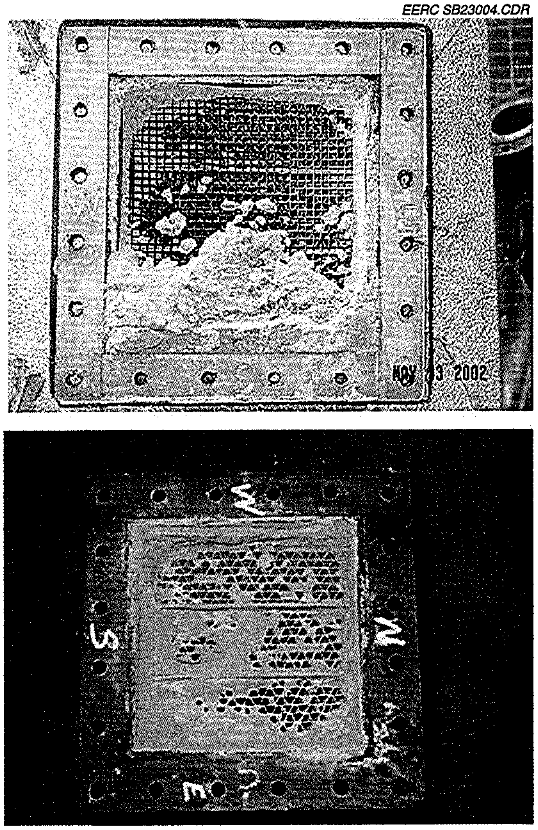
discern mechanisms of SCR blinding. Entrained ash was collected at Columbia Station only and characterized to composition and size.

2.3. Analysis of flue gas constituents across the catalyst—Ontario Hydro method for mercury speciation

At the Coyote Station, the Ontario Hydro (OH) mercury speciation sampling train was used to determine mercury forms across the SCR test section. The OH extractive mercury speciation sampling technique was used to measure potential mercury conversion across the SCR system over a period of several hours after fresh installation of the SCR test chamber and again just prior to removal of SCR catalyst sections.

The procedure used to conduct the mercury speciation sampling was American Society for Testing and Materials (ASTM) Method 06784-02 entitled "Standard Test Method for Elemental, Oxidized, Particle-Bound and Total Mercury in Flue Gas Generated from Coal-Fired Stationary Sources (Ontario Hydro Method)" [19].



Baldwin Station after 4 months

Coyote Station after 4 months

Fig. 14. Pictures of catalyst inlet after about 4 months of exposure to flue gas and particulate.

The OH method follows standard EPA methods for isokinetic flue gas sampling (EPA Methods 1–3 and EPA Method 5/17). A sample is withdrawn from the flue gas stream isokinetically through the filtration system, which is followed by a series of impingers in

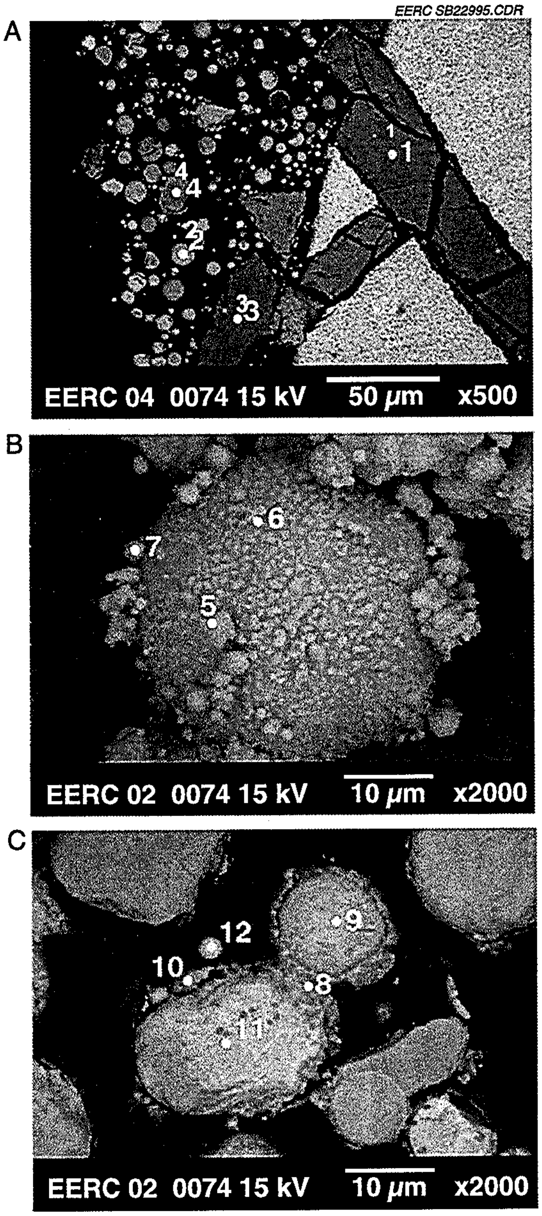


Fig. 15. SEM images of ash collected on catalyst surface at the Baldwin Station after 2 months of exposure. (A) Low-magnification image of ash deposit on catalyst surface, (B) high-magnification image of coated ash particle, and (C) high-magnification image of polished cross section showing coatings on particles.

an ice bath. Particulate-bound mercury is collected on the filter; Hg^{2+} is collected in impingers containing 1 N potassium chloride solution; and elemental mercury is collected in one impinger containing a 5% nitric acid and 10% peroxide solution and in three impingers containing a solution of 10% sulfuric acid and 4% potassium permanganate. An impinger containing silica gel collects any remaining moisture. The filter media is quartz fiber filters. The filter holder is glass or Teflon-coated. An approximate 2-h sampling time was used, with a target sample volume of 1 standard cubic meter.

3. Results and discussion

3.1. Pressure drop

3.1.1. Testing at the Baldwin Station

The reactor was installed at the Baldwin Station and operated for a 6-month time period on the Haldor Topsoe catalyst. The information obtained from testing included pressure drop, sootblowing cycles, and reactor temperatures. Table 6 summarizes the operating conditions of the reactors during the testing periods at all plants. Figs. 5–7 show the pressure drop across the catalyst test periods from 0 to 2 months, 2 to 4 months, and 4 to 6 months, respectively. During the first 2 months of operation, the pressure shown in Fig. 6 was about 0.5 in. of water; at the end of 2 months, the pressure drop was about 0.8 in. of water, indicating plugging had occurred. The air was pulsed a minimum of every 8 h in an attempt to maintain cleanliness. The reactor was monitored on a daily basis, and adjustments in pulsing cycles were made in order to minimize deposit accumulation. However, for the first 2 months, the pressure drop steadily increased. There are several periods where the unit was taken off-line; during those times, the temperature of the catalyst was maintained. At 2-month intervals, a section of catalyst was removed and replaced with a new one.

For Months 2 through 4, the pressure drop was highly variable initially but was about 0.8 in. of water. From Months 4 through 6, the pressure drop was maintained between 0.6 and 0.8 in. of water. This is due to the installation of a fresh catalyst section and leaving two thirds of the catalysts in place that partially plugged. The gas velocity in the single section of new, clean catalyst was high because of channeling, and the result of the high gas flow was less deposition and accumulation. Gas velocity has a significant impact on the potential for deposits to form. However, at high gas velocity, low NO_x conversion is likely.

3.1.2. Testing at Columbia

The reactor was installed at the Columbia Station and operated for a 6-month period of time for the Babcock Hitachi catalyst. The information obtained from the testing included pressure drop information, sootblowing cycles, and reactor temperature. Table 6 shows the reactor temperature, air-pulsing cycles, and airflow rates. Figs. 8–10 show the test periods from 0 to 2 months, 2 to 4 months, and 4 to 6 months, respectively. The pressure drop across the SCR upon installation was about 0.4 in. of water and increased to an average of

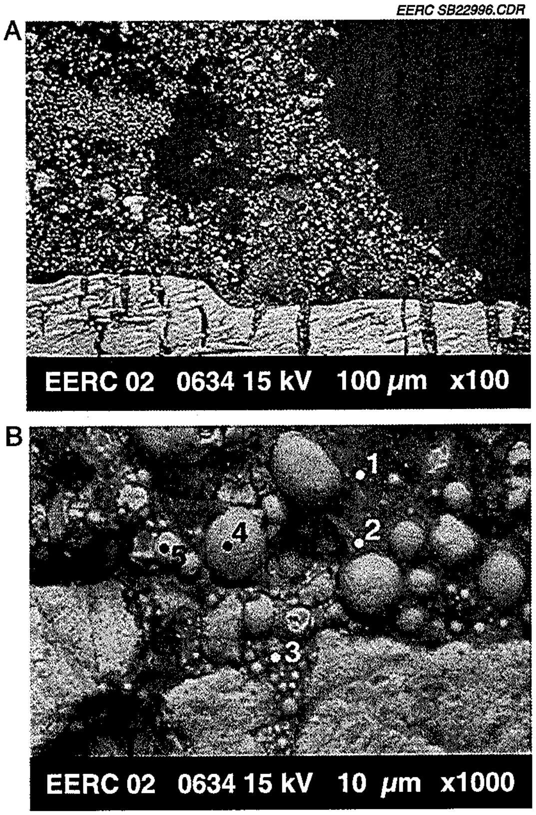

Fig. 16. SEM images of ash collected on catalyst surface at the Baldwin Station after 4 months of exposure. (A) Low-magnification image of ash deposit on catalyst surface, and (B) high-magnification image of polished cross section showing particles in a matrix of calcium- and sulfur-rich materials.

about 0.5 in. of water, but ranged from less than 0.4 to greater than 0.8 in. of water. **Fig. 9** shows the pressure drop for Months 2 to 4. The pressure drop increased from about 0.5 to 0.7 in. of water because of accumulation of ash. **Fig. 10** shows a rapid increase in pressure drop across the catalyst at about 3000 h of operation, and aggressive pulsing brought it down to 0.4 in. of water until the catalyst section was changed out at about 3200 h. After cleaning the reactor and replacing one catalyst section, the pressure drop was about 0.3 but increased to over 0.6 in. of water up to about 4100 h. There was an outage at the plant, and aggressive pulsing of the reactor was conducted; the pressure drop was brought back down to 0.3 but rapidly increased to over 0.5 in. of water within 500 h.

3.1.3. *Testing at Coyote*

The same reactor that was installed at the Baldwin Station was moved and installed at the Coyote Station. In addition, the same Haldor Topsoe catalyst was used in the reactor. The cleaning cycles, temperatures, and gas flow rates are listed in **Table 6**. The reactor was operated for a 6-month period of time. **Figs. 11 and 12** show the test periods from 0 to 2 months and 2 to 4 months. As this paper is being prepared, the reactor is still operating on-site. The pressure drop across the catalyst upon installation was about 0.4 in. of water. After only 750 h, the pressure drop was 1.5 in. of water, indicating significant plugging. Very aggressive air pulsing was conducted, with little success in removing the deposits. The pressure drop for the catalyst was over two times greater than the pressure drop observed for the Baldwin Station utilizing the same reactor and same catalyst. At about 1700 h, the reactor was cleaned, and a section of catalyst was removed for characterization. The pressure drop after cleaning was about 0.8 to 1.0 in. of water. The pressure drop did not increase as rapidly because of the higher velocities through the clean section of the catalyst.

3.1.4. *Visual observations of deposit characteristics*

The tops of the catalysts were photographed during inspection and sampling of the catalyst sections. **Fig. 13** shows the ash materials that accumulated on the catalyst inlet after 2 months of operation. The most significant accumulation was noted for the Coyote

Station, followed by Columbia and Baldwin. The Coyote Station had some larger pieces of ash deposit material on the surface as well as plugging of the catalyst passages. The Baldwin Station showed some obvious deposition along the walls of the reactor and some accumulation on the inlet sections. The Columbia Station showed more significant accumulation and plugging than the Baldwin Station.

After 4 months, the tops of the catalysts were photographed during inspection and sampling of the catalyst sections, as shown in Fig. 14. The most significant accumulation was noted for the Coyote Station and some accumulation for the Baldwin Station.

3.2. Deposit characteristics

The characteristics of the ash materials that collected on the catalyst surfaces and pores were characterized by SEM and X-ray microanalysis and, in selected cases, XRD was used to determine the crystalline phases present. The catalysts were sampled after 2, 4, and 6 months. The sections were sampled, and approximately 2.5-cm squares were mounted for SEM analysis on double-stick tape and in epoxy resin. The double-stick tape samples allowed for characterization of the external morphology of the particles and catalyst surface. The samples mounted in resin were cross-sectioned and polished, which allowed for more detailed and quantitative analysis of the bonding materials and materials that accumulated in the pores of the catalyst.

3.2.1. Plugging deposit characteristics

3.2.1.1. Baldwin Station deposits. Samples of catalyst were removed from the Baldwin Station after exposure to flue gases and particulate after 2, 4, and 6 months. Fig. 15 shows the characteristics of the ash deposit material on the SCR catalyst after 2 months of exposure. This is a polished cross section of a deposit on the surface of the catalyst. Fig. 15A shows particles on the surface of the catalyst that range in size from <1 to 15 μm. The larger particles range from oxides of solely silicon and iron to complex mixtures rich in

aluminum and calcium; aluminum, silicon, and calcium; aluminum, calcium, and iron; and sodium, calcium, aluminum, and silicon. Chemical analysis of selected particles is summarized in Table 7. The samples of ash mounted on double-stick tape allow for the characterization of the external surfaces of the particles. The surface of a typical particle that is accumulating on the surface of the catalyst is shown in **Fig. 15B**. The blebs on the surface are composed of calcium and sulfur, with some iron and minor amounts of sodium and potassium. **Fig. 15C** shows a cross section of the deposited particles showing calcium- and aluminum-rich particles bonded together with a calcium- and sulfur-rich phase. This phase is in the form of calcium sulfate based on XRD analysis conducted on the deposited ash samples.

The 4-month sample from the Baldwin Station showed more extensive sulfation of the alkaline-earth elements present in the deposits. **Fig. 16** shows the images of a polished cross section of an ash deposit on the surface of the catalyst. The deposit formed both on the surface of the catalyst and within the catalyst pores as shown in **Fig. 16A**. **Fig. 16B** shows a higher magnification view of the deposit on the catalyst surface. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The chemical composition of selected points shown in **Table 8** shows high levels of calcium and sulfur. There is much more extensive bonding of the materials with the sulfate matrix as compared to the 2-month sample.

The 6-month sample from the Baldwin Station showed extensive sulfation of the alkaline-earth elements present in the deposits. **Fig. 17A and B** shows regions of the catalyst where all the pores were blocked and a minimal amount of deposit on the surface of the catalyst. **Fig. 17C** shows a higher magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The chemical compositions of selected points that indicate the presence of high levels of calcium and sulfur are listed in **Table 9**. There is much more extensive bonding of the materials with the sulfate matrix as compared to the 2-month sample. In addition, there are some regions of high levels of calcium, aluminum, and sulfur present. The calcium aluminum materials are likely derived from the calcium aluminum phosphate minerals found in the coal fired at this plant.

magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The presence of sodium enhances the bonding and sulfation of the particles to form a strongly bonded matrix.

The 4-month sample from the Coyote Station showed particles adhering to the surface and completely filling and masking the pores in the catalyst as shown in **Fig. 22**. **Fig. 22A** shows the external morphology of the catalyst surface showing the masking of the catalyst surface. Chemical compositions of selected points are shown in **Table 14**. The 4-month sample shows more sulfation than the 2 months of exposure samples. **Fig. 22B and C** shows a higher magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of sodium-, calcium-, and sulfur-rich material, likely in the form of calcium sulfate. The presence of sodium and potassium enhances the bonding and sulfation of the particles to form a strongly bonded matrix. Significant sodium was found in the deposits, as shown in **Table 14**.

3.2.2. Deposit formation mechanisms

The mechanism for the formation of deposits that blind SCR catalysts involves the transport of very small particles rich in alkali and alkaline-earth elements, the surface of the catalyst, and reactions with SO_2/SO_3 to form sulfates. The formation of SO_3 from SO_2 is catalyzed by the SCR; this, in turn, increases the reaction rate of SO_3 to form sulfates. In some cases, the alkali and alkaline-earth elements will also react with CO_2 to form carbonates. XRD analysis shown in **Fig. 23** identified $CaSO_4$ as a major phase and $Ca_3Mg(SiO_4)_2$ and $CaCO_3$ as minor phases.

Lignite and subbituminous coals contain high levels of organically associated alkali and alkaline-earth elements including sodium, magnesium, calcium, and potassium, in addition to mineral phases. The primary minerals present in these coals include quartz, clay minerals, carbonates, sulfates, sulfides, and phosphorus-containing minerals [18].

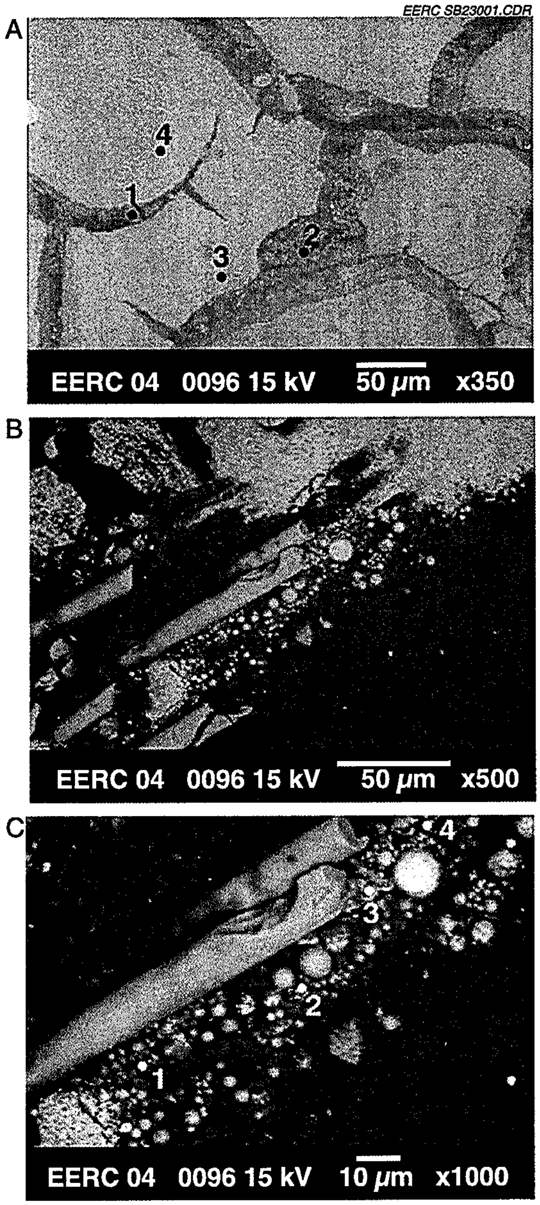

Fig. 21. SEM images of ash collected on catalyst surface at the Coyote Station after 2 months of exposure. (A) Low-magnification image of ash deposit on catalyst surface, (B) low-magnification image of polished cross section showing particles in a matrix of calcium- and sulfur-rich materials, (C) higher magnification image of bonding.

During combustion, the inorganic components in the coal are partitioned into various size fractions based on the type of inorganic component, their association in the coal, and combustion system design and operating conditions. There has been

Table 13

significant research conducted on ash formation mechanisms and relationships to impacts on power plant performance [18–34]. Typically, during combustion the inorganic components associated with western subbituminous and lignite coal are distributed into various size fractions of ash, as shown in **Fig. 24**. The results shown in Fig. 24 were obtained from isokinetic sampling and aerodynamically size-fractionating ash particles from a full-scale pulverized-coal-fired boiler firing subbituminous coal and analyzing each size fraction. The results show that the smaller size fractions of ash are dominated by partially sulfated alkali and alkaline-earth elements. These ash particles are largely derived from the organically associated cations in the coal. The larger size fraction has higher levels of aluminum and silicon derived from the mineral fraction of the ash-forming component of the coal. Entrained ash was extracted from the Columbia Station at the point of the inlet to the SCR reactor and was aerodynamically classified and analyzed. The composition of the size fractions was compared to the chemical composition of the ash deposited on and in the catalyst, as shown in Fig. 25. The comparison shows that the composition of the particle captured in the SCR catalyst is very similar to the <5-μm size fraction. The deposited material shows significantly more sulfation than the entrained-ash size fraction, indicating that the sulfation process occurs after the particles are deposited in the catalyst.

The mechanism of SCR catalyst blinding when firing lignite or subbituminous coals is shown in Fig. 26 [35]. The requirements for the formation of deposits that blind SCR catalyst include firing a coal that produces significant levels of <5-μm-sized particles. The particles are transported into the pores of the catalyst and subsequently reacted with SO_3 to form sulfates. The sulfate forms a matrix that bonds other ash particles. The SCR catalyzes the formation of SO_3 and thereby increases the rate of sulfation [9,15]. The sulfation of CaO increases the molar volume, resulting in the filling of the pore. For coals that have high sodium contents, formation of low-melting-point phases such as pyrosulfates are possible [36]. Pyrosulfate materials can melt at temperatures as low as 535 °F in coal-fired power systems.

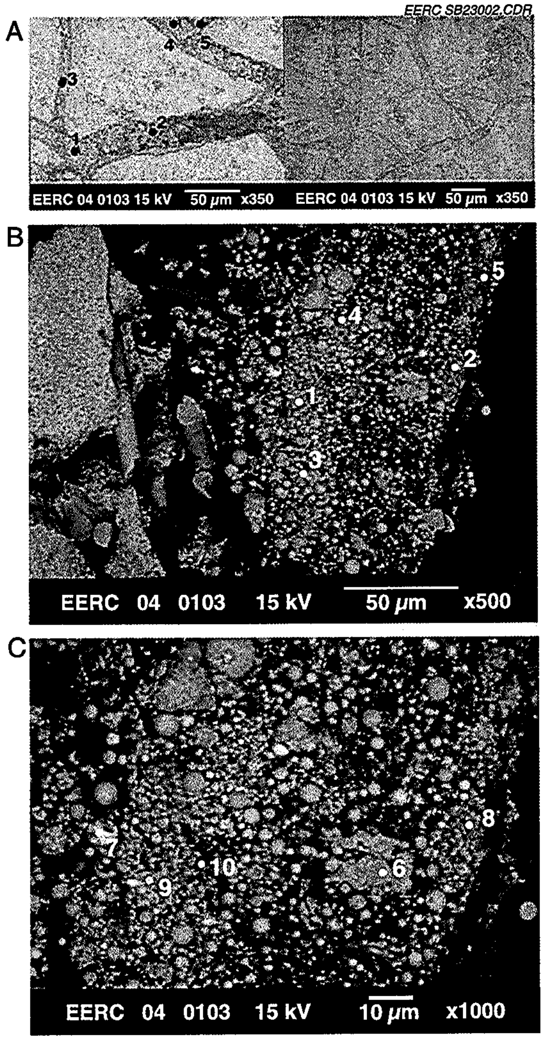

Fig. 22. SEM images of ash collected on catalyst surface at the Coyote Station after 4 months of exposure. (A) Low-magnification image of ash deposit on catalyst surface, (B) low-magnification image of polished cross section showing particles in a matrix of calcium- and sulfur-rich materials, (C) higher magnification image of bonding.

3.3. Flue gas measurements

3.3.1. Mercury transformations

The ability of mercury to be oxidized across the SCR catalyst was investigated at the Coyote Station. The Coyote Station is fired on North Dakota lignite, and the flue gases are dominated by elemental mercury. Measurement of mercury speciation was conducted using the OH method at the inlet and the outlet of the SCR catalyst. The measurements were made upon installation of the catalyst and after 2 and 4 months of operation. The

results of the mercury speciation measurement at the inlet and outlet of the SCR catalyst conducted upon installation are shown in Fig. 27. The inlet and outlet measurements were repeated three times and are shown in Fig. 27. The level of elemental mercury at the inlet was approximately 76% to 92%, with the remaining in the oxidized form ranging from 8% to 24%. Very little was in the form of particulate mercury at the inlet. Measurement of mercury speciation was conducted with the ammonia on and off. The results with the ammonia off showed an increase in the oxidized mercury to 43% of the total mercury occurring across the SCR catalyst. However, when the ammonia was introduced into the

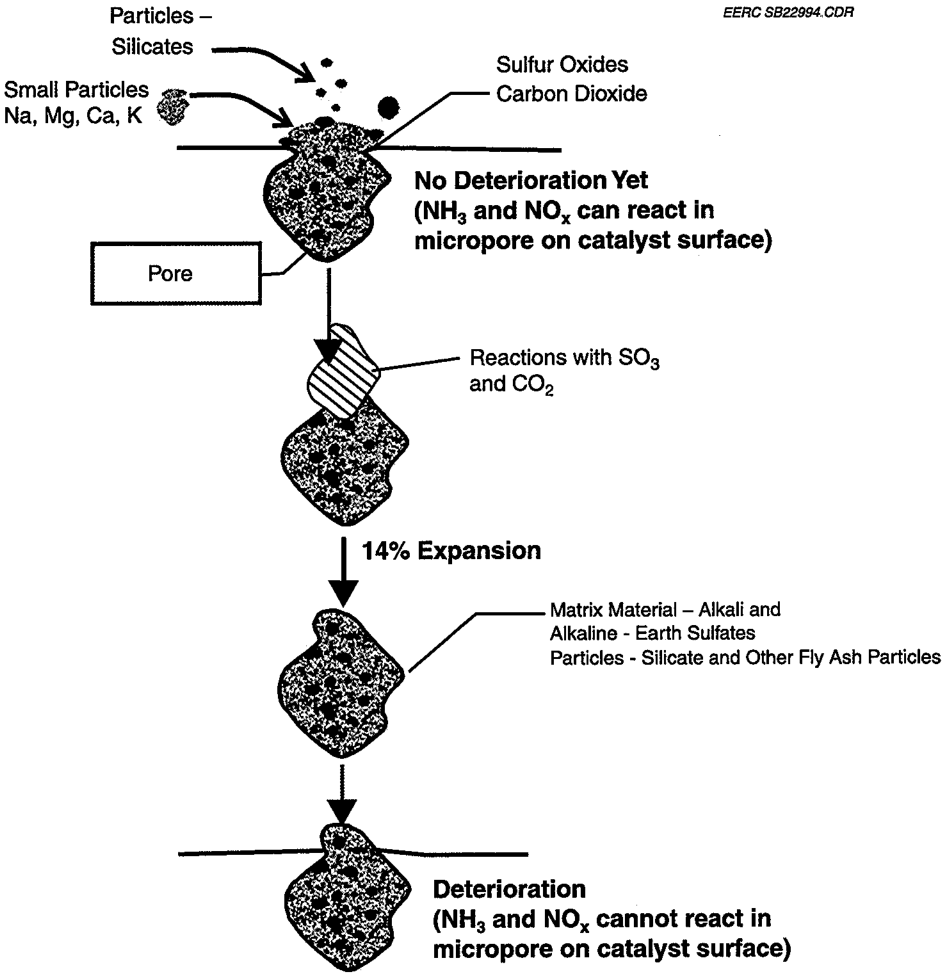

Fig. 26. Mechanism of SCR catalyst blinding via the formation of sulfates and carbonates (modified after Pritchard et al. [35]).

SCR catalyst, the amount of mercury oxidation decreased from 43% to 19%. There was an increase in the particulate mercury from 1.0% to 7.2%.

The mercury oxidation after the SCR catalyst was exposed to flue gas and particulate for 2 months is shown in Fig. 28. The level of oxidized mercury at the inlet ranges from 7.5% to 11.1% of the total mercury. The level of oxidized mercury at the outlet ranged from 7.6% to 14% of the total mercury. The level of particulate mercury increased from a negligible level to 3% of the total mercury at the outlet.

The results of mercury oxidation across the SCR catalyst after 4 months of exposure to flue gases and particulate are shown in Fig. 29. The results show a higher level of oxidized mercury at the inlet as compared to testing conducted at installation and after 2 months. The level of oxidized mercury at the inlet ranges from 32% to 38% of the total,

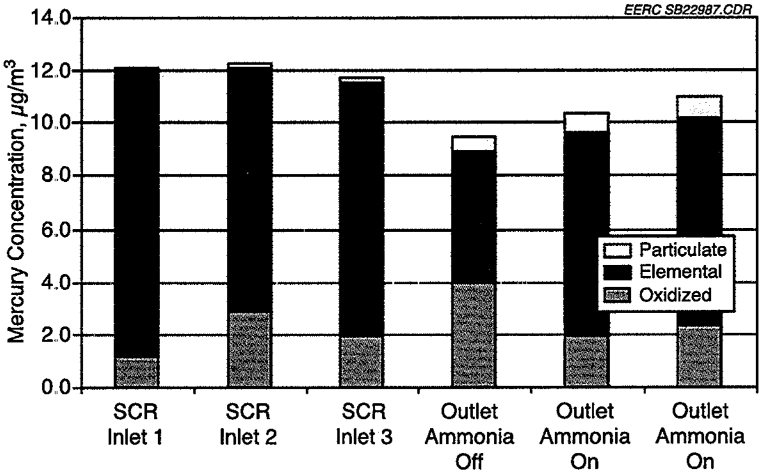

Fig. 27. Mercury speciation measurement at the inlet and outlet of the SCR catalyst upon installation of the catalyst.

with about 5% of the total in the particulate form. The outlet levels of oxidized mercury decrease after passing through the catalyst to about 20% of the total. The level of particulate mercury remained about the same across the catalyst.

4. Conclusions

A slipstream reactor is designed to expose SCR catalyst to coal combustion-derived flue gases and particulate. The system is computer-controlled and operates in an automated

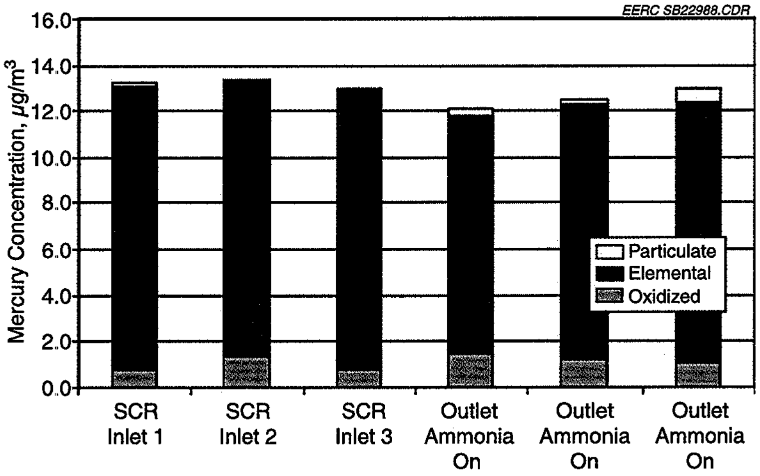

Fig. 28. Mercury speciation measurement at the inlet and outlet of the SCR catalyst after exposure to flue gases and particulate for 4 months.

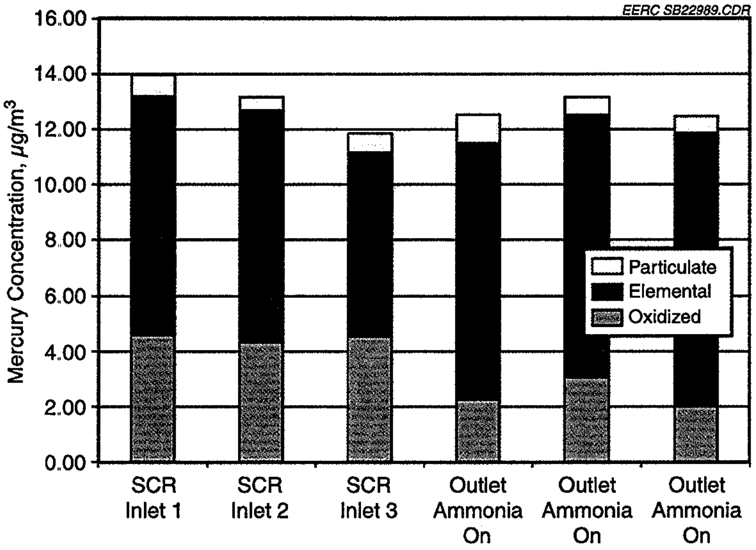

Fig. 29. Mercury speciation measurement at the inlet and outlet of the SCR catalyst after exposure to flue gases and particulate for 2 months.

mode. The system can be operated and monitored remotely through a modem connection. SCR catalyst testing was conducted at two subbituminous-fired plants and one lignite-fired plant. The boiler configurations for the subbituminous-fired plants included a cyclone- and a tangentially fired boiler. The boiler configuration for the lignite plant was a cyclone-fired system.

The pressure drop across the catalyst was found to be the most significant for the lignite-fired plant as compared to the subbituminous-fired plants. Both coals had significant accumulations of ash on the catalyst, on both macroscopic and microscopic levels. On a macroscopic level, there were significant observable accumulations that plugged the entrance as well as the exit of the catalyst sections. On a microscopic level, the ash materials filled pores in the catalyst and, in many cases, completely masked the pores within 4 months of operation.

The deposits on the surfaces and within the pores of the catalyst consisted of mainly alkali and alkaline-earth element-rich phases that have been sulfated. The mechanism for the formation of the sulfate materials involves the formation of very small particles rich in alkali and alkaline-earth elements, transport of the particles to the surface of the catalyst, and reactions with SO_2/SO_3 to form sulfates. XRD analysis identified $CaSO_4$ as a major phase and $Ca_3Mg(SiO_4)_2$ and $CaCO_3$ as minor phases.

Lignite and subbituminous coals contain high levels of organically associated alkali and alkaline-earth elements, including sodium, magnesium, calcium, and potassium in addition to mineral phases. During combustion, the inorganic components in the coal are partitioned into various size fractions based on the type of inorganic component and their association in the coal and combustion system design and operating conditions. The results of this testing found that the smaller size fractions of ash are dominated by partially sulfated alkali and alkaline-earth elements. The composition of the size fractions was compared to the chemical composition of the ash deposited on and in the catalyst. The comparison shows that the composition of the particle captured in the SCR catalyst is very similar to the <5-μm size fraction.

The ability of mercury to be oxidized across the SCR catalyst was investigated at the Coyote Station. The Coyote Station is fired on North Dakota lignite, and the flue gases are dominated by elemental mercury. Measurement of mercury speciation was conducted using the OH method at the inlet and the outlet of the SCR catalyst. These results show limited oxidation of mercury across the SCR catalyst when firing lignite coals. The reasons for the lack of mercury oxidation include the following: no or low chlorine present in the coal and flue gas to catalytically enhance the oxidation of Hg^0, high levels of alkali and alkaline-earth elements acting as sorbents for any chlorine present in the flue gas, and low levels of acid gases present in the flue gas.

Subject: Stanton Draft Reponses to Select EPA FLM Comments
Attachments: 080918 draft Stanton BART responses to FLM.doc

Craig,

Here are Stanton's Draft Responses to the EPA FLM comments. Please take a look and let me know if any areas need more or less information. I will be out of the office thru Wednesday next week and will respond upon return.

Also, we would like to meet the department in the next few weeks to discuss long term options for Stanton. I would suggest sometime after Oct 2. Please let me know availability from your end and I will try to match schedules on ours.

Thanks in advance!

DRAFT Responses – 9/19/08

The Federal Land Managers and EPA recently commented on the State's Draft BART SIP and Stanton's Draft Permit-to-Construct, which incorporates the State's proposed BART limits. In response to certain EPA/FLM questions, GRE provides the following responses, at the request of NDDH.

EPA NOx Comment 48 (B) – "The State's proposal of LNB+OFA+SNCR is commendable since it goes beyond what can be achieved with just combustion controls. However, the BART limit should be tightened since current (pre-BART) emissions using PRB coal at Stanton are already very close to the proposed limit (0.26 lb/mmbtu vs. 0.23 lb/mmbtu)"

GRE Response – As discussed in Stanton's BART analysis, there are several justifications for the proposed NOx limits. While it is true that Stanton has hit roughly 0.26 lb/mmbtu NOx as an annual average, this emission rate must be viewed within the context of Stanton's operational configuration and with respect to the BART limit that is expressed as a 30-day rolling average, inclusive of startup and shutdown emissions.

In terms of operational justifications for a higher NOx emission rate, there are many. First, NOx emissions are impacted by variable load operations over shorter averaging periods. Under normal station operating conditions, Unit 10 is run at full utilization while Unit 1 varies (swings) to meet Midwest Independent System Operators (MISO) power demands. Unit 1 has a wider load range than Unit 10 to swing to meet load. (As the larger unit, Unit 1 swings rather than Unit 10 because of back draft problems that can cause Unit 10 to trip.) On PRB, Unit 1 only needs to operate 2 of its 3 mills at any time to follow load. So, by rotating the 2 mill configuration over a year, they have demonstrated an ability to operate at 0.26 lb/mmbtu as an annual average. Again, short term operational variability is muted as an annual average, but becomes more of a concern over shorter term compliance limits such as 30 days.

Specifically, Stanton rotates mill operation so that they all wear equally. However, if the lower mill is out-of-service, the upper two mills must support the load. The lower mill can have a mechanical breakdown, which requires it to be taken out of service. Therefore, over shorter term averaging periods, NOx emissions will be higher while running on the two upper mills.

Second, if Unit 10 trips due to a tube leak or other maintenance problem, Unit 1 needs to operate all three mills in order to fully supply steam to the single turbine. Under the three mill operational scenario, NOx emission rates are higher than two mill operation. Depending on the extent of the unplanned Unit 10 outage, it is possible for Unit 1 to operate on all three mills for as much as 30-days.

Third, nitrogen can vary by coal type, which will impact NOx emissions. Fuel bound nitrogen association with the range of lignite and PRB coals available to Stanton was inherently included in the safety factors that were applied to the Alstom target emission rates.

As discussed in the Alstom NOx Evaluation (Stanton BART Analysis Appendix D) and as discussed in Section 4.3 of Stanton's BART Analysis. The proposed BART limits are reflective of these operational scenarios.

EPA Wet Scrubber Comment 45 – "A wet scrubber was eliminated from consideration based on environmental considerations, but it is not clear how significant these other considerations and why they were not important at other plants."

GRE Response – In addition to cost effectiveness and incremental deciview arguments described in Stanton's BART analysis, there are other environmental considerations that would also support ruling out a wet scrubber as BART. Most importantly, Stanton Station, unlike other plants in ND, currently has a spray dry baghouse on its Unit 10. Therefore, in addition to other environmental considerations described below, there are significant operational efficiencies associated with installing another spray dry baghouse on Unit 1.

Site Constraints – Stanton Station is located on the Missouri River, which is immediately north of the plant, and is bounded by the state highway on the south. Basin Electric is located immediately east and Coyote Pump house and existing rail lines constrict the western boundary. See BART Analysis Appendix G – Site Diagram. There are realistically only two potential areas on site that could be considered for the additional ponding associated with a wet scrubber. They are either, the existing ash pile, which would need to be excavated and moved, or the abandoned ash disposal area adjacent to the river, which reportedly has geotechnical deficiencies. The levee along this area had started to erode, which instigated the abandonment of the Old Ash Disposal Area.

Water Use – The wet scrubbing technology will use more water than dry scrubbing. According to Washington Group's preliminary estimates, wet scrubbing can use as much as 20% more water or approx. 15MM gallons/yr. Since water use in the western United States has been and will continue to be a contentious issue, the plant must be cognizant of it as a resource use. Further, with respect to Clean Water Act 316(b) requirements, an increase in water withdrawal may trigger alternative cooling water intake requirements such as cooling towers. These additional costs were not fully incorporated into the analysis, but present other environmental considerations and regulatory risks as part of the BART analysis.

Wastewater Discharge – It is assumed that a wet scrubber system would require additional on-site ponding. Again, it is important to note the site diagram and the proximity to the river. Although there appears to be an available area immediately adjacent to the river, this area is geologically unsound for scrubber sludge ponding. Since a comprehensive geological site assessment including structural improvements and pond lining was not completed, this item was listed as a non-air quality environmental consideration. Any wastewater generated by wet scrubbing is expected to have concentrations that may require further on-site treatment prior to discharge. Finally, once mercury controls are installed, it is logical to assume that some mercury will be transferred to the wastewater ponds and treatment system, which will prove problematic for discharge.

Operational Efficiencies with Dry Scrubbing Technology – Stanton Station Unit 10 currently has a spray dry baghouse to control SO2. The plant is very familiar with this technology. There are cost savings associated with lime handling, ash handling and operator coverage if an additional spray dry baghouse combination is installed on Unit 1.

Pending Mercury Air Emission Controls – For almost 10 years, Stanton has consistently conducted mercury reduction research in conjunction with EPRI, EERC, DOE, NDIC, LEC and others. This research has not only supported national efforts to reduce mercury through the development of improved carbons, but it has provided plant specific mercury control information that will be used to comply with CAMR, if re-instated, or MACT requirements when promulgated. A great deal of Stanton's research was conducted with the Unit 10 spray dry baghouse. It is clear that spray dry baghouse with carbon injection combinations work substantially better than wet scrubber mercury controls, especially on western coals, like PRB and Lignite, that have a higher elemental mercury percentage. If a wet scrubber technology were required, Stanton would have to work much harder to remove the same amount of mercury from the exhaust gas. Further, there would be wastewater issues associated with mercury, and other exhaust gas constituents as mentioned. .

In addition to cost effectiveness and incremental deciview arguments in Stanton's BART analysis, it is the combination of these other environmental considerations that support our proposed BART controls and associated emission rates.

EPA Comments 44, 45 and 46– "We believe that the 'inferior' control technology proposed for Stanton Unit 1 (spray dryer/fabric filter) coupled with, what we find to be, an inflated uncontrolled emission rate, produces too high of an SO2 limit (0.24 for lignite and 0.16 for PRB)."

'Inferior' Control - Stanton Station has completed a BART analysis for SO2 controls that includes wet scrubber, spray dryer/fabric filter, dry sorbent injection and other SO2 controls. According to the five factor analysis, the spray dryer/fabric filter was determined to be the most appropriate control to cover the range of permitted fuels and sulfur contents.

As discussed in Section 5.1 of Great River Energy's Stanton Station BART Analysis (Rev Jan 2008), the plant is currently permitted for both PRB and Lignite coals. The current fuel contract expires in November 2009 and the plant is evaluating several coal suppliers. Appendix E of Stanton' BART analysis provides detailed discussion for some future coals and their potential uncontrolled sulfur emissions.

As one example, Stanton Station recently completed a test burn of Absaloka PRB. According to the CEMS data (See Table), there was significant hourly variability associated with sulfur emissions from one train of the Absaloka. We do not have enough familiarity with the Absaloka or the Rosebud Mine plans in order to speculate on future sulfur content or consistent sulfur content within deliveries over a 30 day period. Although limited, the CEMS data for part of trial burn is supportive of NDDH's uncontrolled emission calculations, which was actually based on the higher sulfur Rosebud Mine. The NDDH proposed SO2 PRB emission rate is reflective of these prospective fuel options and sulfur uncertainties.

As described in Appendix E of the Stanton's BART analysis, the nearest active lignite mine on Stanton's side of the Missouri River is at Minnkota's plant. Sulfur emission rates were derived from this mine as representative of uncontrolled emissions associated with a prospective lignite fuel source. Although different than historical lignite emission rates, it is reflective of the most probable lignite fuel available to Stanton at this time.

Absaloka SO2 CEMS Data

Average	1.30
Minimum	0.89
Maximum	2.12
Summation	124.66
Included Data Points	96

EXECUTIVE SUMMARY

On July 6, 2005, the U.S. EPA finalized the Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations. The final regulations require eligible sources to be analyzed to determine a BART emission limit for nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM). The North Dakota Department of Health (NDDH) reviewed the operational history of North Dakota sources and determined which sources were BART eligible and provided a state specific modeling protocol for use in the analysis. Minnkota Power Cooperative, Inc.'s (Minnkota's) Units 1 and 2 at the Milton R. Young Station (MRYS) were determined to be BART eligible by the NDDH. As discussed in the introduction to the analysis, small emission units at MRYS produce emissions in levels anticipated to be too small to affect visibility in Class 1 areas and were excluded from further consideration in the study. This BART determination was conducted in accordance with the eligibility conclusion made by NDDH and follows the NDDH protocol.

Once a source is determined to be eligible, there are five predefined steps for conducting a BART analysis for each pollutant. The result of conducting this five step analysis is a list of control technologies for regulated pollutants that provides a cost effective system of emission reduction and visibility impact reduction. However, prior to the completion of this analysis, Minnkota entered into a Consent Decree (CD) that requires the MRYS to install Best Available Control Technology-level (BACT-level) controls for NO_X, SO_2, and PM. As discussed in detail within the report, BACT is considered to be more stringent than BART. Thus, the BART analysis was reduced to an evaluation of the BACT-level control technologies and emission reductions specified by the CD. Because BACT and BART analyses have similar steps, the only remaining step for recommending BART was to perform a visibility impairment impact analysis and discern if there was an acceptable impact reduction.

Based upon an evaluation of the 90th percentile visibility impairment modeling results, the control technologies and emission reductions specified by the CD for all pollutants and both units had an acceptable impact reduction. Because there was an impact reduction in all cases, the BART recommendation consists of the control technologies recommended as BACT for NO_X emissions and those specified by the CD for SO_2 and PM emissions at the modeled emission rates. The BART recommendations for each pollutant and each unit are summarized in the tables below. The recommended BART emission rates are presented as a 30-day rolling average to account for variations in boiler operation, fuel sulfur content and fly ash properties.

MRYS Unit 1 Recommended BART 30-Day Rolling Average

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.36*
SO_2	Dry Flue Gas Desulfurization (FGD) Process	0.24
PM	Fabric Filter Baghouse	0.015**

* Excludes startups. See Appendix A for a detailed discussion.

** See discussion in Section 5.1

MRYS Unit 2 Recommended BART 30-Day Rolling Average

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.35*
SO_2	Upgrade of Existing Wet Flue Gas Desulfurization (FGD) Process	0.31
PM	Maintain Existing Electrostatic Precipitator (ESP)	0.030

* Excludes startups. See Appendix A for a detailed discussion.

1.0 INTRODUCTION

The U.S. EPA finalized the Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations[1] in the Federal Register on July 6, 2005 (70 FR 39104). BART is defined as "an emission limitation based on the degree of reduction achievable through the application of the best system of continuous emission reduction for each pollutant which is emitted by a BART-eligible source. The emission limitation must be established on a case-by-case basis, taking into consideration the technology available, the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology" (70 FR 39163). This document presents the BART analysis for each of three major pollutants (nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM)) for Minnkota Power Cooperative, Inc.'s (Minnkota's) Units 1 and 2 at the Milton R. Young Station (MRYS) located near Center, North Dakota.

A BART eligible source is one that meets three criteria identified by EPA in the guidelines for the determination of BART. A source is BART eligible if operations fall within one of 26 specifically listed source categories (70 FR 39158), the source entered into service between August 7, 1962 and August 7, 1977, and the source has the potential to emit 250 tons per year or more of a visibility-impairing air pollutant (SO_2, NO_X or PM). The North Dakota Department of Health (NDDH) reviewed the operational history of sources within North Dakota and independently determined which sources are BART eligible. The NDDH classified the electric generating units (EGUs) at Milton R. Young Station as BART eligible. For the purposes of this report, the NDDH's determination will be used and Units 1 and 2 at MRYS are assumed to be subject to a BART analysis.

Where a particular source is determined to be eligible, the general steps for determining BART for each pollutant are as follows (70 FR 39164):

STEP 1 - Identify all available retrofit control technologies (within the BART Guidelines).
STEP 2 - Eliminate technically infeasible options.
STEP 3 - Evaluate control effectiveness of remaining control technologies.

---

[1] "Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations"; Environmental Protection Agency; Federal Register, Volume 70, No. 128; July 6, 2005.

STEP 4 - Evaluate the following impacts for each feasible control technology and document results: (70 FR 39166).

- The cost of compliance.
- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

STEP 5 – Evaluate the visibility impacts.

Minnkota Power Cooperative, Inc. retained Burns & McDonnell to assist in the completion of the Best Available Retrofit Technology analysis for Milton R. Young Station. Burns & McDonnell is a full service engineering, architectural, construction and environmental firm. The company plans, designs and constructs electric generating facilities and has been providing environmental services to the power industry since the 1970s. As a result of their long history providing these services, Burns & McDonnell has extensive experience in permitting, Best Available Control Technology (BACT) studies and control technology analysis similar to a BART analysis.

1.1 BACKGROUND

Minnkota Power Cooperative, Inc. operates the Milton R. Young Station near Center, North Dakota. MRYS is a steam electric generating plant with two units. Unit No. 1 is a Babcock & Wilcox (B&W) cyclone-type coal-fired boiler burning lignite coal, serving a turbine generator with a nameplate rating of 257 MW.[2] Particulate control is provided by a Research-Cottrell Electrostatic Precipitator rated at approximately 99% control. Unit 1 has no sulfur dioxide (SO_2) control system and exhausts to a 300 foot tall stack. Unit No. 2 is a B&W cyclone-fired unit burning lignite coal, with a turbine-generator name plate rating of 477 MW.[2] Particulate control for Unit 2 is provided by a Wheelabrator-Lurgi precipitator rated at approximately 99% control. Unit 2 has a Combustion Equipment Associates wet flue gas desulfurization (FGD) system (modified by Combustion Engineering) that treats approximately 78 percent of the flue gas with the remaining flue gas by-passed for stack gas reheat. The FGD system achieves approximately 75 percent SO_2 removal and exhausts to a 550 foot tall stack. Unit 1 began commercial operation on November 20, 1970 and Unit 2 on May 11, 1977.

---

[2] "Generator Nameplate Data"; Emissions & Generation Resource Integrated Database (eGRID); U.S. Environmental Protection Agency; April, 2003.

On 17 June 2002, Minnkota Power Cooperative, Inc. received a Notice of Violation (NOV) from EPA. The NOV states that Minnkota allegedly violated the Prevention of Significant Deterioration (PSD) regulations. The NOV was issued pursuant to Section 113 of the Clean Air Act. The alleged violation was caused by modifications to both Unit 1 and 2 at MRYS which allegedly resulted in a potential increase of SO_2, NO_X and PM. Without an admission of liability, Minnkota entered into a settlement in the form of a Consent Decree (CD) with the EPA and NDDH to resolve the issues. The CD requires that Minnkota install a level of control for SO_2, NO_X and PM on both Unit 1 and 2 at MRYS, equivalent to BACT. The effect of the CD on the BART analysis and the requirement to install BACT-level controls are discussed later in the report.

1.2 APPROACH

The purpose of the Regional Haze Rule is to address visibility impairment in mandatory Class 1 areas that results from the emission of SO_2, NO_X, PM, Volatile Organic Compounds (VOCs) and ammonia from certain major sources. The only control method for VOCs identified in the RACT/BACT/LAER Clearinghouse (RBLC) database is good combustion practices. This control technique is already in place at MRYS. If an analysis were performed for VOCs, good combustion practices would be the most probable method chosen for BART. The visibility impact of VOCs and ammonia are considered negligible for a BART analysis, according to the NDDH's November 2005 modeling protocol[3], and are not addressed further in this report. Before the actual BART analysis can begin for SO_2, NO_X, and PM, the approach used to conduct the analysis should be addressed. The following sections present specific subjects related to MRYS's background, which warrant mention due to their effects on the contents of the report.

1.2.1 CONTROL TECHNOLOGY EVALUATION AND BACT VS. BART

As stated above, once a source is determined to be eligible, there are general steps for conducting a BART analysis for each pollutant. All retrofit control technologies are first identified. A brief review of the processes and their capabilities is then performed to determine availability and feasibility. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to control capability and an analysis then reviews the probable impacts of each technology.

---

[3] "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota"; North Dakota Department of Health, Division of Air Quality; November, 2005.

The visibility impact is included in the impact analysis. Finally, the results of the analyses are tabulated and possible BART control options are listed.

As stated in the proposed BART guidelines dated 5 May 2004 (69 FR 25218), a BART analysis is similar to a Best Available Control Technology (BACT) analysis.

> "The process for a BART analysis is very similar to the BACT review as described in the New Source Review Workshop Manual (Draft, October 1990). Consistent with the Workshop Manual, the BART engineering analysis requires that all available control technologies be ranked in descending order of control effectiveness (i.e. percent control). You [meaning States] must examine the most stringent alternative first. That alternative is selected as the ''best'' unless you demonstrate and document that the alternative cannot be justified based upon the consideration of the five statutory factors discussed below. If you eliminate the most stringent technology in this fashion, you then consider the next most stringent alternative, and so on.
>
> Although very similar in process, BART reviews differ in several respects from the BACT review described in the NSR Draft Manual."

The proposed guidelines stated that a BART analysis is similar to a BACT review and provided a few examples of similarities and differences, but it did not explicitly state how the two analyses could be used in conjunction to obtain a determination. Because BACT and BART are similar, there are many aspects that can be combined to reduce the steps of an analysis. However, because there are some differences, a BART analysis must address some additional aspects that a BACT review does not.

A BART analysis is always conducted for existing sources and a BACT review is usually conducted for a new source. Because BACT is usually performed for a source that is a new design or reconstruction, the review must take into account all available technologies and must include the most effective controls that have been demonstrated on similar units. BACT is considered to be more stringent than BART because it usually is not limited by the design of existing equipment or current operating conditions as is required for a retrofit application. Although MRYS is eligible to perform an analysis to determine BART, the Consent Decree (CD) also requires that MRYS install levels of control equivalent to BACT. Thus, the BART analysis can be shortened to only include the BACT-level control technologies specified in the CD.

With the specification of BACT-level technologies in the CD, the first four evaluation steps of the BART analysis can be eliminated. The first four steps of BART are usually used to identify technologies, determine feasibility and evaluate cost, energy, non-air quality and useful life impacts. Because the control technologies are already specified by the CD, the visibility impacts evaluation is the only remaining step in the determination that must be performed to satisfy BART. This analysis evaluates the visibility impairment impacts of the BACT-level control technologies specified in the CD and provides a BART recommendation based upon an acceptable degree of visibility improvement in Class 1 areas.

1.2.2 CONDENSABLE PARTICULATE

Particulate matter emissions are composed of filterable and condensable particles. The filterable particles are characterized using EPA standard reference methods (i.e., Method 5, 17, 201, or 201A). The reference method used for characterization is dependent upon the size of the particle and the temperature of the flue gas, and is usually specified in the applicable permit. Solid particles are captured using a heated filter while the majority of condensable particles are not collected as they are in the gaseous form until after the flue gas has passed through the filter.

Condensable particulate matter (condensable PM) may react with atmospheric or flue gas constituents as flue gas moves through the different processes and then either condenses into a droplet, coalesces into a solid particle, or forms a solid particle as more volatile components evaporate. Condensable PM is characterized using EPA standard reference Method 202. Using Method 202, the flue gas passes through a heated filter to remove filterable PM and condensable flue gas constituents are condensed by bubbling them through water at 20^oC. During post-test sample recovery, the water is evaporated and the remaining residue is weighed to determine condensable PM emissions. However, Method 202 has an inherent flaw because the means by which condensable particulate is collected differs from how particulate condenses in the stack. Method 202 can result in inaccurate measurements due to the creation of PM artifacts in the sampling water that would not normally condense in the stack plume (e.g., SO_2 and NH_3 compounds). For a fixed operating condition, Method 202 can provide inconsistent emission rate measurements and can result in overstatement of emission rates. Thus, there is considerable uncertainty surrounding emissions measured with Method 202 for the purpose of PM compliance demonstration.

Condensable PM may include both organic and inorganic constituents. Organic constituents in the flue gas can exist as a vapor at stack temperatures and a liquid or solid at ambient temperatures. Control technologies designed to minimize the formation of condensable organic emissions are the same technologies that are used to minimize carbon monoxide (CO) and volatile organic compound (VOC) emissions. A review of the RBLC database shows that good combustion practices are universally used to control CO/VOC emissions for similar units. Both MRYS units already practice good combustion practices while maintaining combustion efficiency in the boiler and controlling NO_X emissions. Because good combustion practices would likely be considered BART and are already in use at both units, the organic portion of condensable PM is not addressed further in this report.

Sulfuric acid (H_2SO_4) mist is the most widely recognized form of inorganic condensable PM emitted by combustion sources. Other inorganic condensable PM constituents may include to a lesser extent other acid gases, ammonium sulfate ($(NH_4)_2SO_4$), and unidentified inorganic species. Control technologies designed to reduce sulfuric acid mist will also reduce the other inorganic constituents. H_2SO_4 is typically generated in the flue gas when sulfur trioxide (SO_3) reacts with water. SO_3 is a by-product created during the combustion of fuels containing sulfur and is formed when sulfur dioxide (SO_2) in the flue gas is oxidized. Limited data is available on the quantity of SO_2 that will be converted to SO_3 in a lignite fired unit. Estimates of the conversion range from 0.2 to 1.0 percent.

Combustion controls commonly used to control NO_X (e.g., staged combustion and separated overfire air) provide a co-benefit of sulfuric acid mist control by limiting the oxygen available in the boiler and reducing formation of SO_3 in the boiler. The H_2SO_4 vapor will adsorb on the fly ash as the flue gas cools under appropriate temperature and moisture conditions. Consequently, when those conditions exist, H_2SO_4 is removed from the gas stream by particulate control equipment. Control technologies designed to remove SO_2 will also achieve SO_3 removal and reduce emissions of H_2SO_4. Typical SO_3 removal associated with a wet FGD process is 40 to 60 percent, and higher removal is typical for semi-dry FGD processes. The Southern Company estimates a minimum 50% reduction in H_2SO_4 emissions for use of a FGD process.[4] Thus, control technologies used to control NO_X, SO_2 and filterable PM are also able to provide H_2SO_4 control.

---

[4] "An Updated Method for Estimating Total Sulfuric Acid Emissions from Stationary Power Plants"; Monroe, Larry S. & Harrison, Keith E.; Southern Company Generation and Energy Marketing; Revised March, 2003.

Recommended BART for condensable PM is the co-benefit of NO_X, SO_2 and filterable PM control devices to be analyzed in this report and is not addressed further. Therefore this BART analysis for particulate emissions investigates control methods to reduce filterable PM only.

1.2.3 EMISSION SOURCE APPLICABILITY

There are two subjects within the Guidelines related to the applicability of BART to emission sources. The first subject deals with the presumptive BART emission limits and their application to power plants smaller than 750 MW in size. The Guidelines for BART Determination include the following statement with regard to presumptive BART for SO_2 (70 FR 39171):

> "You [meaning States] must require 750 MW power plants to meet specific control levels for SO_2 of either 95 percent control or 0.15 lbs/mmBtu, for each EGU greater than 200 MW that is currently uncontrolled unless you determine that an alternative control level is justified based on a careful consideration of the statutory factors. For a currently uncontrolled EGU greater than 200 MW in size, but located at a power plant smaller than 750 MW in size, such controls are generally cost effective and could be used in your BART determination….."

Similarly for NO_X, the EPA states (70 FR 39171):

> "For coal-fired EGUs greater than 200 MW located at greater than 750 MW power plants and operating without post-combustion controls, we have provided presumptive NO_X limits differentiated by boiler design and type of coal burned. You may determine that an alternative control level is appropriate based on a careful consideration of the statutory factors. For coal-fired EGUs greater than 200 MW located at power plants 750 MW or less in size and operating without post-combustion controls, you should likewise presume that these same levels are cost-effective."

For power plants greater than 750 MW in size, the EPA requires state agencies to apply the presumptive limits for BART as a floor for NO_X control. However, for power plants smaller than 750 MW in size, the presumptive limits are described as being "cost-effective" but not set as a minimum performance requirement. Thus, BART for EGUs at power plants smaller than 750 MW in size, like MRYS, is not required to meet the presumptive limits. This BART analysis for MRYS will evaluate potential control options that achieve the BACT-level limits set forth in the Consent Decree.

Consequently, based upon the visibility analysis, the recommended control options may not achieve the EPA's presumptive BART limits.

The second part of the Guidelines that should be addressed relates to which emission units are subject to BART for a particular pollutant. The Guidelines state that:

> "Once you determine that a source is subject to BART for a particular pollutant, you must establish BART for that pollutant. The BART determination must address air pollution control measures for each emissions unit or pollutant emitting activity subject to review." (70 FR 39163)

According to this statement, the BART determination must consider any emission unit that emits the pollutant of concern (i.e., NO_x, SO_2 and PM) regardless of size. The BART analysis for MRYS will review control options for the main boilers for Unit 1 and Unit 2. Smaller emissions sources at the facility are anticipated to provide negligible contribution to visibility impacts from MRYS in Class 1 areas. Smaller sources at MRYS are discussed in Section 1.2.4 and 1.2.5.

1.2.4 SMALL SOURCE EMISSION UNITS

The BART determination must consider any emission unit that emits the pollutant of concern (i.e., NO_x, SO_2 and PM) regardless of size. However, smaller emissions sources (e.g., auxillary boilers and emergency generators) at the facility are anticipated to provide negligible contributions to visibility impairment in Class 1 areas. The nearest Class 1 area is Theodore Roosevelt National Park (TRNP) located approximately 160 km to the west. Although technically eligible, smaller source emissions units were not reviewed because they have limited hours of operation or they are material handling sources with a level of emissions anticipated to be too small to affect visibility impact on TRNP. Consequently, small emission sources are excluded from further consideration in the study.

1.2.5 FUGITIVE DUST

The primary source of fugitive dust is from the outside coal storage area and other plant activities normally found at a coal-fired electrical generating facility. The coal stockpile, access roads and plant activities are performed and maintained with good operating practices. On the coal stockpile and on other applicable fugitive sources, dust suppression is achieved through the use of water sprays or surfactants. The level of fugitive PM emissions is not expected to affect the visibility in Class 1 areas based upon the approximate 160 km distance to the nearest Class 1 area, the large particle size and relatively small emission rates. As such, fugitive sources were not evaluated in this BART analysis for MRYS.

1.2.6 METHODOLOGY FOR VISIBILITY IMPACTS DETERMINATION

In the BART Determination Guidelines, as discussed in Section 1.0 of this report, the EPA provides five basic steps for a case-by-case BART analysis. The fifth step involves evaluating visibility impacts utilizing dispersion modeling. Visibility impairment impacts for modeled pre-control and post-control emission levels and visibility improvements are to be assessed in deciViews (dV). The BART guidelines describe the thresholds for visibility impairment as:

> "A single source that is responsible for a 1.0 dV change or more should be considered to "cause" visibility impairment; a source that causes less than a 1.0 dV change may still contribute to visibility impairment..... any threshold that you (the States) use for determining whether a source "contributes" to visibility impairment should not be higher than 0.5 dV." (70 FR 39161)

The NDDH BART protocol does not distinguish between a source that "causes" or "contributes" to visibility impairment but follows the EPA's Regional Haze Rule threshold recommendations. Thus, 0.5 dV is the deminimis threshold level of visibility impairment impact for an otherwise BART-eligible source under the NDDH BART protocol. In other words, a BART-eligible source for which modeling predicts a visibility impairment impact of greater than 0.5 dV is deemed to have a visibility impairment impact and thus is subject to a BART analysis under the NDDH BART protocol. A BART-eligible source for which the modeling predicts less than a 0.5 dV impact would be deemed to not have a visibility impairment impact, and thus could be exempted from BART on that basis. Most noticeably, the EPA refrains from addressing the question of whether or not a difference in visibility impairment impact improvement of less than 0.5 dV between two BART alternatives would constitute equivalency under the visibility analysis, or if any difference in the model results, no matter how slight, should be interpreted as ranking one solution over the other.

The approach taken in the BART analysis for MRYS incorporates the visibility impact analysis results as a verification of visibility improvement. Because the Consent Decree specifies the control level and technology that must be used for SO_2 control, the emission rate for control of PM, and the use of a BACT "Top Down" analysis for NO_X emissions control, the visibility analysis is not used to differentiate between control technologies used to control each pollutant. Rather, the visibility analysis is used to determine if control levels and technologies specified in the Consent Decree provide visibility improvement in Class 1 areas.

1.3 THE ROLE OF MODELING AND CALPUFF IN A BART ANALYSIS

The BART guidelines list visibility impact at a Class I area as one of the factors in a BART determination. The EPA interpreted the statutory provision of Section 169A of the Clean Air Act to require that a BART-eligible source is one that is "reasonably anticipated to cause or contribute" to regional haze if it can be shown that the source emits pollutants within a geographic area from which pollutants can be emitted and transported downwind to a Class I area (70 FR 39161). A Class I area, as listed by the EPA, is an area of the country with pristine air quality that is sensitive to changes in visibility. Two Class 1 areas have been identified for inclusion in the visibility analysis for MRYS. These are the Theodore Roosevelt National Park (TRNP), and the Lostwood National Wildlife Refuge (Lostwood NWR), which are approximately 160 and 180 km (100 and 112 miles), from Milton R. Young Station, respectively. For Class I areas more than 50 km from a source, the EPA has identified CALPUFF as a guideline model for long-range transport that is suitable for predicting potential changes in visibility. CALPUFF is a non-steady-state meteorological and air quality dispersion modeling system used to access long-range transport of pollutants.

The NDDH modeling protocol confirmed that the two Class I areas to be considered for visibility impairment analysis are the TRNP and Lostwood NWR. However, the three units or areas of the TRNP are to be treated as separate Class I areas for the analysis.

1.3.1 CALPUFF MODELING METHODOLOGY

Visibility impairment is caused by a combination of particles and gases in the atmosphere. Some particles and gases scatter light, others absorb light. The combined effect of scattering and absorption is called "light extinction" which is most commonly seen as haze. This haziness is measured in deciView (dV) units, and is related to light extinction coefficient by the following equation:

$$dV = 10 \ln(b_{ext}/10)$$

Where b_{ext} is light extinction coefficient in inverse megameters.

Visibility impairment is a function of light extinction. Light extinction occurs when light energy is either scattered or absorbed by particles in the air. The amount of moisture in the air also plays a role in light extinction. Certain gases combine with moisture in the air to form small light scattering particles. These gases, most notably SO_2 and NO_X, are significant components of coal-fired power plant emissions. Particulate Matter (PM) also contributes to light extinction. In the BART Determination Guidelines, the EPA states that "You [the State] may use PM_{10} as an indicator for particulate matter. We do not recommend the use of Total Suspended Particulates (TSP). As emissions of PM_{10} include the components of $PM_{2.5}$ as a subset, there is no need to have separate 250 ton thresholds for PM_{10} and $PM_{2.5}$; 250 tons of PM_{10} represents at most 250 tons of $PM_{2.5,}$ and at most 250 tons of any individual particulate species such as elemental carbon, crustal material, etc." (70 FR 39160). The NDDH modeling protocol states that particulate matter emissions should be specified as either coarse (PM_{10} minus $PM_{2.5}$) or fine ($PM_{2.5}$). The distinction between coarse and fine particulate occurs in the modeling.

The NDDH modeling protocol recommends a specific version of the CALPUFF modeling system as modified by the NDDH to specifically address terrain, climate, and emission characteristics of MRYS. (CALMET and CALPUFF were recompiled by the NDDH while the CALPOST executable used for this visibility analysis was the EPA guideline executable). Along with the CALPUFF modeling system, the NDDH also provided the RUC2-MM5 gridded wind field data (2000-2002), surface, upper air, and precipitation files, and CALMET and CALPUFF input files. The input files contained the specific coordinate grid points, wind field options, terrain, dispersion options, receptor coordinates and plume characteristics and other model parameters that the NDDH has determined best represents the region. The NDDH version of CALPUFF was used for modeling.

In order to predict the change in light extinction at TRNP and Lostwood NWR areas, SO_2, NO_X, and PM were modeled with CALPUFF using pre-control and post-control emission scenarios. A variety of post-control scenarios were used to determine the reduction in visibility impact for each control technology. The NDDH identified 104 receptors allocated over both TRNP and Lostwood NWR. These receptors are location points for which CALPUFF was used to perform a visibility calculation.

The BART guideline states that a visibility improvement is based upon the modeled change in visibility impacts, measured in deciViews, for the pre-control and post-control emission scenarios. The comparison should be made for the 98th percent days (70 FR 39170). The NDDH modeling protocol provides additional clarification about BART applicability by stating, "…the context of the

98th percentile 24-hour delta-deciView prediction is with respect to days of the year, and is not receptor specific. A 24-hour prediction greater than 0.5 delta-deciView at any receptor in a Class I area would constitute a day of exceedance, and up to 7 days of exceedance would be allowed per year per Class I area (i.e., the 98th percentile is approximated by the eighth-highest daily prediction)." In other words, visibility impacts should be compared on an annual basis using the eighth highest day for comparison (365 * (1-.98) = 7 days of acceptable exceedance). However, NDDH subsequently advised that the delta-deciView comparison should be made at the 90th percentile to be consistent with the Western Regional Air Partnership (WRAP) protocol. Therefore, the visibility impairment impact reduction presented for each control scenario in this section is based on the 90th percentile value.

1.3.2 MODELING SCENARIOS

Since a BART analysis is based on the degree of reduction achieved by the application of control technologies, the CALPUFF analysis examined multiple operating scenarios based upon the feasible control technologies identified for each pollutant. These scenarios represent the emissions of SO_2, NO_X, and PM under the following conditions:

- NDDH BART Modeling Protocol emission rates
- Post-Control emissions based upon BACT-level emission rates as required by the Consent Decree

The emission rates modeled in each scenario are presented in Table 1.3-1.

Table 1.3-1 – Milton R. Young Station Modeling Scenarios

Scenario	Unit 1			Unit 2		
	NO_X (lb/hr)	SO_2 (lb/hr)	PM Coarse/Fine (lb/hr)	NO_X (lb/hr)	SO_2 (lb/hr)	PM Coarse/Fine (lb/hr)
Screening	Protocol	Protocol	Protocol	Protocol	Protocol	Protocol
1	1,070.7	Protocol	Protocol	2,011.6	Protocol	Protocol
2	Protocol	723.1	Protocol	Protocol	1,574.4	Protocol
3	Protocol	Protocol	38.5 / 5.8	Protocol	Protocol	133.7 / 21.0
4	1,070.7	723.1	38.5 / 5.8	2,011.6	1,574.4	133.7 / 21.0
5	1,070.7	723.1	38.5 / 5.8	2,011.6	1,574.4	133.7 / 21.0

These scenarios represent the emission rates evaluated for consideration in making a BART recommendation. The emission rates presented in Table 1.3-1 correspond to control options and efficiencies required by the Consent Decree. The scenario from the NDDH BART modeling protocol is based on the historical, maximum 24-hour emission rates for MRYS between 2000 and 2002. These rates were supplied to the NDDH by Minnkota, but were based upon operations that were not representative of stack conditions associated with new or modified retrofit control technologies. Due to analyses performed on plant operations and historical emissions data, Minnkota has determined that unit operating conditions associated with these protocol rates are not representative of future maximum 24-hour emissions and has requested NDDH to allow the use of an alternative baseline for modeled post-control emission rates. NDDH agreed to the use of an alternative baseline. The alternative baseline post-control scenarios are based upon various control technology emission reductions being applied to emissions from a maximum 24-hour average heat input of 2,955 mmBtu/hr for Unit 1 and 5,158 mmBtu/hr for Unit 2. The emission rates associated with each scenario are discussed in the section related to the controlled pollutant.

As shown in Table 1.3-1, multiple modeling scenarios were conducted to determine the specific visibility impact reduction associated with the control of each pollutant. To determine a specific visibility impact, the emission rate for the pollutant of concern was changed from the protocol rate to the post-control rate. Thus, any visibility impairment impact reduction for that modeling scenario was due solely to the application of the individual pollutant's control technology. This methodology was used for NO_X, SO_2, and PM. Additional modeling runs were conducted to determine the overall visibility impairment impact reduction caused by simultaneous application of all control technologies. In Table 1.3-1, modeling scenario 4 was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies for each unit individually. Modeling scenario 5 was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies for both units combined. The modeling results are summarized and discussed in the sections below.

2.0 NO_X BART EVALUATION
