The BART analyses for NO_X emissions from MRYS Unit 1 and Unit 2 are described in this section. Technical descriptions of MRYS Unit 1 and Unit 2 boilers and existing air pollution control equipment are provided. As discussed in the introduction, Minnkota has entered into a Consent Decree (CD) that requires MRYS to install BACT-level NO_X control technologies on both units. For NO_X, the CD required that a complete BACT analysis be performed to determine the applicable control technologies for each unit. The BACT analysis report is included as Appendix A. Because BACT is considered to be more stringent than BART, the analysis can be shortened to use control technologies identified by the NO_X BACT analysis for meeting BART. The remaining portion of the BART analysis considers visibility impairment impacts on the nearest Class 1 area.

2.1 NO_X EVALUATION BASIS – UNIT 1

Milton R. Young Station Unit 1 includes a Babcock and Wilcox steam generator installed in 1970. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation. Original unit design steam generating capacity is 1.714 million lbs/hr at 1,920 psi with a fuel heat input of 2,510 mmBtu/hr. The boiler is fired by seven ten-foot diameter cyclone burners, arranged “three over four” across the front wall of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the electrostatic precipitator (ESP). Unit 1 has a nominal 235 MW net design output capacity rating, is typically capable of sustained output of approximately 253 MW gross, and has an ultimate short-term maximum gross output (URGE) rating of 278 MW. The Unit 1 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boiler.

The modeling for Unit 1 uses two NO_X emission rates as a basis for the visibility impairment impacts. One emission rate was based upon the NDDH Modeling Protocol value of 2,855.2 lb NO_X/hr. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. The second emission rate of 1,070.7 lb NO_X/hr was based upon application of Selective Non-Catalytic Reduction (SNCR) and Advanced Separated Overfire Air (ASOFA) at a more representative maximum heat input of 2,955 mmBtu/hr. According to the BACT analysis required by the Consent Decree, SNCR used in conjunction with ASOFA was considered the best technology and therefore was evaluated as BART for Unit 1.

2.1.1 NO$_X$ VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 1

The remaining step for the BART NO$_X$ analysis was to conduct a visibility improvement determination for Unit 1. Due to the association of the Consent Decree and requisite BACT analysis, the visibility analysis was the only impact evaluation necessary to establish BART. In addition, because the BACT analysis resulted in one control technology, only one related emission rate was modeled to determine the visibility impairment impacts. The NDDH BART protocol[5] emission rate was modeled to determine a baseline visibility impact. The baseline visibility impact was then compared with the results predicted from a modeled post-control NO$_X$ emission rate based upon the control technology specified for Unit 1 in the BACT analysis.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 1. The post-control CALPUFF model scenario for MRYS Unit 1 was conducted with the protocol SO$_2$ and PM emission rates and the post-control NO$_X$ emission rate as discussed in Section 2.1 and Table 1.3-1.

The results of the visibility modeling at the protocol baseline NO$_X$ emission rate for MRYS Unit 1 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control NO$_X$ emission rate showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for all Class 1 areas at the post-control BACT-level NO$_X$ emission rate was below the 0.50 dV threshold level. The modeling results are presented in Table 2.1-1.

[5] "Protocol for BART-Related Visibility Impairment Modeling Analyses in North Dakota (Final)", November, 2005, North Dakota Department of Health (NDDH), Division of Air Quality.

Table 2.1-1 – NO_X Visibility Impairment Impacts and Reductions, MRYS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	Post-Control Emissions[2]	
TRNP-South Unit	0.549	0.376	0.173
TRNP-North Unit	0.628	0.410	0.218
TRNP-Elkhorn Ranch	0.374	0.263	0.111
Lostwood NWR	0.750	0.487	0.263

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

2 - NO_X emissions reduction by 62.5% over protocol baseline case. This scenario assumes protocol emission rates for SO_2 and PM.

The number of days predicted to have visibility impairment due to MRYS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results are summarized and presented in Table 2.1-2. Similarly, the same information for the post-control NO_X emission rates is summarized and shown in Table 2.1-2. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control NO_X emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 1. The impact in terms of days exceeding 0.50 dV varies from an approximately 17% reduction for TRNP – Elkhorn in 2001 to an approximately 40% reduction for TRNP – South in 2000. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 15% for TRNP – Elkhorn in 2002 to approximately 53% for TRNP – South in 2000.

2.2 NO$_X$ EVALUATION BASIS – UNIT 2

Milton R. Young Unit 2 is a Babcock and Wilcox steam generator installed in 1977. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation assisted with circulation pumps. Original unit design steam generating capacity is 3.20 million lbs/hr at 2,620 psi with a fuel heat input of 4,696 mmBtu/hr. The boiler is fired by twelve ten-foot diameter cyclone burners, arranged "three over three" across the front and rear walls of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Unit 2 has a nominal 439 MW net design output capacity rating, is capable of sustained output of approximately 462 MW gross, and has an ultimate short-term maximum gross output (URGE) of 512 MW. The Unit 2 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boilers.

The modeling for Unit 2 uses two NO$_X$ emission rates as a basis for the visibility impairment impacts. One emission rate was based upon the NDDH Modeling Protocol value of 5,364.2 lb NO$_X$/hr. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. The second emission rate of 2,011.6 lb NO$_X$/hr was based upon application of Selective Non-Catalytic Reduction (SNCR) and Advanced Separated Overfire Air (ASOFA) at a more representative maximum heat input of 5,158 mmBtu/hr. According to the BACT analysis required by the Consent Decree, SNCR used in conjunction with ASOFA was considered the best technology and therefore was evaluated as BART for Unit 2.

2.2.1 NO$_X$ VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 2

The remaining step for the BART NO$_X$ analysis was to conduct a visibility improvement determination for Unit 2. Due to the association of the Consent Decree and requisite BACT analysis, the visibility analysis was the only impact evaluation necessary to establish BART. In addition, because the BACT review resulted in one control technology, only one related emission rate was modeled to determine the visibility impairment impacts. The NDDH BART protocol[6] emission rate was modeled to determine a baseline visibility impact. The baseline visibility impact was then

compared with the result predicted from a modeled post-control NO_X emission rate based upon the control technology specified for Unit 2 in the BACT analysis.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 2. The post-control CALPUFF model scenario for MRYS Unit 2 was conducted with the protocol SO_2 and PM emission rates and the post-control NO_X emission rate as discussed in Section 2.2 and Table 1.3-1.

The results of the visibility modeling at the protocol baseline NO_X emission rate for MRYS Unit 2 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control NO_X emission rate showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for three of the Class 1 areas at the post-control BACT- level NO_X emission rate were below the 0.50 dV threshold level. The Lostwood NWR Class 1 area had a modeled visibility impairment impact of 0.544 dV. The modeling results are presented in Table 2.2-1.

Table 2.2-1 – NO_X Visibility Impairment Impacts and Reductions, MRYS Unit 2

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	Post-Control Emissions[2]	
TRNP-South Unit	0.580	0.406	0.174
TRNP-North Unit	0.619	0.438	0.181
TRNP-Elkhorn Ranch	0.360	0.277	0.083
Lostwood NWR	0.775	0.544	0.231

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

2 - NO_X emissions reduction by 62.5% over protocol baseline case. This scenario assumes protocol emission rates for SO_2 and PM.

The number of days predicted to have visibility impairment due to MRYS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results are summarized and presented in Table 2.2-2. Similarly, the same information for the post-control NO_X emission rates is summarized and shown in Table 2.2-2. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control NO_X emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 2. The impact in terms of days exceeding 0.50 dV varies from an approximately 9% reduction for TRNP – Elkhorn in 2001 to an approximately 37% reduction for TRNP – South in 2000. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 15% for TRNP – Elkhorn in 2002 to approximately 50% for TRNP – North in 2000.

3.0 SO_2 BART EVALUATION

In this section, the BART analysis for Milton R. Young Station (MRYS) is described for SO_2 and a brief description of the existing control technology for MRYS Unit 2 is presented. Unit 1 does not currently use SO_2 controls. As discussed in the introduction, Minnkota has entered into a Consent Decree (CD) that requires MRYS to install or modify SO_2 control technologies on both units to achieve BACT-level emission rates. Because BACT is considered to be more stringent than BART, the analysis can be shortened to use CD identified control technologies for meeting BART. The remaining portion of the analysis assess technologies for their potential visibility impairment impact reduction capability via visibility modeling results.

3.1 SO_2 EVALUATION BASIS – UNIT 1

Milton R. Young Station Unit 1 is a Babcock and Wilcox steam generator including a lignite-fired boiler with multiple cyclone-furnaces. The original unit design has a fuel heat input of 2,510 mmBtu/hr. The Unit 1 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a mine located adjacent to the site. The lignite significantly influences the resulting SO_2 concentration of the flue gases emitted from the boilers. Unit 1 currently does not use any SO_2 control technology.

The modeling for Unit 1 uses two SO_2 emission rates as a basis for the visibility impairment impacts. One emission rate was based upon the NDDH Modeling Protocol value of 7,231.2 lb SO_2/hr. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. The second emission rate of 723.1 lb SO_2/hr was based upon application of dry Flue Gas Desulfurization (FGD) process applied to a more representative maximum heat input of 2,955 mmBtu/hr. The Consent Decree defines the BACT-level SO_2 control technology options and removal efficiencies applicable for installation on MRYS Unit 1. The control technologies included in the CD are a wet FGD process achieving 95% removal efficiency, a dry FGD process achieving 90% removal efficiency or an equivalent alternative technology to be approved by the NDDH. At the time of this report, Minnkota had not selected the SO_2 control technology for MRYS Unit 1. Thus, a dry FGD process that achieves a worst case 90% removal was selected and evaluated as BART for Unit 1. Because a dry FGD process was evaluated as worst case, this analysis will still be applicable if Minnkota chooses to utilize an equivalent or more efficient control technology.

3.1.1 SO_2 VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 1

The remaining step for the BART SO_2 analysis was to conduct a visibility improvement determination for Unit 1. Due to the association of the Consent Decree, the visibility analysis was the only impact evaluation necessary to establish BART. In addition, because the CD specified applicable BACT-level control technologies, one technology (i.e., the dry FGD process) and related emission rate was selected for modeling to determine the visibility impairment impacts. The NDDH BART protocol[7] emission rate was modeled to determine a baseline visibility impact. The baseline visibility impact was then compared with the result predicted from a modeled post-control SO_2 emission rate based upon the BACT-level control technology specified in the CD.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 1. The post-control CALPUFF model scenario for MRYS Unit 1 was conducted with the protocol NO_X and PM emission rates and the post-control SO_2 emission rate as discussed in Section 3.1 and Table 1.3-1.

The results of the visibility impairment modeling at the protocol baseline SO_2 emission rate for MRYS Unit 1 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control SO_2 emission rate showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for all Class 1 areas at the post-control SO_2 emission rate was below the 0.50 dV threshold level. The modeling results are presented in Table 3.1-1.

Table 3.1-1 – SO_2 Visibility Impairment Impacts and Reductions, MRYS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	Post-Control Emissions[2]	
TRNP-South Unit	0.549	0.250	0.299
TRNP-North Unit	0.628	0.269	0.359
TRNP-Elkhorn Ranch	0.374	0.160	0.214
Lostwood NWR	0.750	0.322	0.428

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

2 - SO_2 emissions reduction by 90% over protocol baseline case. This scenario assumes protocol emission rates for NO_X and PM.

The number of days predicted to have visibility impairment due to MRYS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results are summarized and presented in Table 3.1-2. Similarly, the same information for the post-control SO_2 emission rates is summarized and shown in Table 3.1-2. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control SO_2 emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 1. The impact in terms of days exceeding 0.50 dV varies from an approximately 17% reduction for TRNP – Elkhorn in 2001 to an approximately 74% reduction for TRNP – South in 2000. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 27% for TRNP – South in 2001 to approximately 89% for Lostwood NWR in 2000.

Table 3.1-2 – Visibility Impairment Improvements – MRYS Unit 1 SO_2 Scenarios

Class 1 Area	SO_2 Control Technique	Days[2] Exceeding 0.5 dV in 2000	Days[2] Exceeding 0.5 dV in 2001	Days[2] Exceeding 0.5 dV in 2002	Days[2] Exceeding 1.0 dV in 2000	Days[2] Exceeding 1.0 dV in 2001	Days[2] Exceeding 1.0 dV in 2002	Consecutive Days[2] Exceeding 0.5 dV 2000	Consecutive Days[2] Exceeding 0.5 dV 2001	Consecutive Days[2] Exceeding 0.5 dV 2002

2 - Number of days for predicted visibility impairment impacts provided in Appendix B.

3.2 SO_2 EVALUATION BASIS – UNIT 2

Milton R. Young Station Unit 2 is a Babcock and Wilcox steam generator including a lignite-fired boiler with multiple cyclone-furnaces. Installed in 1977, the original unit design has a fuel heat input of 4,696 mmBtu/hr. The Unit 2 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a mine located adjacent to the site. The lignite significantly influences the resulting SO_2 concentration of the flue gases emitted from the boilers. Unit 2 has a Combustion Equipment Associates wet flue gas desulfurization (FGD) system (modified by Combustion Engineering) that treats the majority of the flue gas with the remaining flue gas by-passed for stack gas reheat.

The modeling for Unit 2 uses two SO_2 emission rates as a basis for the visibility impairment impacts. One emission rate was based upon the NDDH Modeling Protocol value of 6,879.0 lb SO_2/hr. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. The second emission rate of 1,574.4 lb SO_2/hr was based upon application of wet Flue Gas Desulfurization (FGD) process at a more representative maximum heat input of 5,158 mmBtu/hr. The Consent Decree requires MRYS to modify the existing wet FGD on Unit 2 to achieve a removal efficiency of at least 90%. The modified wet FGD process that achieves at least 90% removal, considered to be BACT-level control technology by the CD, was selected and evaluated as BART for Unit 2.

3.2.1 SO_2 VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 2

The remaining step for the BART SO_2 analysis was to conduct a visibility improvement determination for Unit 2. Due to the association of the Consent Decree, the visibility analysis was the only impact evaluation necessary to establish BART. In addition, because the CD specified the applicable BACT-level control technology, one technology (i.e., the modified wet FGD process) and related emission rate was selected for modeling to determine the visibility impairment impacts. The NDDH BART protocol[8] emission rate was modeled to determine a baseline visibility impact. The baseline visibility impact was then compared with the result predicted from a modeled post-control SO_2 emission rate based upon the BACT-level control technology specified in the CD.

---

[8] Ibid, NDDH Modeling Protocol.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 2. The post-control CALPUFF model scenario for MRYS Unit 2 was conducted with the protocol NO_X and PM emission rates and the post-control SO_2 emission rate as discussed in Section 3.2 and Table 1.3-1.

The results of the visibility impairment modeling at the protocol baseline SO_2 emission rate for MRYS Unit 2 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control SO_2 emission rate showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for all Class 1 areas at the post-control SO_2 emission rate was below the 0.50 dV threshold level. The modeling results are presented in Table 3.2-1.

Table 3.2-1 – SO_2 Visibility Impairment Impacts and Reductions, MRYS Unit 2

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	Post-Control Emissions[2]	
TRNP-South Unit	0.580	0.390	0.190
TRNP-North Unit	0.619	0.370	0.249
TRNP-Elkhorn Ranch	0.360	0.225	0.135
Lostwood NWR	0.775	0.493	0.282

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

2 - SO_2 emissions corresponding to improvement of FGD SO_2 removal performance to 90%. This scenario assumes protocol emission rates for NO_X and PM.

The number of days predicted to have visibility impairment due to MRYS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results are summarized and presented in Table 3.2-2. Similarly, the same information for the post-control SO_2 emission rates is summarized and shown in Table 3.2-2. The visibility impairment impact and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control SO_2 emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 2. The impact in terms of days exceeding 0.50 dV varies from an approximately 9% reduction for TRNP – Elkhorn in 2001 to an approximately 61% reduction for TRNP – Elkhorn in 2000. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 14% for TRNP – North in 2002 to approximately 56% for TRNP – South in 2000.

Table 3.2-2 – Visibility Impairment Improvements – MRYS Unit 2 SO_2 Scenarios

2 - Number of days for predicted visibility impairment impacts provided in Appendix B.

4.0 PARTICULATE MATTER BART EVALUATION

The BART analyses for PM emissions from MRYS Unit 1 and Unit 2 are described in this section. A brief description of MRYS Unit 1 and Unit 2 existing PM air pollution control equipment is provided. As discussed in the introduction, Minnkota has entered into a Consent Decree (CD). The CD requires MRYS to maintain or upgrade the existing PM controls on both units to achieve specified emission rates. Because the CD specified the PM controls and associated emission rate, the analysis was shortened to use the CD specified PM emission rates for meeting BART. The remaining portion of the analysis assesses potential visibility impairment impact reduction capability for the CD specified emission rates via visibility modeling results.

4.1 PM EVALUATION BASIS – UNIT 1

MRYS Unit 1 is a B&W cyclone-type coal-fired boiler. The quantity of uncontrolled PM emissions is a strong function of the type of boiler utilized. Different boiler types generate different splits between bottom ash, which is collected in the bottom of the boiler, and fly ash, which is entrained in the flue gas and becomes boiler particulate matter emissions. Unit 1 is a cyclone-type boiler that has an inherently lower percentage of fly ash due to the method of combustion. Particulate control is currently provided by a Research-Cottrell Electrostatic Precipitator rated at approximately 99% control.

The modeling for Unit 1 uses two PM emission rates that distinguish between coarse and fine particulate as a basis for the visibility impairment impacts. One emission rate scenario was based upon the NDDH Modeling Protocol values of 36.7 lb PM_{Coarse}/hr and 5.5 lb PM_{Fine}/hr. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. However, as discussed in Section 1.3.2, the protocol emission rates are based upon actual maximum historical 24-hour emissions that are not representative of future maximum 24-hour emissions. After obtaining approval from NDDH to use alternative emission rates based upon representative stack conditions, Minnkota based the post-control emission rates of 38.5 lb PM_{Coarse}/hr and 5.8 lb PM_{Fine}/hr upon application of CD specified rates applied to a more representative maximum heat input of 2,955 mmBtu/hr. The Consent Decree requires MRYS to maintain or upgrade the PM controls on Unit 1 to achieve an emission rate of 0.015 lb PM/mmBtu if a dry FGD process is selected for SO_2 control or 0.030 lb PM/mmBtu if a wet FGD process is selected. Because a dry FGD process is considered the worst case for SO_2 control, the associated emission rate of 0.015 lb PM/mmBtu is being used for PM.

The post-control emission rate on a lb/hr basis is slightly higher because the existing ESP performance used to derive the protocol emission rate was very good and due to the use of a higher yet more representative heat input.

4.1.1 PM VISIBLITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 1

The remaining step for the BART PM analysis was to conduct a visibility improvement determination for Unit 1. Due to the association of the Consent Decree, the visibility analysis was the only impact evaluation necessary to establish BART. In addition, because the CD specified the PM control technology and associated emission rate, one emission rate (the 0.015 lb/mmBtu specified in the CD) was selected for modeling to determine the visibility impairment impacts. The NDDH BART protocol[9] emission rate was modeled to determine a baseline visibility impact. The baseline visibility impact was then compared with the result predicted from a modeled post-control PM emission rate based upon the emission rate specified in the CD.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 1. The post-control CALPUFF model scenario for MRYS Unit 1 was conducted with the protocol NO_X and SO_2 emission rates and the post-control PM emission rate as discussed in Section 4.1 and Table 1.3-1.

The results of the visibility impairment modeling at the protocol baseline PM emission rate for MRYS Unit 1 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control PM emission rate showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for two of the Class 1 areas at the post-control PM emission rate was below the 0.50 dV threshold level. The TRNP – North Class 1 area had a modeled visibility impairment impact of 0.500 dV and Lostwood NWR Class 1 area had a modeled visibility impairment impact of 0.587 dV. The modeling results are presented in Table 4.1-1.

---

[9] Ibid, NDDH Modeling Protocol.

Table 4.1-1 – PM Visibility Impairment Impacts and Reductions, MRYS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	Post-Control Emissions[2]	
TRNP-South Unit	0.549	0.465	0.084
TRNP-North Unit	0.628	0.500	0.128
TRNP-Elkhorn Ranch	0.374	0.328	0.046
Lostwood NWR	0.750	0.587	0.163

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

2 - PM emissions corresponding to the 0.015 lb/mmBtu specified in the CD. This scenario assumes protocol emission rates for NO_X and SO_2.

The number of days predicted to have visibility impairment due to MRYS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results are summarized and presented in Table 4.1-2. Similarly, the same information for the post-control PM emission rates is summarized and shown in Table 4.1-2. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control PM emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 1. The impact in terms of days exceeding 0.50 dV varies from an approximately 3% reduction for TRNP – Elkhorn in 2002 to an approximately 27% reduction for TRNP – South in 2001. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 3% for TRNP – North in 2002 to approximately 33% for TRNP – Elkhorn in 2000.

Table 4.1-2 – Visibility Impairment Improvements – MRYS Unit 1 PM Scenarios

1 - Predicted visibility impairment impacts (90th percentile) for 2000-2002 for protocol and post-control PM emission levels.

2 - Number of days for predicted visibility impairment impacts provided in Appendix B.

4.2 PM EVALUATION BASIS – UNIT 2

MRYS Unit 2 is a B&W cyclone-type coal-fired boiler. The quantity of uncontrolled PM emissions is a strong function of the type of boiler utilized. Different boiler types generate different splits between bottom ash, which is collected in the bottom of the boiler, and fly ash, which is entrained in the flue gas and becomes boiler particulate matter emissions. Unit 2 is a cyclone-type boiler that has an inherently lower percentage of fly ash due to the method of combustion. Particulate control for Unit 2 is provided by a Wheelabrator-Lurgi electrostatic precipitator rated at approximately 99% control.

The modeling for Unit 2 uses two PM emission rates that distinguish between coarse and fine particulate as a basis for the visibility impairment impacts. One emission rate scenario was based upon the NDDH Modeling Protocol values of 178.7 lb PM_{Coarse}/hr and 28.1 lb PM_{Fine}/hr. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. However, as discussed in Section 1.3.2, the protocol emission rates are based upon actual maximum historical 24-hour emissions that are not representative of future maximum 24-hour emissions. After obtaining approval from NDDH to use alternative emission rates based upon representative stack conditions, Minnkota based the post-control emission rates of 133.7 lb PM_{Coarse}/hr and 21.0 lb PM_{Fine}/hr upon application of CD specified rates applied to a more representative maximum heat input of 5,158 mmBtu/hr. The Consent Decree requires MRYS to maintain or upgrade the PM controls on Unit 2 to achieve an emission rate of 0.030 lb PM/mmBtu.

4.2.1 PM VISIBLITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 2

The remaining step for the BART PM analysis was to conduct a visibility improvement determination for Unit 2. Due to the association of the Consent Decree, the visibility analysis was the only impact evaluation necessary to establish BART. In addition, because the CD specified the PM control technology and associated emission rate, one technology (i.e., the existing ESP) and related emission rate was selected for modeling to determine the visibility impairment impacts. The NDDH BART protocol[10] emission rate was modeled to determine a baseline visibility impact. The baseline visibility impact was then compared with the result predicted from a modeled post-control PM emission rate based upon the emission rate specified in the CD.

---

[10] Ibid, NDDH Modeling Protocol.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 2. The post-control CALPUFF model scenario for MRYS Unit 2 was conducted with the protocol NO_X and SO_2 emission rates and the post-control PM emission rate as discussed in Section 4.2 and Table 1.3-1.

The results of the visibility impairment modeling at the protocol baseline PM emission rate for MRYS Unit 2 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control PM emission rate showed a reduction in visibility impairment impact for all Class 1 areas. The modeling results are presented in Table 4.2-1.

Table 4.2-1 – PM Visibility Impairment Impacts and Reductions, MRYS Unit 2

Federal Class 1 Area	**Visibility Impairment Impacts[1] (deciView)**		**Visibility Impairment Reduction (deciView)**
	Protocol Emissions	**Post-Control Emissions[2]**	
TRNP-South Unit	0.580	0.563	0.017
TRNP-North Unit	0.619	0.570	0.049
TRNP-Elkhorn Ranch	0.360	0.345	0.015
Lostwood NWR	0.775	0.739	0.036

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

2 - PM emissions corresponding to the 0.030 lb/mmBtu specified in the CD. This scenario assumes protocol emission rates for NO_X and SO_2.

The number of days predicted to have visibility impairment due to MRYS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results were summarized and presented in Table 4.2-2. Similarly, the same information for the post-control PM emission rates was summarized and is shown in Table 4.2-2. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control PM emission rates were reduced in the majority of cases. The TRNP – South Class 1 area in 2001 and 2002 each had one additional day with a visibility impairment impact exceeding 0.50 dV. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 2. The TRNP – South Class 1 area in 2001 and 2002 each had a impact increase of one day in terms of days exceeding 0.50 dV. The approximate visibility impact increase for 2001 was 4% and for 2002 was 2%. The impact reduction in terms of days exceeding 0.50 dV varies from approximately 0% in multiple areas and years to approximately 14% for TRNP – North in 2001. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 0% in multiple areas and years to approximately 13% for Lostwood NWR in 2000.

There are several plausible explanations for an increase in the number of days with a visibility impairment impact exceeding 0.50 dV for TRNP – South in 2001 and 2002. One possible cause could be the reduced exit velocity that was due to an increase in stack diameter and an increased flow rate caused by scrubbing of all of the flue gas. Because the modeling results presented in Table 4.2-1 showed a reduction in visibility impairment impacts for all Class 1 areas, additional research was not conducted to determine the cause of the increase.

Table 4.2-2 – Visibility Impairment Improvements – MRYS Unit 2 PM Scenarios

Class 1 Area	PM Control Technique	Days[2] Exceeding 0.5 dV in 2000	Days[2] Exceeding 0.5 dV in 2001	Days[2] Exceeding 0.5 dV in 2002	Days[2] Exceeding 1.0 dV in 2000	Days[2] Exceeding 1.0 dV in 2001	Days[2] Exceeding 1.0 dV in 2002	Consecutive Days[2] Exceeding 0.5 dV 2000	Consecutive Days[2] Exceeding 0.5 dV 2001	Consecutive Days[2] Exceeding 0.5 dV 2002

5.0 BART RECOMMENDATIONS

This report presents the analysis of control technologies for each of three major pollutants (nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM)) for Minnkota Power Cooperative Inc.'s (Minnkota's) Milton R. Young Station (MRYS) Units 1 and 2. The final result of this analysis is a recommendation of the Best Achievable Retrofit Technology (BART) for each unit based upon "improvement in visibility which may reasonably be anticipated to result from the use of such technology" (70 FR 39163). The presented emission rates in this section are the BART recommendation.

As stated previously, this report uses the determinations made in the Consent Decree (CD) and associated NO_X BACT analysis as part of the analysis. BACT is considered to be more stringent than BART because it usually is not limited by the design of existing equipment or current operating conditions as is required for a retrofit application. Because BACT is similar to BART and BACT-level controls are required by CD, the visibility impacts evaluation was the only step in the determination performed to satisfy BART. This analysis evaluated the visibility impairment impacts of the BACT-level control technologies specified in the CD and results in a BART recommendation based upon an acceptable amount of visibility improvement in Class 1 areas. This section summarizes the visibility analysis performed for each Unit and its associated pollutants.

5.1 UNIT 1 BART RECOMMENDATIONS

The remaining step for the BART analysis was to conduct a visibility improvement determination for MRYS Unit 1. Due to the association of the Consent Decree, which required a NO_X BACT analysis, along with the specification of SO_2 and PM control technologies or emission rates for each pollutant, the visibility impairment impact analysis was the only impact evaluation necessary to establish BART. To conduct a visibility impairment impact analysis, the baseline visibility impairment impact was compared with the predicted impact from a post-control emission rate modeled separately for each pollutant. A control technology and associated emission rate are considered to meet BART requirements when the 90th percentile modeling results show a reduction in visibility impairment impact. The MRYS Unit 1 modeling results for all pollutants showed a reduction in visibility impairment impact for all Class 1 areas. Thus, the control technologies recommeded as BACT for NO_X emissions and those specified by the CD for SO_2 and PM emissions along with the modeled emission rates are recommended as BART. Table 5.1-1 summarizes the control technologies and associated emission rates that are recommended as BART for each pollutant. The recommended BART emission rates are presented as a 30-day rolling average to account for variations in boiler operation, fuel sulfur content and fly ash properties.

Table 5.1-1 – Recommended BART 30-Day Rolling Average, MRYS Unit 1

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.36*
SO_2	Dry Flue Gas Desulfurization (FGD) Process	0.24
PM	Fabric Filter Baghouse	0.015**

* Excludes startups. See Appendix A for a detailed discussion.

** Emission rate is associated with SO_2 control technology and applies to dry FGD process only.

The pollutant specific modeling results for MRYS Unit 1 described previously in the analysis represent the visibility impairment impact reduction attributable to a technology used to control an individual pollutant of concern. While this result supports an individual technology in terms of visibility impact reduction, the result is not representative of actual plant-wide operations. Application of the BART-recommended technologies will result in simultaneous control of all pollutants. Thus, a comparison of the visibility impairment reduction due to reducing the protocol emission rates to post-control emission rates for all pollutants simultaneously is more representative of actual expected results. A modeling scenario was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies and the results are presented in Table 5.1-2.

Table 5.1-2 – Visibility Impairment Impacts for Control of all Pollutants, MRYS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction
	Protocol Emissions	Post-Control Emissions	
TRNP-South Unit	0.549	0.091	0.458
TRNP-North Unit	0.628	0.093	0.535
TRNP-Elkhorn Ranch	0.374	0.057	0.290
Lostwood NWR	0.750	0.127	0.623

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

The simultaneous control of all pollutants for MRYS Unit 1 results in visibility impairment impacts that are approximately one fourth of the threshold the EPA designates as contributing to visibility impairment. These modeling results provide additional support for recommending the control technologies recommended as BACT for NO_X emissions and those specified by the CD for SO_2 and PM emissions as BART.

The BART analysis for MRYS was conducted before determining the SO_2 control technology for Unit 1. The Consent Decree provides the acceptable BACT-level SO_2 emission control technologies for Unit 1. SO_2 emissions were modeled using a dry FGD process at 90% control. A 90% reduction is the minimum reduction allowed by the CD and results in the worst case SO_2 post-control emission rate. Because a dry FGD process was evaluated as worst case, this analysis will still be applicable if Minnkota chose to utilize an equivalent or more efficient SO_2 emission control technology. However, if the final selection of SO_2 control technology and the corresponding post-control emission rate required by the CD changes, the post-control PM emission rate required by the CD may also change.

As discussed previously in this report, the Consent Decree requires MRYS to maintain or upgrade the PM controls on Unit 1 to achieve an emission rate of 0.015 lb PM/mmBtu if a dry FGD process is selected for SO_2 control or 0.030 lb PM/mmBtu if a wet FGD process is selected. Because a dry FGD process is considered the worst case for SO_2 control, the associated emission rate of 0.015 lb PM/mmBtu is being used for PM (only applies with utilization of dry FGD for SO_2 control). If Minnkota determines that a wet FGD process with 95% SO_2 control should be used for Unit 1, the PM emission rate dictated by the Consent Decree will increase to 0.030 lb PM/mmBtu (only applies with utilization of wet FGD for SO_2 control). Although the PM emission rate would change as a result of the SO_2 control scenario, when considering the effect of all pollutants on visibility impacts, reducing SO_2 emissions would have a greater effect. The modeling results in Appendix B provide the percent contribution of each pollutant to the visibility impact. For Unit 1, the PM contribution to the visibility impact ranges from 0.13% to 2.22%. The SO_2 contribution to the visibility impact ranges from 7.64% to 67.12%. Because the contribution of SO_2 is more than double the PM contribution in all cases, reducing SO_2 emissions by an additional 50% by going from 90% to 95% control would have a greater effect than doubling PM emissions. Thus, this analysis will still be applicable if Minnkota chooses to utilize a wet FGD process for SO_2 control and incorporate the corresponding increase in the PM emission rate as dictated by the Consent Decree.

5.2 UNIT 2 BART RECOMMENDATIONS

The remaining step for the MRYS Unit 2 BART analysis was to conduct a visibility improvement determination. Due to the association of the Consent Decree which required a NO_X BACT analysis along with the specification of SO_2 and PM control technologies or emission rates for each pollutant, the visibility impairment impact analysis was the only subsequent impact evaluation necessary to establish BART. To conduct a visibility impairment impact analysis, the baseline visibility impairment impact was compared with the predicted impact from a post-control emission rate modeled separately for each pollutant. A control technology and associated emission rate are considered to meet BART requirements when the 90th percentile modeling results show a reduction in visibility impairment impact. The MRYS Unit 2 modeling results for all pollutants showed a reduction in visibility impairment impact for all Class 1 areas. Thus, the control technologies recommended as BACT for NO_X emissions and those specified by the CD for SO_2 and PM emissions along with the modeled emission rates are recommended as BART. Table 5.2-1 summarizes the control technologies and associated emission rates that are recommended as BART for each pollutant. The recommended BART emission rates are presented as a 30-day rolling average to account for variations in boiler operation, fuel sulfur content and fly ash properties.

As discussed previously in this report, the CD required that a complete BACT analysis be performed to determine the applicable NO_X control technology for Unit 2. Due to amount of time necessary to complete a BACT analysis and a BART analysis, both reports were assembled concurrently. A preliminary BACT analysis based on historical emissions records and estimated control technology capabilities resulted in an emission rate of 0.39 lb NO_X/mmBtu to be assumed for the post-control 24-hour average emission rate for the visibility impairment impact modeling. However, further analysis conducted after the completion of the CALPUFF modeling resulted in a 30-day rolling average NO_X emission rate of 0.35 lb NO_X/mmBtu. Because the final recommended BART 30-day rolling average emission rate is lower than the modeled rate and the associated visibility impact would be reduced, dispersion modeling was not redone.

Table 5.2-1 – Recommended BART 30-Day Rolling Average, MRYS Unit 2

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.35*
SO_2	Upgrade of Existing Wet Flue Gas Desulfurization (FGD) Process	0.31
PM	Maintain Existing Electrostatic Precipitator (ESP)	0.030

* Excludes startups. See Appendix A for a detailed discussion.

The pollutant specific modeling results for MRYS Unit 2 described previously in this analysis represent the visibility impairment impact reduction attributable to a technology used to control an individual pollutant of concern. While this result supports an individual technology in terms of visibility impact reduction, the result is not representative of actual plant-wide operations. Application of the BART recommended technologies will result in simultaneous control of all pollutants. Thus, a comparison of the visibility impairment reduction due to reducing the protocol emission rates to post-control emission rates for all pollutants simultaneously is more representative of actual expected results. A modeling scenario was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies and the results are presented in Table 5.2-2.

Table 5.2-2 – Visibility Impairment Impacts for Control of all Pollutants, MRYS Unit 2

Federal Class 1 Area	**Visibility Impairment Impacts[1] (deciView)**		**Visibility Impairment Reduction**
	Protocol Emissions	**Post-Control Emissions**	
TRNP-South Unit	0.580	0.173	0.407
TRNP-North Unit	0.619	0.169	0.450
TRNP-Elkhorn Ranch	0.360	0.104	0.256
Lostwood NWR	0.775	0.243	0.532

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.3-1 and the modeling results are presented in Appendix B.

The simultaneous control of all pollutants for MRYS Unit 2 results in visibility impairment impacts that are approximately one half of the threshold the EPA designates as contributing to visibility impairment. These modeling results provide additional support for recommending the control technologies recommended as BACT for NO_X emissions and those specified by the CD for SO_2 and PM emissions as BART.

In addition to the visibility impairment impact modeling scenario conducted to determine the effects of simultaneous control of all pollutants for the individual units, another modeling scenario was conducted to combine the effects of both units. The modeling showed that the visibility impairment impact for all Class 1 areas was reduced to below the threshold the EPA designates as contributing to visibility impairment. Results of this scenario (labeled Run 5) are provided in Appendix B.

EXECUTIVE SUMMARY

The Milton R. Young Station of Minnkota Power Cooperative, Inc. (Minnkota) and Square Butte Electric Cooperative (Square Butte) includes two cyclone-furnace, lignite-fired steam-electric generating units (SEGUs). The units both fire North Dakota lignite supplied from the adjacent mine, near Center, North Dakota. Unit 1 has a nominal 235 MW net design output capacity rating, is typically capable of sustained output of approximately 250 MW_g (gross), and has a gross design output capacity rating of 257 MW_g. Unit 1 is owned and operated entirely by Minnkota. Unit 2 has a nominal 439 MW net design output capacity rating, is capable of sustained output of approximately 460 MW_g (gross), and has a gross design output capacity rating of 477 MW_g. Unit 2 is owned by Square Butte Electric Cooperative (Square Butte), and operated by Minnkota.

A Notice of Violation (NOV) from the United States Environmental Protection Agency (US EPA or EPA) was issued to Minnkota Power Cooperative on June 21, 2002. The NOV alleged that modifications had been made at the Milton R. Young Station that would have required a construction permit under New Source Review (Code of Federal Regulations 40 CFR 52.21, and North Dakota Administrative Code NDAC 33-15). As a result of this allegation, a civil complaint was filed by the United States of America and the State of North Dakota against Minnkota Power Cooperative Inc. ("Minnkota") and Square Butte Electric Cooperative ("Square Butte") in the United States District Court for the District of North Dakota. A Consent Decree (CD) has been approved that represents a final negotiated settlement of the United States' and North Dakota's claims against Minnkota and Square Butte. The Consent Decree requires Minnkota and Square Butte to perform a "NO_X Top-Down Best Available Control Technology (BACT) Analysis" to describe the emission limits for NO_X that will be required at Units 1 and 2, expressed as a 30-Day Rolling Average NO_X Emission Rate [Consent Decree paragraph 24, page 7, and paragraph 5, page 4].

Burns & McDonnell was retained to conduct a Top-Down BACT Analysis for nitrogen oxides (NO_X) at the Milton R. Young Station. The results of the BACT analysis are presented in this study report.

The procedures mandated by the Consent Decree for performing a Top-Down BACT Analysis are outlined in Chapter B of the U.S. EPA's New Source Review Workshop Manual: Prevention of Significant Deterioration and Nonattainment Area Permitting, Draft, October 1990 ("EPA's NSR Manual"). The MRY Station BACT analysis was performed in accordance with this procedure. The

EPA's NSR Manual outlines five basic steps that are to be followed in this BACT analysis. These basic steps for such a BACT analysis are summarized as follows:

Step 1 – Identify All Control Technologies
Step 2 – Eliminate Technically Infeasible Options
Step 3 – Rank Remaining Control Technologies by Control Effectiveness
Step 4 – Evaluate Most Effective Controls and Document Results
Step 5 – Select BACT

A Best Available Control Technology (BACT) analysis was performed for Milton R. Young Unit 2 for NO_X using the EPA's "top-down" approach. Best Available Control Technology is defined as "an emissions limitation (including a visible emission standard) based on the maximum degree of reduction for each pollutant subject to regulation under Act which would be emitted from any proposed major stationary source or major modification which the Administrator, on a case-by-case basis, taking into account energy, environmental, and economic impacts and other costs, determines is achievable for such source or modification through application of production processes or available methods, systems, and techniques, including fuel cleaning or treatment or innovative fuel combustion techniques for control of such pollutant" (40 CFR 52.21, NSR Manual B.1).

Unit 1 at Milton R. Young Station is a cyclone-fired boiler that burns North Dakota lignite. The method of firing is very significant in analyzing control options for NO_X emissions. A cyclone boiler produces inherently higher uncontrolled NO_X levels than pulverized-coal and circulating fluidized bed boilers. There have been no new coal-burning cyclone-fired boilers built and installed in the United States since the early 1980's. Consequently, there are no examples of BACT control options listed in the RACT/BACT/LAER Clearinghouse database for consideration and direct application of published NO_X emission permit limits on the Milton R. Young cyclone-fired boilers.

Step 1 – Identify All Control Technologies

The Consent Decree requires that the NO_X Top-Down BACT Analysis for the Milton R. Young Station "include an evaluation of Selective Catalytic Reduction (SCR), Selective Non-Catalytic Reduction (SNCR), Overfire Air (OFA), Rich Reagent Injection (RRI), as well as other NO_X control technologies" potentially applicable for lignite-fired cyclone boilers [Consent Decree paragraph 65, page 19]. Other identified control techniques, such as fuel switching and fuel cleaning, and combustion-related emission control technologies, such as fuel reburn and oxygen-enhanced combustion, were also considered.

Step 2 – Eliminate Technically Infeasible Options

The BACT evaluation determined that not all the technologies identified were considered available and applicable. The technically infeasible alternatives were eliminated from further evaluation, along with feasible technologies with economic impacts that were unreasonable compared to other cost-efficient alternatives to control NO_X emissions for MRY Station Unit 1.

The technical feasibility of applying NO_X emission reduction techniques and technologies at Milton R. Young Station is dominated by the composition and combustion characteristics of the North Dakota lignite supplied solely from a surface mine adjacent to the plant. This mine is the only supplier of solid fuel for this station, as there are no railroad facilities provided to service the Milton R. Young plant. North Dakota lignite has high moisture and high sodium content, moderate higher heating values, and can have a widely variable and high ash content compared to other coals. These characteristics create difficulties in promoting consistent, steady combustion and slag formation in the cyclone burners. It also results in producing a flyash that has severe deposition characteristics.

Both boilers include a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boilers.

Ash deposition in each boiler and air preheater is a significant operational challenge for the facility. Significant equipment and manpower resources are devoted to on-going removal of fireside ash accumulations. Unit outages must be conducted at regular intervals to clean each boiler (approximately every 80-120 days). There are a number of issues that make selective catalytic reduction (SCR) technically infeasible for NO_X emission control for Milton R. Young Unit 1. The consistent long-term operation of SCR technology on lignite-fired cyclone boilers will be drastically inhibited by the susceptibility of the SCR catalyst to severe fouling, deactivation, and erosion resulting from the actions of the emitted flue gases and flyash, and ash deposit removal operations. SCR technology is considered technically infeasible for application on the cyclone boilers at the Milton R. Young Station.

Rich Reagent Injection has been demonstrated on boilers burning bituminous and subbituminous coal. However, it has not been commercially installed and placed in continuous operation on a cyclone-fired boiler burning lignite coal with high fouling and slag temperature sensitivities associated and a highly variable heat content. RRI adds urea reagent to the hot furnace gases near the cyclones, which must be devoid of free oxygen in order to avoid oxidation of the urea, and thus creating NO_X. While RRI is specifically intended for NO_X emissions control on cyclone boilers, RRI is considered technically infeasible for application on the lignite fired cyclone boilers at the Milton R. Young Station due to the variable heat content of the lignite fuel which allows the creation of oxygen-rich conditions in the boiler.

The application of separated overfire air (SOFA) for NOx emissions control on Milton R. Young Unit 1's boiler was evaluated as part of the BACT analysis. A version of separated overfire air specifically designed for increased NO_X emission reduction performance for lignite-fired cyclone boilers, referred to as "Advanced SOFA" in this analysis, can be installed on both units at M.R. Young Station. This highest-performing form of SOFA can be applied alone and in combination with other technologies. Key aspects of successfully applying and operating a separated overfire air system on a cyclone-fired boiler are the ability to:

- Accurately measure the fuel heat input rate (BTUs) and combustion air inputs on a real-time, individual cyclone by cyclone basis, to allow the ability to determine and control the desired air/fuel ratio, especially when "starved air" (i.e. substoichiometric) combustion conditions are required.
- Maintain adequate molten coal ash (slag) formation and flow within the barrels and slag taps.

The degree to which the individual cyclone furnaces can be operated with less-than-theoretical (substoichiometric) combustion air, which corresponds to operation of a SOFA system, directly contributes to less combustion-related NO_X formation and further in-furnace emission reduction but also risks solidification of the molten coal ash. This places great emphasis on achieving tight control over the air/fuel ratios on each cyclone during air-staged combustion operation with SOFA in order for air-staged combustion to be successful in producing significant additional NOx emissions reduction on lignite-fired cyclone boilers.

In the case of MRY Station Unit 1's boiler, air-staged combustion must be sufficient to reduce NO_X emissions while releasing enough heat to continue to melt the fuel ash so that it flows effectively within and from the cyclone burners. Due to the short-term variability of the combustible and ash components of North Dakota lignite supplied from the current mine near Center, ND, and the complex behavior of lignite ash when exposed to high temperatures, the extent of air-staging and thus the level of NO_X control while operating the highest-performing version of SOFA system is expected to be modest.

Selective Non-Catalytic Reduction (SNCR) technology has been used to reduce NO_X emissions on numerous utility boilers burning eastern bituminous coal, midwestern bituminous coal, and, to a lesser extent, western subbituminous coal. SNCR has also been used on fuel oil and natural gas-fired units. SNCR does not appear to be dependent directly on the type of burners (wall-fired, tangentially-fired, and cyclone-fired) employed in the boilers where it has been installed, with or without air-staged combustion with overfire air in full operation.

There are significant concerns associated with effective long-term SOFA operation for Milton R. Young Station Unit1‘s boiler. The ability of basic combustion equipment and improvements to precisely measure the boiler’s heat input rate in real-time on an individual cyclone by cyclone basis with compensation for the short-term variability of the combustible content of the Center lignite to consistently maintain substoichiometric operation of every cyclone during air-staged combustion is unproven.

Several other techniques and technologies were considered technically feasible for NOx emissions control at MRY Station: Fuel Blending/Switching; Basic Combustion Control Improvements; and various forms of Fuel Reburn. Fuel switching/blending was not evaluated further because of expected unreasonably high capital and operating costs and no additional emission reduction compared to continued lignite firing.

Other NOx emissions control techniques and technologies for MRY Station that were evaluated and determined to be technically infeasible were: Fuel Cleaning; Low NOx Burners (LNB); Flue Gas Recirculation; Oxygen-enhanced Combustion (OEC); Water/steam injection (combustion tempering); and Electro-Catalytic Oxidation (ECO®).

Step 3 – Rank Remaining Control Technologies by Control Effectiveness

The third step in the “top-down” BACT evaluation ranked the remaining control technologies by effectiveness. The purpose of ranking the control technologies was to establish a hierarchy that places at the “top” the control technology that achieves the lowest emission level. The technologies in order of their effectiveness, from highest to lowest, are: SNCR with ASOFA; Gas Reburn with ASOFA; Lignite Reburn with ASOFA; Fuel Lean Gas Reburn with ASOFA; and Advanced Separated Overfire Air (ASOFA). None of these control options has been installed on a cyclone-fired boiler burning North Dakota lignite. As such, the expressed control percentages reflect the use of engineering judgment, based on the listed technique or technology application.

Step 4 – Evaluate Most Effective Controls and Document Results

Additional criteria besides technical feasibility were utilized for technology selection in this BACT analysis. These included estimates of control effectiveness (i.e. percent pollutant removed), capital plus operating and maintenance costs, annual emission reduction (tons per year), energy impacts, average and incremental cost effectiveness ($/ton), and environmental impacts (other media and emissions of toxic and hazardous air pollutants).

The economic analysis examined the capital cost of each feasible BACT alternative evaluated and any other powerplant upgrade costs necessary to implement the alternative. In addition, the economic analysis examined the operating and maintenance cost associated with the highest-performing forms of each feasible BACT alternative evaluated. These costs were then combined into a levelized total annual cost for a comparative assessment of the total implementation cost of each alternative. Finally, as part of the top-down analysis, a dominant controls cost curve was plotted and the unit control cost for each alternative was evaluated.

Two alternatives were on the dominant controls cost curve and thus were identified as the more cost effective alternatives. The two BACT NO_X control alternatives evaluated for incremental cost, energy, and environmental impacts applicable to Milton R. Young Station Unit 1 were:

- Selective Non-Catalytic Reduction (SNCR) combined with a special form of separated overfire air (SOFA) specifically for lignite-fired cyclone boilers (referred to as Advanced SOFA or ASOFA); and
- ASOFA alone.

The two most cost-effective feasible control alternatives for reduction of NO_X emissions were reviewed to determine if the use of the technique or technology would result in any significant or unusual energy penalties or benefits. Potential increase in power plant energy consumption or net generation reductions, for ASOFA alone, or ASOFA with SNCR were relatively small.

The predicted environmental impacts from implementation of the two most cost-effective feasible NO_X emissions control alternatives from slightly higher unburned carbon in the emitted fly ash, carbon monoxide, and excess ammonia (“slip”) emissions was expected to be small in comparison with the significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NO_X emission reduction.

Step 5 – Select BACT

Taking into account technical feasibility, energy, environmental, and economic impacts and other costs, the recommended Best Available Control Technologies and associated emission rates for nitrogen oxides emissions produced by Milton R. Young Station Unit 1 boiler are provided in the table below.

NO_X Emission Control Technology and Rate Recommended as BACT

Control Technology and Emission Rate Recommended as BACT			
Unit	**Pollutant**	**Control Method**	**12-Month Rolling Average NOx Emission Rate (lb/ million Btu)**
1	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.355

This recommended BACT 12-month NO_X emission rate is based upon a historic pre-control 12-month baseline average annual NO_X emission rate used in the control and cost-effectiveness analysis of 0.849 lb/mmBtu for Unit 1. The baseline emission was determined from the 12 consecutive month period with the highest historic summation of NO_X mass emissions (pounds) reported for actual operation between January 1,2001 and December 31, 2005.

To complete the BACT determination process, the Consent Decree (CD) requires that “specific control technologies to be installed and a specific Phase II 30-day Rolling Average NO_X Emission Rate limitation (lbs/MMBtu)” must be established for each subject emission Unit [CD Paragraph 66, pg 20]. Because there are expected to be minor short term variations in operating conditions where Minnkota has not, in fact, materially changed any of their normal daily operating practices, a margin between the 12-month average operating conditions and the 30-day permit limit is proposed. This recommended emission rate should be suitably higher such that operation consistent with the technological limitations, manufacturer’s specifications, and good engineering and maintenance practices to the extent practicable for the recommended NOx BACT alternative would not result in an exceedance (violation) of an enforceable emission permit limit.

The Consent Decree also requires that the North Dakota Department of Health's (NDDH) NO_X BACT Determination address specific emission limitations during Unit startups at Milton R. Young Station [CD Paragraph 66, pg 20]. The type and duration of firing during startups, and the limited ability of available and feasible technologies to control startup NO_X emissions, both significantly influence the 30-day rolling average BACT NO_X emission rate limit recommended for Milton R. Young Station boilers. A 24-hour rolling average NO_X emission rate limit applied to startup periods is also recommended for Milton R. Young Station boilers.

The SEGU startup operating period is usually not defined in emission permits. However, for the purpose of this NO_X BACT analysis, Unit startup was defined as the period from initial fuel combustion to the point in time when:

- the measured Heat Input to the boiler on a 6-hour rolling average basis is greater than or equal to 2500 million BTU/hr for Unit 1; or
- the amount of time reported for the longest individual Unit 1 startup period during actual operation between January 1, 2001 and December 31, 2005 elapses, whichever occurs first; or
- fuel firing is discontinued prior to satisfying either previous criteria.

For MRYS Unit 1, the recommended 30-day rolling average NO_X emission permit limit rate that includes the impact of startups is based upon recognized operational factors and equipment designs that influence whether the startup emissions result in higher 30-day emissions compared to normal continuous operation excluding such startup periods:

- The uncontrolled emission rate (i.e. without separated OFA or SNCR in operation) and its variability during operation from a cold startup up to and including maximum continuous rated output;
- The operating conditions that are required to exist for the selected NO_X BACT control techniques to be initiated and be effective; and
- The effectiveness of these two particular control techniques if invoked at less-than-MCR steady-state operating conditions.
- The number of startups and their range of typical durations per 30-day period time frame.

The Consent Decree and the EPA's NSR Manual do not describe the method for determining a 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT applied to Milton R. Young Station Unit 1. The approach taken in this analysis was to establish a historic pre-control 30-day baseline average NO_X emission rate (lb/mmBtu) from the 30-consecutive day period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation between January 1,2001 and December 31, 2005. This reflects unit NO_X emissions that were generated during periods of high unit operations, not affected by unit shutdowns, startups, or malfunctions. This was then compared to the 12-month historic pre-control baseline average NO_X emission rate (lb/mmBtu) from the 12-consecutive month period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation during the same 5-year look-back period. An estimate of NO_X emission reduction for the proposed BACT NO_X alternative operating at the historic pre-control 30-day baseline average NO_X emission rate (lb/mmBtu) was made. This rate considered recognized operational factors and equipment designs applied to "steady state" conditions with sustained output close to maximum continuous capacity ratings. The potential impact of startups, recognizing operational and technical limitations on NO_X emission control performance, was then applied to the steady-state rate, to establish a recommended 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT for Milton R. Young Station Unit 1. This is summarized below.

Recommended NO_X BACT Control Method and 30-Day Rolling Average NO_X Emission Rate Limit Without Startups

Unit	Pollutant	Control Method	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)
1	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.360

This recommended BACT 30-day NO_X emission rate limit is based upon a historic pre-control 30-day baseline average NO_X emission rate of 0.884 lb/mmBtu for Unit 1. The baseline emission was determined from the 30-consecutive day period with the highest historic unit NO_X emissions rate reported for actual operation between January 1,2001 and December 31, 2005.

An incremental adjustment to the proposed 30-day rolling average steady-state unit NO_X BACT emission rate without startups of 0.36 lb/mmBtu for Unit 1 is recommended for the 30-day rolling average NO_X emission permit limit periods as defined and applied to Milton R. Young Station. This is summarized in the table below.

Recommended BACT 30-Day Rolling Average NO_X Emission Rate Limit and Startup Impact

Unit	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)	Impact on 30-day Rolling Average NOx Emission Rate Limit Due to Startups (lb/million Btu)
1	0.36	+0.041 per startup

This recommended adjustment to the proposed 30-day rolling average steady-state NO_X BACT emission rate limit without startups is based upon average historic pre-control NO_X emission rates of 0.766 lb/mmBtu for Unit 1 reported for the longest individual Unit 1 startup period during actual operation between January 1, 2001 and December 31, 2005. These emissions occurred during the 61-hour June 27-29, 2005 startup for Unit 1.

A 24-hour rolling average BACT NO_X emission rate limit applied to startup periods is also recommended for each of the Milton R. Young Station boilers.

This is summarized in the table below.

Recommended 24-Hour Rolling Average NO_X Emission Rate Limit During Startups

Unit	24-hour Rolling Average NOx Emission Rate Limit During Startups (lb/million Btu)
1	0.980

These emissions occurred during the 61-hour June 27-29, 2005 startup for Unit 1.

Compliance with these emission rate would be measured at the stack of the Unit, verified with Continuous Emission Monitoring (CEM) systems in accordance with the reference methods specified in 40 C.F.R. Part 75, and would be determined on a 30 consecutive Operating Day and 24-consecutive hour rolling average basis, respectively.

A trial demonstration period of 18 months after the completion of Consent Decree Phase II NO_X emission reduction system installation commissioning at Milton R. Young Station is recommended. It is proposed to allow Minnkota to demonstrate the actual control system capabilities of the combined NO_X BACT emissions reduction system. Operating experience during the trial period will:

- confirm steady-state control performance of the combined NO_X BACT emissions reduction system;
- allow determination of the ability to further control Unit start-up emissions;
- allow the determination of the permitted 30-day rolling average NO_X emission limit including startups, shutdowns, and malfunctions; and
- address the specific emission limitations during Unit startups at Milton R. Young Station and their impact on the proposed 30-day rolling average emission rate limit (without startups).

Based upon the information obtained during the trial period, final emission limits can then be determined.

The means that will be employed to minimize emissions during startup will primarily be based on operating procedures, both before and after the level of upper furnace gas temperatures and/or heat input rate are considered sufficient to start the NO_X controls and operating conditions are conducive for effective emissions reduction. These could be similar to Minnkota's current MRYS practices, or could be different, depending upon the capabilities of the NO_X controls and their impacts on Unit operations.

1.0 INTRODUCTION

The Milton R. Young Station of Minnkota Power Cooperative, Inc. (Minnkota) and Square Butte Electric Cooperative (Square Butte) includes two cyclone-furnace, lignite-fired boilers producing steam for electric generation. Both units fire North Dakota lignite supplied from an adjacent mine, near Center, North Dakota.

A Notice of Violation (NOV) from the United States Environmental Protection Agency (US EPA or EPA) was issued to Minnkota on June 21, 2002. The NOV alleged that modifications have been made at the Milton R. Young Station that would require a construction permit under New Source Review (Code of Federal Regulations 40CFR52.21, and North Dakota Administrative Code NDAC 33-15). As a result of this allegation, a civil complaint was filed by the United States of America and the State of North Dakota against Minnkota Power Cooperative Inc. ("Minnkota") and Square Butte Electric Cooperative ("Square Butte") in the United States District Court for the District of North Dakota. A Consent Decree[1] has been entered that represents a final negotiated settlement of the United States and North Dakota's claims against Minnkota and Square Butte. The Consent Decree requires Minnkota and Square Butte to perform a NO_X "Top-Down" Best Available Control Technology (BACT) Analysis to describe the emission limits for NO_X that will be required at Units 1 and 2, expressed as a 30-Day Rolling Average Emission Rate (lbs/million Btu)[2].

Burns & McDonnell was retained by Minnkota to conduct a "Top-Down" Best Available Control Technology (BACT) Analysis for nitrogen oxides (NO_X) at the Milton R. Young Station. Burns & McDonnell is a full service engineering, architectural, construction and environmental firm. The company plans, designs and constructs electric generating facilities and has been providing environmental services since the 1970s. As part of those services, Burns & McDonnell has extensive experience in permitting, Best Available Control Technology (BACT) studies and control technology analysis. The results of the BACT analysis are presented in this report.

[2] Ibid – footnote number 1, CD paragraph 65, page 19.

The primary guidance utilized in preparation of this BACT analysis is the U.S. EPA's New Source Review Workshop Manual: Prevention of Significant Deterioration and Nonattainment Area Permitting, Draft, October 1990[3] ("NSR Manual").

In the next section of the report, the approach to the BACT Analysis is described. Following that, a quick summary of the plant conditions and report basis is given and then the BACT Analysis begins. The impact portion of the report is broken down into separate subsections. Within the last section, the results of all of the BACT Analysis steps are summarized for NO_X control options for Unit 1's boiler at the Milton R. Young Station.

[3] Chapter B of the U.S. EPA's New Source Review Workshop Manual: Prevention of Significant Deterioration and Nonattainment Area Permitting, Draft, October 1990.

2.0 "TOP-DOWN" NO_X BACT ANALYSIS APPROACH

Best Available Control Technology (BACT) is an emissions limitation for each pollutant from a source determined to be achievable using control technologies(s) that provide the "maximum degree of emission reduction…taking into account energy, environmental, and economic impacts"[4]. A BACT review does not result in an emissions removal efficiency requirement. The generally accepted procedures for performing a BACT analysis are outlined in the EPA's draft NSR Manual. The BACT analysis for Milton R. Young Station Unit 1's boiler NO_X emissions was performed in accordance with this procedure. The EPA's draft NSR Manual outlines five basic steps that are to be followed in the "top-down" BACT evaluation. These steps are as follows:

Step 1 – Identify All Control Technologies
Step 2 – Eliminate Technically Infeasible Options
Step 3 – Rank Remaining Control Technologies by Control Effectiveness
Step 4 – Evaluate Most Effective Controls and Document Results
Step 5 – Select BACT

The predefined steps of a BACT analysis are described in this section, and results presented. Available NO_X control techniques and technologies are defined, identified, and a technical description of the emission reduction process and capabilities are reviewed in the following section. Subsequently, those techniques and technologies deemed feasible for retrofit application are ranked according to nominal NO_X control capability. An engineering analysis reviews the estimated capital and operations and maintenance (O&M) costs for each feasible alternative, including taking a look at Balance of Plant (BOP) requirements. Following the cost impact determination, the energy and environmental impacts are reviewed for each feasible technology. Finally, the results of the engineering analyses are tabulated and a NO_X BACT selection is recommended for each unit.

2.1 STEP 1 – IDENTIFY ALL CONTROL TECHNOLOGIES

The first step in a "top-down" NO_X BACT analysis is to identify, for the emissions unit in question, a comprehensive list of all "available" control options. In the EPA's draft NSR Manual,

> "available control options are those air pollution control technologies or techniques with a practical potential for application to the emissions unit and the regulated pollutant under evaluation. Air pollution control technologies and techniques include the application of

---

[4] Ibid footnote number 2, NSR Manual B.1

production process or available methods, systems, and techniques, including fuel cleaning or treatment or innovative fuel combustion techniques for control of the affected pollutant"[5].

According to the EPA's draft NSR Manual, "a technology is considered "available" if it can be obtained by the applicant through commercial channels or is otherwise available within the common sense meaning of the term"[6]. Also, "a control technique is considered available, within the context presented above, if it has reached the licensing and commercial sales stage of development"[7].

In order to identify available NO_X emission control technologies and techniques appropriate for potential application to MRY Station units, the following information sources were reviewed for coal-fired electric generating unit powerplants:

- EPA's RACT/BACT/LAER Clearinghouse (RBLC) database and Control Technology Center (website).
- Federal (EPA) and State, including North Dakota Department of Health internet websites for air emission permits and recently-submitted applications, including BACT Evaluations following New Source Review procedures.
- Federal (EPA and Department of Justice) and State, including North Dakota Department of Health internet websites for Consent Decrees issued as a result of legal actions taken by the United States government for alleged violations of the Prevention of Significant Deterioration (PSD) provisions and New Source Review provisions of the Clean Air Act, and/or federally-approved and enforceable State Implementation Plans.
- Control technology vendor information.
- Published and available information from technical, engineering, and environmental consultants.
- Technical literature found in journals, reports, internet websites, newsletters, proceedings of technical seminars and conferences pertaining to studies, engineering, designs, and testing of air pollution controls.

[6] Ibid, NSR Manual B.17
[7] Ibid, NSR Manual B.18

2.2 STEP 2 – ELIMINATE TECHNICALLY INFEASIBLE OPTIONS

The second step of the "top-down" BACT process is to evaluate the available NO_X control technologies and techniques identified in Step 1 in terms of the specific factors that apply to the emissions unit in question. In accordance with EPA's draft NSR Manual, "an available technology is "applicable" if it can be reasonably installed and operated on the source type under consideration. A technology that is available and applicable is technically feasible[8]".

The EPA's NSR Manual states a technology may be determined to be not applicable if "a technical assessment considering physical, chemical and engineering principles and/or empirical data showing the technology would not work on the emissions unit under review or that unsolvable technical difficulties would preclude the successful deployment of the technique"[9]. Also, a "showing of unresolvable technical difficulty with applying the control would constitute a showing of technical infeasibility (e.g., size of the unit, location of the proposed site, and operating problems related to specific circumstances of the source)"[10]. After a determination is made that any of the processes are technically infeasible, options are eliminated if technical challenges would preclude or prevent the successful long-term use of the control option or technique on the emission unit under consideration. This is performed prior to any economic analysis.

However, the EPA's NSR Manual also states "…control options incapable of meeting an applicable New Source Performance Standard (NSPS) or State Implementation Plan (SIP) limit would not meet the definition of BACT under any circumstances. The applicant does not need to consider them in the BACT analysis"[11]. Also, it states "An NSPS simply defines the minimum level of control to be considered in the BACT analysis"[12]. The NSR Manual further states "When developing a list of possible BACT alternatives, the only reason for comparing control options to an NSPS is to determine whether the control option would result in an emission level less stringent than the NSPS. If so, the option is unacceptable"[13]. New Source Performance Standards (NSPS) for NO_X emissions from EGUs firing North Dakota lignite are 0.8 lb/mmBtu. The EPA Acid Rain Program's Title IV NO_X emission limit for Group 2, cyclone-fired coal boilers with outputs greater than 155 MWe is 0.86 lb/mmBtu.

[9] Ibid, NSR Manual B.20
[10] Ibid, NSR Manual B.19
[11] Ibid, NSR Manual B.12
[12] Ibid, NSR Manual B.12
[13] Ibid, NSR Manual B.12

EPA’s draft NSR Manual also states ”A source would not be required to experience extended time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required to experience extended trials to learn how to apply a technology on a totally new and dissimilar source type. Consequently, technologies in the pilot scale testing stages of development would not be considered available for BACT review”[14].

Also in the EPA’s draft NSR Manual is a qualification for technical feasibility, as described by the statement “Commercial availability by itself, however, is not necessarily a sufficient basis for concluding a technology to be applicable and therefore technically feasible. Technical feasibility, as determined in Step 2, also means a control option may reasonably be deployed on or “applicable” to the source type under consideration”[15].

2.3 STEP 3 – RANK REMAINING CONTROL TECHNOLOGIES BY CONTROL EFFECTIVENESS

The third step in the “top-down” BACT evaluation is to rank the control technologies remaining after the feasibility analysis by control effectiveness. The purpose of ranking the control technologies is to establish a hierarchy that “places at the “top”, the control technology that achieves the lowest emission level”[16].

Selecting common units in order to compare emissions performance levels amongst options is one of the two key issues that must be addressed in a BACT analysis. EPA’s draft NSR Manual states “it is generally most effective to express emissions performance as an average steady state emissions level per unit of product produced or processed”[17]. For fossil fuel-fired boilers, pounds of nitrogen oxides per unit of fuel heat input (i.e. lb/mmBtu), is a common means of comparing and calculating NO_X emissions.

Many control techniques, including both add-on controls and inherently lower polluting processes can perform at a wide range of levels. The EPA’s draft NSR Manual states “It is not the EPA’s intention to require analysis of each possible level of efficiency for a control technique, as such an analysis would

---

[14] Ibid, NSR Manual B.18
[15] Ibid, NSR Manual B.18
[16] Ibid, NSR Manual B.25
[17] Ibid, NSR Manual B.22

result in a large number of options"[18]. Also, "manufacturer's data, engineering estimates, and the experience of other sources provide the basis for determining achievable limits"[19].

2.4 STEP 4 – EVALUATE THE MOST EFFECTIVE CONTROLS AND DOCUMENT RESULTS

The fourth step of a "top-down" BACT review is to evaluate the technically-feasible emission controls, beginning with the most effective. Economic, energy, and environmental impacts are to be assessed and quantified, where possible, in the control technology analysis. The purpose of the evaluation is to determine if there are any identified impacts that would eliminate the top control technology from consideration. In the case where the most effective control alternative is determined to incur or produce adverse energy, economic or environmental impacts, the basis of the determination is documented, and the next most stringent control alternative is evaluated. This analysis process continues until the control technology under consideration cannot be eliminated by identification of any source-specific adverse energy, economic or environmental impacts.

The economic impacts are based on estimates of capital equipment pricing, procurement, installation and estimated operating and maintenance costs. The total installed capital costs along with the operating costs for each control technology are summarized in the economics of each respective section. The Levelized Total Annual Cost (LTAC) represents the levelized cost of procurement, construction, operation and maintenance over an assumed service life. Cost effectiveness ($/ton) of a control technique or technology is calculated by dividing the LTAC ($/yr) by the annual amount of NO_X removed (tons/yr). Baseline pre-control emissions are calculated using realistic upper boundary operating assumptions, considering inherent physical or operational constraints on the source. Plotting of the annual amount of NO_X removed (tons/yr) versus the levelized total annual control cost ($/yr) for the various control options on an x-y graph allows visualization of the cost-effectiveness. A "least-cost envelope" can be readily identified to indicate the inferior control options which should not be considered in the subsequent analyses. The incremental cost-effectiveness (difference in $/ton) between control techniques or technologies can also be calculated and compared. This allows evaluation of the dominant controls included on the least-cost envelope (curve).

---

[18] Ibid, NSR Manual B.23
[19] Ibid, NSR Manual B.24

2.5 STEP 5 – SELECT BACT

The final step in the "top-down" evaluation process is to select BACT for the applicable pollutant and emission unit. Per the EPA guidance document, BACT is "the most effective control technology not eliminated in Step 4"[20]. The methodology described above was applied to the Milton R. Young Station Unit 1's boiler for emissions of nitrogen oxides.

3.0 BACT ANALYSIS for MRY STATION UNIT 1 NO_X EMISSIONS

The approach taken in this BACT analysis for Milton R. Young Station included a technical analysis of demonstrated control alternatives for NO_X emissions. This approach followed the predefined steps of a BACT analysis process as generally described in Section 2. Potential NO_X control techniques and technologies were identified, and a technical description of the emission reduction process and capabilities were provided. Subsequently, those techniques and technologies deemed available and feasible for retrofit application were ranked according to nominal NO_X control capability. The engineering analysis then developed the estimated capital and O&M costs for each alternative, including taking a look at Balance of Plant (BOP) requirements. Finally, the cost effectiveness points for each feasible technology were plotted, and those that comprise the dominant controls curve were identified.

For the feasible techniques and technologies considered for determining NO_X control cost-effectiveness for the two steam electric generating units at the MRY Station, estimates were produced for predicted NOx reductions that represent achievable long-term expectations of the alternative reduction techniques and technologies being presented in the technical analysis. Each were tabulated and graphed.

3.0.1 EMISSION UNIT DESCRIPTION

Milton R. Young Station Unit 1 is owned and operated entirely by Minnkota. MRY Station Unit 1 includes a Babcock and Wilcox steam generator installed in 1970. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation. Original unit design steam generating capacity is 1.714 million lbs/hr at 1,920 psi with a fuel heat input of 2,510 mmBtu/hr. The boiler is fired by seven ten-foot diameter cyclone burners, arranged “three over four” across the front wall of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the electrostatic precipitator (ESP). Exhaust gases leave the air heater and pass through an ESP for particulate collection and removal prior to the two induced draft fans (installed in parallel) which discharge to the stack. Unit 1 has a nominal 235 MW net design output capacity rating, is typically capable of sustained output of approximately 253 MW gross, and has an ultimate short-term maximum gross output (URGE) rating of 278 MW.

The EPA's Technical Support Document[21] published in the Edocket (EPA's internet website) for the Final BART Guidelines lists nameplate steam turbine-generator capacity of MRY Station Unit 1 as 257 MW (gross), which was assumed for calculating capital cost estimates for control alternatives.

The Unit 1 boiler at M.R. Young Station includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boilers.

Milton R. Young Station Unit 1's boiler design, combustion performance, and NO_X emissions are dominated by the composition and combustion characteristics of the North Dakota lignite supplied solely from a surface mine adjacent to the plant. This mine is the only supplier of solid fuel for this station, as there are no railroad facilities provided to service the Milton R. Young plant. North Dakota lignite has high moisture and high sodium content, moderate higher heating values, and can have a widely variable and high ash content compared to other coals. These characteristics create difficulties in promoting consistent, steady combustion and slag formation in the cyclone burners. It also results in producing a flyash that has severe deposition characteristics.

The design unit operating conditions for this study are presented in Table 3-1. The historical average lignite coal analysis is shown in Table 3-2.

Table 3-1 – Unit Design Parameters

Design Unit Operating Characteristics	**Unit 1 Design**
Boiler Type	Subcritical(1)
Combustion System	Cyclone
Number of Cyclones; arrangement, location	7; 3 over 4, front
Unit Design Capacity Electrical Output(2), MW (net/gross)	235 / 257

(1) – Balanced draft, single drum, superheated steam with single stage of steam reheat.
(2) – These values were established by the original equipment manufacturers, prior to construction.

Total	100.00
Higher Heating Value, Btu/lb	6,662

3.0.2 NITROGEN OXIDES EMISSION FORMATION

Nitrogen oxides (NO_X) are produced when nitrogen in the fuel and combustion air are exposed to high temperatures. There are two primary sources of NO_X emissions, referred to as "thermal" NO_X and "fuel" NO_X. Thermal NO_X emissions are produced when elemental nitrogen in the combustion air is admitted to a high temperature zone and oxidized. Fuel NO_X emissions are created during the rapid oxidation of the fuel containing nitrogen compounds. For most coal-fired units, thermal NO_X emission typically represents approximately 20% and fuel NO_X about 80% of the total NO_X formed. Nitrogen oxide (NO) is typically the most predominant form of NO_X emissions from fossil fuel combustion, along with nitrogen dioxide (NO_2). The formation of these compounds in utility powerplant boilers is sensitive to the method of firing and combustion controls utilized. The techniques employed for mixing the combustion air and fuel, which creates flames and high temperature combustion products, results from the rapid oxidization of carbon, hydrogen, and other exothermic reactions. Cyclone-fired boilers, by design, create intense heat release rates to melt and fluidize the coal ash introduced into the barrel-shaped furnaces. This produces high temperature flue gases and results in very high uncontrolled NO_X emissions. The amount of thermal NO_X emissions produced by cyclone boilers can be considerably higher than fuel NO_X emissions.

3.1 IDENTIFICATION OF NO_X CONTROL OPTIONS FOR MILTON R. YOUNG STATION

The first step in the BACT evaluation is to identify all "demonstrated and potentially applicable control technology alternatives"[23] according to the EPA's draft NSR Manual. In identifying control technologies, "the applicant needs to survey the range of potentially available control options"[24].

---

[24] Ibid, NSR Manual page B.11

3.1.1 REVIEW OF RETROFIT INSTALLATIONS

The BACT determinations listed in the EPA's RACT/BACT/LAER Clearinghouse (RBLC) database are for new facilities. The Milton R. Young Station is an existing powerplant facility with two coal-fired EGUs. A BACT evaluation for retrofitting control equipment to coal-fired EGUs in an existing facility will be substantially different than an analysis for installing control equipment on coal-fired EGUs in a new facility. Consequently, in performing the BACT analysis for existing boilers at Milton R. Young Station, it is important to review powerplant facilities, especially cyclone-fired coal boilers, which have retrofitted NO_X control equipment in recent years.

In 1998, EPA issued a NO_X SIP (State Implementation Plan) call. Under the SIP call, utility boilers in the eastern United States were required to substantially reduce NO_X emissions during the "ozone season". The compliance date for the NO_X SIP call is May 31, 2004. A high percentage of the fired electric generation facilities in the eastern United States have or are in the process of retrofitting NO_X controls to comply with the NO_X SIP call. The EPA's NO_X SIP call was not applicable to North Dakota utility boilers.

There are a number of fossil fuel-fired EGU powerplants around the United States that have implemented or are planning to implement modifications to reduce NO_X emissions. The NO_X emission control system installations are in response to Acid Rain requirements, EPA's NO_X SIP call, the Clean Air Interstate Rule (CAIR), the Regional Haze Rule (RHR), and local regulations.

In addition to the facilities that have had to retrofit emissions controls as a result of the Title IV Part 76 Acid Rain requirements and/or EPA's NO_X SIP call, a few installations have had to retrofit controls in recent years as the result of court decisions resulting from litigation and regulatory action. None of the boilers associated with identified consent decrees are cyclone-fired. They are also located in a region requiring compliance with an EPA-approved State Implementation Plan for nitrogen oxides emissions controls (i.e. NO_X SIP call). As mentioned above, North Dakota utility boilers were not subject to the EPA's NO_X SIP call.

3.1.2 POTENTIALLY FEASIBLE NOx CONTROL OPTIONS FOR MILTON R. YOUNG STATION

A review of available information on retrofit installations performed at utility and industrial coal-fired powerplants during the past fifteen years was undertaken. NO_X emission control technologies and techniques with potential application to Milton R. Young Station boilers were identified, and are listed in Table 3-3.

TABLE 3-3 – Potentially Available NO_X Control Technologies Identified for BACT Analysis

NOx Control Technology
Pre-Combustion Controls
Fuel Cleaning/Blending/Switching
Combustion Controls
Basic Combustion Control Improvements
Low NOx Burners (LNB)
Separated Overfire Air (SOFA)(1)
Flue Gas Recirculation
Fuel Reburn
Oxygen-enhanced combustion (OEC)
Water/steam injection (combustion tempering)
Post-Combustion Controls
Selective Non-Catalytic Reduction (SNCR)(2)
Selective Catalytic Reduction (SCR)
Electro-Catalytic Oxidation (ECO®)(3)

Notes: these are basic forms of the identified techniques.
Not all variations or combinations are included.
(1) – SOFA technologies include Boosted SOFA and Rotating Opposed Fired Air (ROFA)
(2) – SNCR technologies include Rich Reagent Injection, and Hydrocarbon-enhanced SNCR, commercially available as "NOxStar™".
(3) – Multi-pollutant control technology currently under commercial development by Powerspan Corp.

A comprehensive literature search, with sources including technical papers and presentations made at conferences by nationally-recognized technical organizations, utilities and other parties involved with design, construction, and testing of NO_X control techniques, plus hardware supplier experience lists, was performed. The results of this search are presented in Appendix A2, which includes a summary of various selected U.S. NO_X emission reduction retrofit projects.

3.2 FEASIBILITY ANALYSIS

The second step of the "top-down" BACT process is to evaluate the control processes that have been identified and determine if any of the processes are technically infeasible.

An available technology is "applicable" if it can be reasonably be installed and operated on the source type under consideration. Also, a control technique is considered available if it has reached the stage of licensing and commercial availability. For the purposes of this analysis, the term "commercial" is further defined to mean "capable of establishing a full contractual agreement with commercial and performance guarantees supported by appropriate financial backing" for the implementation of full-scale, full-time systems of the technique or technology application. A technology that is available and applicable is technically feasible.

There are three basic categories of NO_X emission control techniques and technologies:

- Pre-combustion controls;
- Combustion controls; and
- Post-combustion controls

Uncontrolled NO_X emissions from a coal-fired electric generating unit are highly dependent on type of firing method, amount of solid fuel fired per unit time and furnace volume, and the fuel's basic combustion properties and elemental composition. The basic methods for reduction of such emissions:

- either prevent pollution, i.e. use inherently lower-emitting processes/practices which produce fewer NO_X emissions during the power generation process; or
- involve improvements to, or provide new add-on controls that, reduce emissions after they are produced before they are emitted from the facility; or
- are combinations of inherently lower-emitting processes and add-on controls.

Most of the identified control options have been commercially-available, installed, and operating in many full-scale, permanent coal-fired utility boiler installations in the United States for five years or more.

Pre-combustion controls, such as fuel switching, fuel blending, and fuel cleaning have been practiced and performed at numerous utility power plants, typically for operational and sulfur emissions control reasons.

Combustion controls, such as low-NO_X burners (LNBs) and overfire air systems, are very commonly applied to reduce NO_X emissions from fossil fuel-fired powerplants. Low-NO_X Burners are typically applied to pulverized coal, gaseous and liquid fuel-fired boilers. They are not applicable to cyclone-fired boilers. Flue gas recirculation (FGR) has been practiced and performed at numerous natural gas and fuel oil-fired utility and industrial powerplants for NO_X emissions control reasons. On large coal-fired utility boilers, FGR has primarily been applied for steam temperature control purposes, not for emissions control. Conventional Gas Reburn (CGR) with overfire air has been installed and placed in commercial operation on several cyclone-fired boilers, primarily in the eastern region of the United States. Coal Reburn (CR) with overfire air has been successfully demonstrated on two cyclone-fired boilers and commercially installed on three pulverized coal-fired boilers in the United States. Combustion tempering (water/steam injection) has been tested but has not been continuously practiced on cyclone-fired coal boilers. Oxygen-enhanced combustion has only been demonstrated and/or installed on a limited number of pulverized coal-fired powerplants, not on any coal-fired cyclone boilers.

Selective Catalytic Reduction (SCR) and Selective Non-Catalytic Reduction (SNCR) are post-combustion technologies that have been applied predominantly on eastern or midwestern bituminous coal-fired boilers. Others, mostly comprised of a combination of available emission reduction technologies, are often referred to as “hybrid” or “layered” controls. Variations of SNCR, such as Rich Reagent Injection (RRI) with and without SNCR, have only been installed or demonstrated on a limited number of cyclone-fired boilers. Other technologies, such as Fuel Lean Gas Reburn™ with SNCR, hydrocarbon-enhanced SNCR (commercially available as NO_XStar^{TM}), and Conventional Gas Reburn with SNCR have only been demonstrated and/or installed on a limited number of pulverized coal-fired power plants.

Emerging post-combustion multi-pollutant control technologies, such as Powerspan’s Electro-Catalytic Oxidation (ECO$^{®}$), which include NO_X control, were also identified. These are typically in the large pilot-scale commercial development phase, and have not been successfully demonstrated on a full scale basis on any pulverized coal, cyclone, or circulating fluid bed boilers.

In most of the combination or “layered” and emerging control cases, the NO_X control technology has been demonstrated to be capable of controlling the targeted pollutant(s) on either:

- a full-scale basis, but only with temporary equipment; or
- a full-scale basis, with permanent equipment but in a limited number of installations; or

- with less than full-scale and full-time application.

3.2.1 SUMMARY OF RETROFIT INSTALLATIONS OF NO_X CONTROL TECHNOLOGIES

There are a number of facilities around the country that have implemented or are planning to implement modifications to reduce NO_X emissions. Table 3-4 summarizes the various NO_X emission control system installations currently installed, or that have been demonstrated on a full-scale, short-term basis, in response to Acid Rain requirements, EPA's NO_X SIP call and local regulations, or a utility investigating the technology.

TABLE 3-4 – Identified NO_X Control System Retrofits on Cyclone Coal-fired Boilers

No. of Units(1)	Cyclone NO_X Control Technology Description
1	Fuel Switching/Blending
39(2)	Separated Overfire Air (SOFA)
2	Selective Non-Catalytic Reduction, with or without SOFA
2(3)	Rich Reagent Injection, with SOFA
7(4)	Conventional fuel reburn (pulverized or micronized coal, gas), w/ SOFA
1(5)	Fuel lean gas reburn, with or without SOFA
22(6)	High-dust or low-dust SCR, with or without other technologies
1(6)	Tail-gas SCR, with or without other technologies

(1) – This list of known NOx control retrofit installations is primarily focused on units in the United States. There may be other installations that are similar but were not identified.

(2) – Installed for NOx control (without fuel reburn). A list of known cyclone boiler SOFA installations is included in Appendix A2.

(3) – RRI has only been demonstrated with temporary equipment for testing. See technical literature references in Appendix A1 and A2 for details.

(4) – Several conventional coal and gas reburn retrofits have discontinued reburn demonstration or routine operation. See Technical Literature Reference list and Appendix A3 for further details.

(5) – Only one example of fuel lean gas reburn retrofit (without OFA) on a cyclone-fired boiler has been demonstrated. This system was installed for short-term reburn testing and has been removed.

(6) – High-dust SCR technology has been retrofitted on sixteen U.S. cyclone-fired boilers, all believed to have SOFA. Low-dust SCRs in U.S. have only been installed only on pulverized coal-fired boilers, none on cyclones. One tail-gas SCR installation on a coal-fired cyclone boiler found in Germany; none in the U.S. See technical literature references in Appendix A1 and A2 for details.

A more detailed description of the various control technology retrofits and their claimed effectiveness is included in the technical descriptions and reference literature in the technical feasibility assessment of

Appendix A1, and Appendix A2, which includes a summary of various selected U.S. NO_X emission reduction retrofit projects.

3.2.2 SUMMARY OF FEASIBLE NO_X CONTROL TECHNOLOGIES FOR MRY STATION

One example of fuel switching applied to a cyclone-fired boiler was identified. Ottertail's Big Stone Unit 1 was originally designed to burn North Dakota lignite and was switched to western subbituminous (PRB) coal for reasons unrelated to NO_X emissions reduction. Big Stone Unit 1 and M.R. Young Station Unit 2 have similar boiler designs, and MRYS Unit 1's boiler is approximately 60% as large as MRYS Unit 2's boiler. Thus, conversion of Milton R. Young Station Unit 1's boiler to fire PRB coal or a lignite/PRB blend is technically possible. There are no railroad facilities provided to service the Milton R. Young plant. Additional operational and capital costs to bring in large quantities of PRB coal will be significant. Based on a comparison of available emission data between Ottertail's Big Stone Unit 1 and M.R. Station Young Unit 1, there is no expected reduction in baseline (i.e. uncontrolled) NO_X emissions from switching to PRB from lignite at Milton R. Young Station. Although fuel switching at Milton R. Young Station is technically feasible, this alternative will not be economically competitive with other NO_X control technologies that offer better results for a much lower combination of capital and operational costs. For these reasons, it has not been considered further as an effective NO_X emissions control option for MRY Station Unit 1 boiler.

Separated Overfire Air (SOFA) is the most commonly-applied, combustion-related NO_X emission reduction technology that has been proven effective on cyclone-fired boilers. A version of separated overfire air specifically designed for increased NO_X emission reduction performance for lignite-fired cyclone boilers, referred to as "Advanced SOFA" in this analysis, can be installed on both units at M.R. Young Station. The potential operational limitations mentioned in the detailed feasibility discussions included in Appendix A1 for deeply air-staged cyclones associated with separated overfire air are expected to limit the control effectiveness of this technique, alone and in combination with other feasible NO_X control options.

Selective Non-Catalytic Reduction (SNCR) technology is a form of post-combustion NO_X emission control that has been successfully applied on numerous utility boilers burning eastern bituminous coal, midwestern bituminous coal, and, to a lesser extent, western subbituminous coal to reduce NO_X emissions. SNCR has also been used on fuel oil and natural gas-fired units. SNCR does not appear to be dependent directly on the type of burners (wall-fired, tangentially-fired, and cyclone-fired) employed in the boilers where it has been installed, with or without air-staged combustion with overfire air in full operation. This control technology adds urea (or ammonia) reagent to the hot furnace gases in the upper furnace to chemically reduce nitrogen oxides. SNCR was considered technically feasible for application on both units at M.R. Young Station. SNCR can be operated with and without SOFA. Variations of SNCR technologies such as Hydrocarbon-enhanced SNCR (HE-SNCR) and "Rotamix" have been installed on pulverized coal-fired boilers but are not proven on cyclone boilers. This is described in detail in Appendix A1.

Rich Reagent Injection (RRI) is a form of SNCR under development specifically intended for NOx emissions control on cyclone boilers. As of October 2006, RRI has been demonstrated but has not been commercially installed and placed in continuous operation on a cyclone-fired boiler, especially one burning coal with high fouling and slag temperature sensitivities associated with lignite supplied from the Center mine. RRI adds aqueous urea reagent to the hot furnace gases near the cyclones, which must be devoid of free oxygen in order to avoid oxidation of the urea which will increase NOx emissions. RRI is considered technically infeasible for application on the cyclone boilers at the Milton R. Young Station at the present time. This is described in detail in Appendix A1.

Various forms of fuel reburn with and without overfire air are types of combustion-related technologies that have been demonstrated and commercially installed on pulverized coal, fuel oil-fired, and cyclone utility and industrial boilers. Natural gas-consuming variations such as Conventional Gas Reburn (CGR) and Fuel-Lean Gas Reburn (FLGR™) have been applied to cyclone boilers burning bituminous and subbituminous coals. High capital costs expected for installing a natural gas pipeline and high operating costs from consumption of large volumes of such fuel make these alternatives economically unfavorable for both units at M.R. Young Station. Pulverized or micronized coal reburn, in combination with SOFA, are technically feasible but will require extensive capital, operating and maintenance costs for fuel grinding equipment and facilities when installed and operated for both units at M.R. Young Station. This is described in detail in Appendix A1.

Fuel cleaning is a technique normally applied to reduce the sulfur or ash content of a fossil fuel prior to combustion. No examples of fuel cleaning of North Dakota lignite or western subbituminous coal strictly for NO_X emissions reduction were found in available technical literature. This technique is considered infeasible for NO_X emissions control of M.R. Young Station boilers at the present time.

High-dust, low-dust, and tail-gas variations of selective catalytic reduction (SCR) technology have been applied on pulverized coal and cyclone boilers as a post-combustion type of NO_X emission control throughout the world and in the United States, except on units firing North Dakota lignite. The severity of catalyst blinding and pluggage from particulate matter and flue gases emitted from cyclone-fired boilers burning North Dakota lignite precludes the technical feasibility for successful application of such SCR technology on the EGUs at the Milton R. Young Station. This is described in detail in Appendix A1 with supporting documentation in Appendix B.

The results of Step 2 of the NO_X BACT Analysis for determining the technical feasibility of potential control technologies, including various "layered" combinations, are listed in Tables 3-5 and 3-6.

TABLE 3-5 – Technically-Feasible Potential NO_X Control Technologies for M.R. Young Station Cyclone Boilers

Control Technology(1)	In Permanent, Full-Scale Service on Existing Coal-Fired Cyclone Utility Boilers?	Technically Feasible on M.R. Young Station Unit 1 boiler?
Selective Non-Catalytic Reduction (SNCR)	Yes(2)	Yes
Conventional Gas Reburn	Yes(3)	Yes(3); Requires SOFA or ASOFA
Coal Reburn	Yes(4)	Yes(4); Requires SOFA or ASOFA
Fuel Lean Gas Reburn	No(5)	Yes(5) (w/ or w/out SOFA or ASOFA)
Advanced SOFA	No(6)	Yes(6). Includes relocated lignite drying vent ports
Separated OFA (basic SOFA)	Yes(6)	Yes(6)
Combustion Improvements	Yes	Yes(7); typically included with separated OFA
Flue Gas Recirculation	Not for NOx control	Yes(8) (not expected to reduce NOx further)
Fuel Switching / Blending	Yes	Yes(9) (not expected to reduce NOx further)

See technical feasibility details and literature References in Appendix A for details.

(1) – All potential combinations of technologies not listed. See discussion of "layered" technologies.

(2) – Assumes use of urea for reagent. Limited number of active installations on cyclone-fired boilers burning western subbituminous (i.e. Powder River Basin or PRB coal).

(3) – Limited number of active conventional gas reburn (CGR) installations on cyclone-fired boilers burning PRB coal.

(4) – Limited number of demonstrations or active installations of pulverized or micronized coal reburn on cyclone-fired boilers. One demonstration of pulverized coal reburning with PRB coal has been performed on a cyclone-fired boiler, no longer active. Only one active permanent coal reburn installation on cyclone-fired boiler burning eastern bituminous coal, none burning western subbituminous coal or lignite.

(5) – Only one short-term test demonstration of FLGR™ on a cyclone-fired boiler burning coal with separated overfire air.

(6) – No cyclone boilers firing North Dakota lignite have installed basic or advanced SOFA. See Appendix A.

(7) – Considered part of SOFA installation for coal boilers without combustion controls for NOx reduction.

(8) – No examples of using recirculated flue gas on coal-fired boilers for NOx emissions control were found in available technical literature. Zero additional NO_X reduction potential expected from this technique alone for MRY Station Unit 1 / 2. Potential NO_X reduction improvement on MRY Unit 1 / 2 considered part of "advanced" SOFA.

(9) – Zero additional NO_X reduction potential expected from this technique (switching from lignite to lignite/PRB blends or 100% PRB) alone for MRY Station Unit 1 / 2.

TABLE 3-6 – Technically Infeasible Potential NO_X Control Technologies for M.R. Young Station Cyclone Boilers

Control Technology(1)	In Permanent, Full-Scale Service on Existing Coal-Fired Cyclone Utility Boilers?	Technically Feasible on M.R. Young Station Unit 1 boiler?
Selective Catalytic Reduction (SCR): conventional (high dust); Low-dust; Tail-gas	Yes(2) / No / Yes(3)	No(4) - Unresolvable fouling and catalyst deactivation problems expected. See discussion of SCR feasibility for ND lignite.
Electro-Catalytic Oxidation (ECO®)	No	No, has not been demonstrated full-scale nor reached commercial availability
HE-SNCR (using ammonia)	No(5)	No(5). Has not been demonstrated on cyclone.
Rotamix (ROFA + SNCR)	No(6)	No(6). Has not been demonstrated on cyclone.
Rich Reagent Injection (RRI) with ASOFA	No(7)	No(7). Requires oxygen-free furnace environment, varying air/fuel would increase NOx emissions.
RRI + SNCR with ASOFA	No(7)	No(7). See footnote and feasibility discussion.
Advanced Conventional Gas Reburn (ACGR) + SNCR	No(8)	No. Has not been demonstrated on cyclone.
Coal Reburn + SNCR	No(8)	No. Has not been demonstrated on cyclone.
Fuel Lean Gas Reburn + SNCR	No(8)	No. Has not been demonstrated on cyclone.
Rotating Opposed-Fired Air	No(6)	No. Has not been demonstrated on cyclone.
Oxygen Enhanced Combustion	No(9)	No. Has not been demonstrated on cyclone.
Water Injection	No(10)	No(10)
Fuel Cleaning	Not for NOx control	No(11) (not expected to reduce NOx further)

See technical feasibility details and literature References in Appendix A for details.

(1) – All potential combinations of technologies not listed. See discussion of "layered" technologies.

(2) – Limited number of active installations on cyclone-fired boilers burning western subbituminous coal.

(3) – No identified installations on coal-fired boilers in the United States. One tail-end SCR on cyclone boiler in Germany.

(4) – See discussion of SCR feasibility for ND lignite in Appendix A1 and Appendix B.

(5) – Hydrocarbon-enhanced SNCR has not been demonstrated on a cyclone-fired boiler, nor any boiler firing western subbituminous coal or lignite.

(6) – Rotating Opposed-Fired Air with or without SNCR has not been demonstrated on a cyclone-fired boiler. No apparent significant advantages over SOFA on cyclone-fired boilers.

(7) – Rich Reagent Injection has been successfully demonstrated for brief periods with SOFA with and without SNCR at two cyclone powerplants. There are no permanent RRI installations completed and operational as of May 2006. Difficulties in maintaining an oxygen-free furnace environment in MRY Station boilers where the urea reagent would be injected due to cyclone air/fuel imbalances during air-starved combustion would increase NOx emissions.

(8) – No known demonstrations or permanent installations of Advanced conventional gas reburn (CGR) or FLGR™ or pulverized/micronized coal reburn (PCR/mCR) in combination with SNCR on cyclone-fired boilers. CGR and PCR/mCR require separated overfire air. FLGR™ has been applied to pulverized coal firing with and without SOFA, with and without SNCR; FLGR™ with SNCR is also called amine-enhanced fuel lean gas reburn (AEFLGR™).

(9) – No known demonstrations or permanent installations of oxygen-enhanced combustion (OEC) on cyclone-fired boilers.

(10) – No permanently installed examples of using this technique continuously on coal-fired boilers were found in available technical literature. Not suitable for high-moisture lignite fuels.

(11) – No known demonstrations or permanent installations of using this technique continuously on coal-fired boilers for NOx emissions control were found in available technical literature.

Additional criteria besides technical feasibility are utilized for technology selection in a BACT analysis have been included in the following sections summarizing control effectiveness estimates, capital plus operating and maintenance cost estimates, energy impacts, and environmental impacts:

- Control effectiveness (i.e. percent pollutant removed)
- Expected emission rate (see Tables 3-7, 3-8) and emission reduction (tons per year)
- Economic impacts (total cost and incremental cost effectiveness)
- Energy impacts
- Environmental impacts (other media and emissions of toxic and hazardous air pollutants)

3.3 RANK OF TECHNICALLY FEASIBLE NO$_X$ CONTROL OPTIONS BY EFFECTIVENESS

The third step in the "top-down" BACT evaluation is to rank the remaining control technologies by effectiveness. The purpose of ranking the control technologies is to establish a hierarchy that "places at the "top" the control technology that achieves the lowest emission level."

The emission reduction (control effectiveness) percentages developed for ranking the available NO$_X$ emission control options considered feasible for Milton R. Young Station Unit 1 are shown in Table 3-7. These are estimates based upon engineering judgments with considerations of:

- Boiler heat input rates associated with realistic upper boundary operating assumptions;
- baseline emission rates corresponding to the realistic upper boundary operating assumptions;
- the general combustion properties of North Dakota lignite;
- published and available emission reduction performance achieved at other similar utility powerplants (cyclone-fired boilers);
- computer-derived predictions; and
- inclusion of performance margins to allow for variations in fuel, weather, equipment condition, and other factors that prevent the ultimate peak short-term performance from being reliably sustained over the course of long-term operation.

These NO$_X$ emission level and reduction percentage estimates include adjustments of previously demonstrated or predicted performance that reflect differences between North Dakota lignite and eastern or midwestern bituminous and western subbituminous coals.

The numbers assume the estimated capability of the employed technique is achievable and sustainable (long-term) and that potential operational limitations mentioned in the feasibility discussions allow the successful practice of the technique or technology. None of the remaining control options has been installed on a cyclone-fired boiler burning North Dakota lignite. As such, the expressed control percentages reflect the use of engineering judgment, based on the listed technique or technology application. This is particularly pertinent to all control options that involve air-staged combustion associated with various forms of separated overfire air. SOFA-based controls for cyclone-fired coal-burning boilers have typically reduced NO_X emission levels significantly from the precontrol baseline, and which allow or enhance further reductions when combined with other control techniques and technologies.

3.3.1 ESTABLISHING BASELINE NO_X EMISSIONS FOR RANKING CONTROL OPTIONS

Before the various feasible NO_X emission control alternatives can be estimated and ranked in order of effectiveness, the precontrol baseline level of emissions and its basis must be determined. The EPA's NSR Manual provides general guidance for establishing estimated baseline emissions to be used for the purpose of calculating and comparing the control and cost-effectiveness of a control option:

> "The baseline emissions rate represents a realistic scenario of upper boundary uncontrolled emissions from the source. The NSPS/NESHAP requirements or the application of controls, including other controls necessary to comply with State or local air pollution regulations, are not considered in calculating the baseline emissions. In other words, baseline emissions are essentially uncontrolled emissions, calculated using realistic upper boundary operating assumptions. When calculating the cost effectiveness of added post-process emissions controls to certain inherently lower polluting processes, baseline emissions may be assumed to be the emissions from the lower polluting process itself. In other words, emission reduction credit can be taken for the use of inherently lower polluting processes"[25].

Also stated in the EPA's NSR Manual:

> "Estimating realistic upper bound case scenario does not mean that the source operates in an absolute worst-case manner all the time. For example, in developing a realistic upper boundary case, baseline emissions calculations can also consider inherent physical or operational constraints on the source. Such constraints should accurately reflect the true

---

[25] Ibid, NSR Manual B.37

> upper boundary of the source's ability to physically operate and the applicant should submit documentation to verify these constraints"[26].

Establishing estimated baseline NO_X emissions for a new or existing source involves determining the design or operational basis of the emission rate. A useful means of comparing such emission rates is to establish the unit emission rate, expressed in pounds of pollutant per unit of process output. For processes such as steam-electric generating powerplants utilizing combustion in boilers, the desired process output (kilowatts or megawatts) can be related to the pollutant-bearing flue gas created by the combustion of fuel. Units of fuel heat input (millions of BTUs) required to create a unit of desired electrical output (kW) and thus the efficiency of converting the fuel heat to such electrical output (unit heat rate, Btu/kW-hr) are important.

A review of reported hourly NO_X emissions for MRY Station Unit 1 boiler, including unit mass rates (lb/mmBtu and lb/hr), boiler heat input (mmBtu/hr), and gross electrical output in megawatts (MW_g), was performed for the operating periods in years 2001-2005 inclusive. A realistic upper bound emission case scenario for each boiler's baseline emissions at Milton R. Young Station determined the highest summation of any rolling 12-month period NO_X mass emissions (pounds), along with the summation of the gross heat input (mmBtus) and the boiler operating hours for the same rolling 12-month period corresponding to the highest NO_X pounds. Dividing the summation of the rolling 12-month NO_X pounds by heat input results in a average unit emission rates (lb/mmBtu). Likewise, the summation of the rolling 12-month gross heat input (mmBtus) divided by the boiler operating hours yields an average gross heat input rate (mmBtu/hr). This emission evaluation revealed that:

- Unit 1 at Milton R. Young Station is typically operated in a base-loaded manner;
- MRYS Unit 1's highest 12-month NO_X mass emissions summation divided by the summation of the same 12-month period's heat input averaged 0.849 lb/mmBtu at a corresponding average unit heat input rate of 2,744 mmBtu/hr and unit gross electrical output of 244.5 MW_g.

3.3.2 ESTIMATING CONTROL-EFFECTIVENESS OF NO_X EMISSIONS CONTROL OPTIONS

The degree of success in operation of separated overfire air alone and in combination with the other selected feasible alternatives is important to the amount of NO_X emission reduction achieved. The emission control performance from the advanced version of separated overfire air (ASOFA) is highly

---

[26] Ibid, NSR Manual B.37

dependent on the degree of success in admitting combustion air insufficient for complete combustion in the cyclones without causing related negative impacts. The control percentages estimated for firing North Dakota lignite in the MRY Station boilers reflect the belief that operating the existing cyclones much below an average cyclone stoichiometric ratio of approximately 0.95 (95% of the theoretical amount of combustion air required for complete combustion) will not be successful. This is due primarily to the expected "starved air" combustion causing a reduction in cyclone furnace gas temperatures, thus creating a strong potential for molten slag solidifying in the cyclone barrels, slag taps, and lower furnace floor openings. This would impose a great interruption to steam production since forced outages would be required to remove this physical obstruction before full load boiler operation could be reestablished. The EPA's draft NSR Manual states "It is not the EPA's intention to require analysis of each possible level of efficiency for a control technique, as such an analysis would result in a large number of options"[27].

The potential operational limitations for deeply air-staged cyclones associated with separated overfire air and coal reburn alternatives are expected to limit the amount of NO_X control potential possible from successful practice of the particular technique or technology. This is described in the detailed feasibility discussions included in Appendix A1.

The advanced form of separated overfire air is expected to be effective in NO_X emission reduction and can be combined with other feasible combustion-related and post-combustion control alternatives for these lignite-fired cyclone boilers. The basic form of SOFA in combination with coal reburn, gas reburn options, and SNCR, was not included in the detailed control effectiveness analysis in order to limit the number of options that were evaluated.

Using an advanced form of SOFA system, M.R. Young Station's Unit 1's boiler operating at MCR is expected to achieve a NO_X emission level of 0.51 lb/mmBtu when operating modestly air-staged cyclone furnaces with suitable combustion controls. This level of NO_X reduction from ASOFA operation, approximately forty percent, is based on the expected ability to reduce emissions without incurring potential significant negative impacts of this technique. This reduction estimate includes the additional amounts of control potential available from operating with relocated lignite drying system vent ports associated with ASOFA operation with modestly air-staged cyclone furnaces.

---

[27] Ibid, NSR Manual B.37

Coal reburn with ASOFA is estimated to reduce NO_X emissions for M.R. Young Station's Unit 1's boiler operating at MCR slightly less than 55 percent from the pre-control baseline NO_X emission rate, considering similar control levels demonstrated by previous coal-reburn retrofits on cyclone-fired boilers and limitations previously discussed with ASOFA.

Conventional Gas Reburn and Fuel Lean Gas Reburn options were both assumed to be installed with ASOFA. NO_X reduction from CGR with ASOFA operation is expected to be approximately fifty six percent. FLGR with ASOFA is expected to reduce NO_X emissions approximately forty six percent. Estimates for NO_X emissions for M.R. Young Station's Unit 1's boiler considered similar control levels demonstrated by previous gas-reburn retrofits on cyclone-fired boilers with modestly air-staged cyclone furnaces and limitations previously discussed with ASOFA.

The NO_X emission rate for Selective Non-Catalytic Reduction (SNCR) (using urea) with ASOFA is expected to be approximately 0.355 / 0.33, resulting from a reduction in NO_X emissions of approximately 58 percent from the 12-month average pre-control baseline NO_X emission rate.

Included in the feasible control option ranking of Table 3-7 are layered alternatives that were shown in Table 3-5. The highest-performing NO_X control alternatives remaining in consideration are ranked in declining order of expected emission reduction. These combined control options refer to "advanced" SOFA, which is expected to have significantly lower NO_X emissions than a typical SOFA system as applied to the Milton R. Young cyclone boilers.

TABLE 3-7 – Ranked NO_X Control Options Feasible for MRY Station Unit 1 Boiler with Expected Control Performance

Alt. Label[(1)]	NO_X Control Technique	Emission Rate (lb/mmBtu)	Control Percentage[(2)]
E	SNCR (using urea) w/ ASOFA	0.355	58.1
D	Gas Reburn with ASOFA	0.374	56.0
C	Lignite Reburn w/ ASOFA	0.385	54.6
B	Fuel Lean Gas Reburn with ASOFA	0.460	45.9
A	Advanced Separated Overfire Air (ASOFA)	0.513	39.5
-	Baseline	0.849	-

(1) - Alternative designation assigned from highest to lowest unit NOx emission rate.

(2) - Control percentages are relative to an average pre-control emission baseline of 0.849 lb/mmBtu based on annual operation at highest pre-control 12-month rolling NOx summation mass emissions divided by the 12-month heat input summation.

The annual emission levels developed for Table 3-7's ranking the feasible alternatives assume that the highest 12-month average pre-retrofit level of unit NO_X emissions for M.R. Young Station's Unit 1's boiler is a baseline of 0.849 lb/mmBtu. This was determined from the highest reported rolling 12 consecutive month period's summation of hourly NO_X emissions (lbs).

The hourly gross fuel heat input (mmBtu) was summed over that same 12-month time period, and divided by the number of boiler operating hours to yield an annual average gross fuel heat input rate (mmBtu/hr). Multiplying the 12-month average heat input rate (mmBtu/hr) by the baseline or control alternative's 12-month average unit emission rate (lb/mmBtu) equals a 12-month average hourly NO_X emissions rate (lb/hr). Annual NO_X emissions (tons) for the baseline pre-control condition were calculated by multiplying the 12-month summation for boiler operating hours during the same period as the highest NO_X emissions by the 12-month average emission rate (lb/hr). The annual tons for the control options were calculated by multiplying the alternative's average annual emission rate (lb/yr) by a reduction factor (if applicable) for heat input or running plant capacity and adjusting boiler operating hours by an annual uptime (availability) factor. Details for these adjustments are included in Appendix C3. Based on these calculations, the annual emissions for M.R. Young Station's Unit 1's boiler are shown in Table 3-8.

TABLE 3-8 – Expected Annual NO_X Control Performance for MRY Station Unit 1 Alternatives

		EMISSIONS				
Alt. Label[1]	**NOx Control Alternative**	**Emission Rate lb/mmBtu**	**Hourly Emission[2] lbs/hr**	**Annual Emission[3] tons/yr**	**Emission Reduction[4] tons/yr**	**NOx Removal Efficiency[5] %**
E	SNCR (using urea) w/ ASOFA	0.355	975	4,025	5,909	58.1
D	Gas Reburn w/ ASOFA	0.374	1,025	4,275	5,659	56.0
C	Lignite Reburn w/ ASOFA	0.385	1,058	4,343	5,591	54.6
B	Fuel Lean Gas Reburn w/ ASOFA	0.460	1,261	5,260	4,674	45.9
A	Advanced Separated Overfire Air (ASOFA)	0.513	1,409	5,874	4,060	39.5
-	Baseline	0.849	2,330	9,934	0	-

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.
(2) - Hourly NO_X emission estimates (lb/hr) were calculated based upon average annual unit emission rate (lb/mmBtu) x 2,744 mmBtu/hr heat input.
(3) - Estimated annual emission tons assume an annual capacity factor specific to each alternative; 94.1% was assumed for the baseline case.
(4) - Estimated annual tons of emission reduction is the difference between annual baseline tons and each alternative's annual emissions (tons).
(5) - Estimated NO_X control level percentage reductions relative to 0.849 lb/mmBtu emission baseline at 2,744 mmBtu/hr MCR heat input.

3.4 NO$_X$ CONTROLS ANALYSIS AND IMPACTS EVALUATION

The fourth step of a "top-down" BACT review is to evaluate the most effective emission controls. Energy, economic, and environmental impacts are to be considered in the control technology evaluation. The purpose of the evaluation is to determine if there are any energy, economic or environmental impacts that would eliminate the top control technologies from consideration.

3.4.1 NO$_X$ CONTROL ECONOMIC IMPACTS FOR MRY STATION UNIT 1

An evaluation was performed to determine the various cost impacts of installing feasible NO$_X$ control alternatives on Milton R. Young Unit 1. This evaluation includes estimated:

- Capital costs;
- Fixed and variable operating and maintenance costs; and
- Levelized total annual costs

to engineer, procure, construct, install, startup, test, and place into commercial operation the particular control technology. The results of this evaluation are summarized in Tables 3-9 through 3-13.

3.4.1.1 CAPITAL COST ESTIMATES FOR NO$_X$ CONTROL ALTERNATIVES

The capital costs to implement the various NO$_X$ control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. In the cases of SNCR, preliminary vendor budgetary cost information was obtained and used in place of, or to adjust, the published unit output cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

The unit nameplate output capacity (gross electrical output in megawatts) assumed for the NO$_X$ control technologies capital cost estimate basis was 257 MW$_g$ for MRY Station Unit 1[28].

A review of the unit capital cost factor range and single point factors applicable to MRY Station Unit 1 NO$_X$ control technologies are presented in Table 3-9. The estimated installed and levelized capital costs for the highest-performing form of the various feasible NO$_X$ emission reduction technologies evaluated for cost-effectiveness are shown in Table 3.10. These are listed in order of control effectiveness, with the highest ranked option at the top.

---

[28] Ibid footnote number 23.

TABLE 3-9 – Unit Capital Cost Factors of Feasible NO_X Control Options for MRY Station Unit 1

Alt. Label(1)	NO_X Control Technique	Range(2) ($/kW)	Single Point Unit Capital Cost Factor(3), ($/kW) MRYS Unit 1
E	SNCR (using urea) w/ ASOFA	20-35(4)	31.6(4),(5)
D	Gas Reburn w/ ASOFA	15-30(6)	70.1(5),(6),(7)
C	Lignite Reburn w/ ASOFA	30-60(6)	181.5(5),(8)
B	Fuel Lean Gas Reburn w/ ASOFA	--(9)	41.4(4),(5),(9)
A	Advanced Separated Overfire Air (ASOFA)	5-10(6)	16.6(5)

(1) – Alternative designation has been assigned from highest to lowest unit NOx emission rate.

(2) – Unit capital cost factors ($/kW) of these individual technologies combined by simple addition. Actual installed costs may differ this due to positive or negative synergistic effects. Range based on published values or vendor proposals.

(3) – Single point cost factor is best estimate for determination of total capital cost for a particular technology or combination, assuming maximum unit capacity is based on EPA’s nameplate rating. Single point cost figures in 2006 dollars.

(4) – Estimated capital cost for SNCR point estimate and FLGR point estimate derived from December 2004 budgetary proposal by Fuel Tech. See Appendix C2 for details.

(5) – The single point unit capital cost factor shown for the “advanced” version of SOFA derived from Burns & McDonnell internal database and cost estimate for North Dakota lignite-fired cyclone boilers.

(6) – NESCAUM 2005 Technical Paper, posted at their website. See technical references in Appendix A1 for details.

(7) – The single point unit capital cost factor shown for a conventional gas reburn system includes the estimated capital cost to install a high-pressure natural gas supply pipeline (31.4 $/kW), and that both boilers share the capital cost in proportion to their respective rated MW gross output capacities.

(8) – The single point unit capital cost factor shown for a lignite reburn system is highly site-specific, and assumes that new pulverizers and building enclosures are required. The general cost range for pulverized coal-fired boilers is included in the NESCAUM 2005 Technical Paper; for cyclone boilers is included in the 2005 WRAP Draft Report, posted at their website. The single point unit capital cost factor for this alternative for increased PM collection capacity included in lignite reburn option is 91.7 $/kW. See technical references in Appendix A1 for details.

(9) – The unit capital cost factor range for FLGR applications on boilers without an existing a high-pressure natural gas supply was not found in available technical literature. The single point unit capital cost factor shown for a fuel lean gas reburn system includes the estimated capital cost to install a high-pressure natural gas supply pipeline (15.7 $/kW), and that both boilers share the capital cost in proportion to their respective rated MW gross output capacities.

TABLE 3-10 – Estimated Capital Costs for NO_X Control Alternatives - MRY Station Unit 1

Alt. Label(1)	NOx Control Alternative	Installed Capital Cost(2) $1,000	Annualized Capital Cost(3) $1,000
E	SNCR w/ ASOFA	8,113	707
D	Gas Reburn w/ ASOFA(4)	18,006	1,570
C	Lignite Reburn w/ ASOFA(5)	46,656	4,068
B	Fuel Lean Gas Reburn w/ ASOFA(4)	10,639	928
A	Advanced SOFA (ASOFA)	4,277	373
	Baseline	0	0

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Installed capital cost is estimated for determination of total capital cost for a particular technology or combination, assuming 257 MWg unit capacity rating. All cost figures in 2006 dollars.

(3) - Annualized capital cost = Installed capital cost x 0.08718 annualized capital cost factor.

(4) - Costs for gas reburn options include high-pressure natural gas supply pipeline installed capital cost of $8,075,000 for CGR and $4,038,000 for FLGR; and annualized capital cost of $704,000/yr for CGR and $352,000 for FLGR. See footnotes #8 and 10 under Table 3-9.

(5) - Costs for increased PM collection capacity included in lignite reburn option are $23,561,000 for installed capital cost, and $2,054,000/yr annualized capital cost.

3.4.1.2 Operating and Maintenance Cost Estimates for MRY Station NO_X Controls

The operational and maintenance costs to implement the various NO_X control technologies were largely estimated from cost factors (percentages of installed capital costs) established in the EPA's Air Pollution Control Cost Manual (OAQPS) for SNCR[29], and from published in technical papers discussing those control technologies. In the cases including various forms of SNCR, preliminary vendor quotes were obtained and used in place of, or to adjust the OAQPS cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

Fixed and variable operating and maintenance costs considered and included in each NO_X control technology's annual O&M costs are estimates of:

- Auxiliary electrical power consumption for operating the additional control equipment;
- Reagent consumption, and reagent unit cost for SNCR alternatives; and
- Reagent dilution water consumption and unit cost for SNCR alternatives.

---

[29] EPA Office of Air Quality Planning and Standards (OAQPS) publication EPA/452/B-02-001, Section 4.2, NO_X Controls – NO_X Post-Combustion, Chapter 1 - Selective Non-Catalytic Reduction, dated October 2000, posted at their website: http://www.epa.gov/ttn/catc/dir1/cs4-2 ch1.pdf

- Increases or savings in auxiliary electrical power consumption for changes in coal preparation equipment and loading, primarily for fuel reburn cases;
- General operating labor, plus maintenance labor and materials devoted to the additional emission control equipment and its impact on existing boiler equipment.
- Reductions in revenue expected to result from loss of unit availability, i.e. outages attributable to the control option, which reduce annual net electrical generation available for sale (revenue).

For economic evaluation purposes, an annual average running plant capacity factor of 96.6 percent compared to a nominal unit output capacity of 253 MW_g combined with an average annual availability (uptime) of 8,528 operating hours (97.3 percent of 8760 hours per year) resulting in an annual unit capacity factor of 94.1% were assumed for Unit 1's pre-control baseline annual operation. A heat input rate of 2,744 mmBtu/hr and a NO_X emission rate of 0.849 lb/mmBtu were assumed for calculating control and cost-effectiveness from pre-control maximum rolling 12 month summation of nitrogen oxides' mass emissions for MRY Station Unit 1.

Table 3-11 show the estimated annual operating and maintenance costs and levelized annual O&M cost values for the highest-performing form of the various feasible NO_X emission reduction technologies. These are listed in order of control effectiveness, with the highest ranked options at the top. The cost methodology summarized in Appendix C3 provides more details for the levelized annual O&M cost calculations and cost factors.

TABLE 3-11 – Estimated O&M Costs for
NO_X Control Alternatives - MRY Station Unit 1

Alt. Label(1)	NOx Control Alternative	Annual O&M Cost(2) $1,000	Levelized Annual O&M Cost(3) $1,000
E	SNCR w/ ASOFA	5,417	6,764
D	Gas Reburn w/ ASOFA	28,641	35,765
C	Lignite Reburn w/ ASOFA	5,862	7,320
B	FLGR w/ ASOFA	12,863	16,062
A	Advanced SOFA (ASOFA)	1,695	2,117
	Baseline	0	0

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.
(2) - Annual operating and maintenance cost for a particular technology or combination is compared to unit baseline operation at an average unit output (244.5 MWg) and assumes a 97.3% average annual availability, which is highest consecutive 12-months of operation from 2001-2005. All cost figures in 2006 dollars.
(3) - Levelized annual O&M cost = Annual O&M cost x 1.24873 annualized O&M cost factor.

(4) - Costs for increased PM collection capacity included in lignite reburn option are $2,024,000/yr for annual O&M cost, and $2,527,000/yr annualized O&M cost.

3.4.1.3 LEVELIZED TOTAL ANNUAL COST ESTIMATES FOR MRY STATION NO_X CONTROLS

In order to compare a particular NO_X emission reduction alternative during the initial engineering analysis portion of the BACT selection process, the sum of estimated annualized installed capital plus levelized annual operating and maintenance costs, which is referred to as "Levelized Total Annual Cost" (LTAC) of expected pollutant removal by implementing that alternative was calculated. The LTAC for all NO_X control alternatives was calculated based on the same economic conditions and a 20 year project life (see Appendix C1 for methodology). The unit control cost was then determined as the LTAC divided by annual tons of pollutant emissions that would be avoided by implementation of the respective alternative. The control alternatives were also compared by calculating the change in unit cost (incremental cost) per incremental ton removed for the next most stringent alternative. This identified which alternatives produced the highest increment of expected pollutant reduction for the estimated lowest average annual cost increment compared with the baseline emission rate. The expected annual number of tons of pollutant removed versus estimated LTAC for each remaining control alternative was then plotted.

The comparison of the cost-effectiveness of the remaining NO_X emission reduction technologies was made and is shown in Table 3-12 and Figures 3-1 and 3-2 for MRY Station Unit 1. These figures plot estimated annual amount of NO_X removal (emission reduction) in tons per year on the ordinate (horizontal axis) and the estimated levelized total annual cost in thousands of U.S. dollars per year on the abscissa (vertical axis), for each of the remaining NO_X control technologies. Points on the graph that are farthest to the right and closest to the horizontal axis are deemed more cost-effective, since they represent controls that achieve more NO_X removal per dollar required for total annual costs of operation, maintenance, and capital recovery (depreciation).

Although the NSR Manual repeatedly prescribes following a "top down" analysis approach for BACT determination, the development of a least cost envelope with dominant controls (as seen in NSR Manual Figure B-1, page B.42) clearly labels points with lower emissions reductions and total annual costs first, i.e. "A", "B", etc. then proceeding with labeling and connecting points plotted further away from the zero emission reduction point. This "bottom-up" approach is for plotting the least-cost (dominant) control curve. The labeling of each unit's NOx control technique alternative has followed this approach.

TABLE 3-12 – Estimated Annual Emissions and Levelized Total Annual Cost for NO_X Control Alternatives - MRY Station Unit 1

Alt. Label(1)	NOx Control Alternative	Annual NOx Emissions(2) Tons/yr	Annual NOx Emissions Reduction(3) Tons/yr	Levelized Total Annual Cost(4) \$1,000	Average Control Cost(5) \$/ton
E	SNCR w/ ASOFA	4,025	5,909	7,472	1,265
D	Gas Reburn w/ ASOFA	4,275	5,659	37,334(6)	6,597
C	Lignite Reburn w/ ASOFA	4,343	5,591	11,388(7)	2,037
B	FLGR w/ ASOFA	5,260	4,674	16,990(6)	3,635
A	Advanced SOFA (ASOFA)	5,874	4,060	2,489	613
	Baseline	9,934	0	0	

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Estimated annual emission tons assume an annual capacity factor specific to each alternative; 94.1% was assumed for the baseline case.

(3) - Estimated annual tons of emission reduction is the difference between annual baseline tons and each alternative's annual emissions (tons).

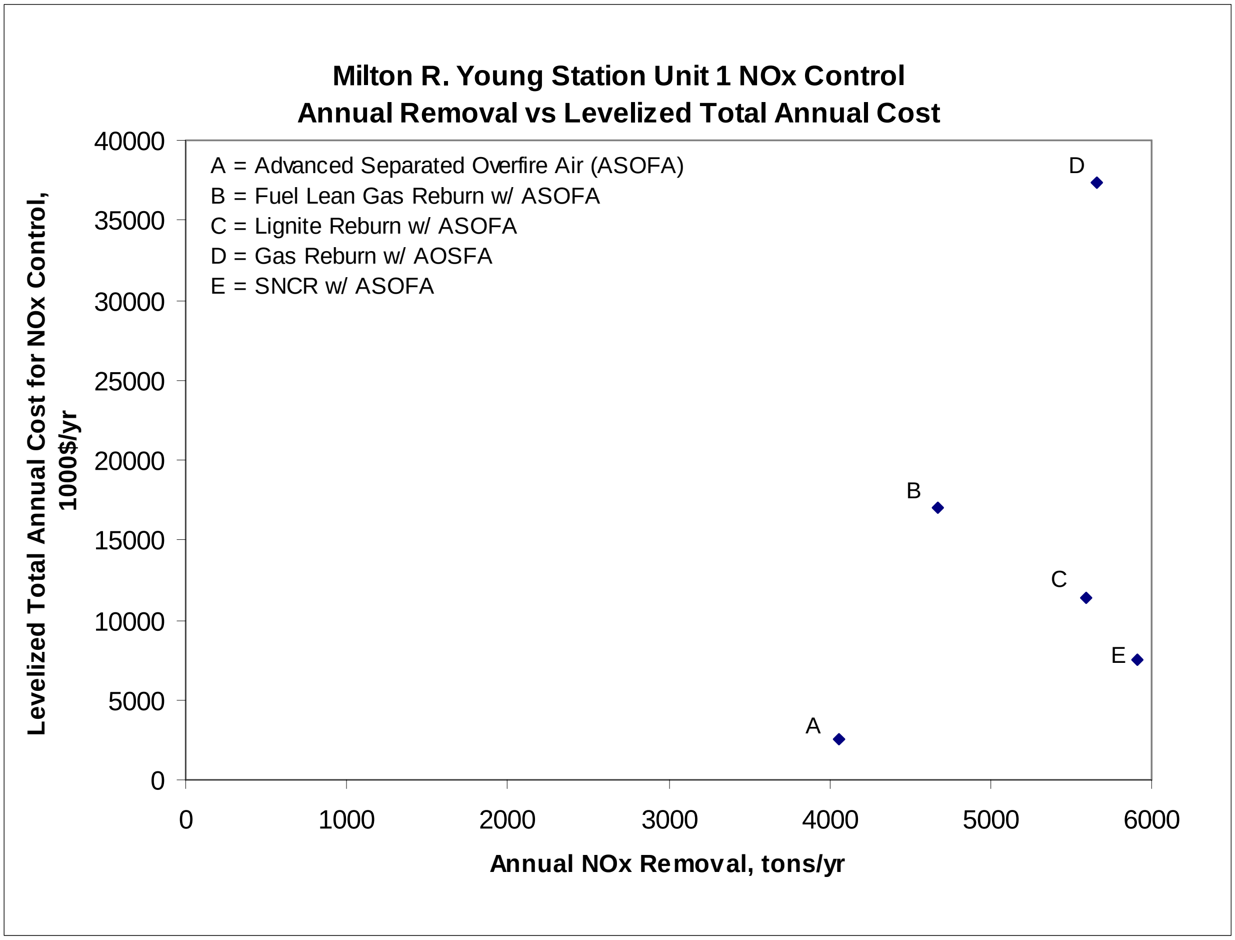
(4) - Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See note #3 for Tables 3-10 and 3-11 for annualized cost factors. Emissions are calculated from unit emission rates, control percentage, hourly heat input, and annual hrs/yr operation compared to pre-control baseline based on annual operation at highest allowable pre-control NOx emission rate.

(5) - Average Control Cost Effectiveness (\$/ton) is the Levelized Total Annual Cost (1000\$/yr) divided by Annual Emission Reduction (tons/yr). All cost figures in 2006 dollars.

(6) - LTAC for gas reburn options include high-pressure natural gas supply pipeline annualized capital cost of \$704,000/yr for CGR and \$352,000 for FLGR. See footnotes #8 and 10 under Table 3-9.1

(7) - LTAC for increased PM collection capacity included in lignite reburn option are approximately \$2,054,000 for annualized capital cost plus \$2,527,000/yr for annualized O&M cost, for a LTAC subtotal of \$4,581,000/yr.

Figure 3-1 – NO_X Control Cost Effectiveness - MRY Station Unit 1(1)



(1) - All cost figures in 2006 dollars. Numbers are listed and qualifiers are noted in Table 3-12.

The purpose of Figure 3-1 is to show the range of control and cost for all feasible NO_X reduction alternatives evaluated. A dominant set of control alternatives were determined by generating what is called the “envelope of least-cost alternatives”. The dominant controls cost curve is the best fit line through the points forming the rightmost boundary of the data zone on a scatter plot of the annual NO_X removal tonnage versus LTAC for the various remaining BACT alternatives. Following a “bottom-up” graphical comparison approach, each of the NO_X control technologies represented by a data point to the left of and above the least cost envelope are inferior control alternatives per the NSR Manual and should be excluded from further analysis on a cost efficiency basis.

Of the technically feasible NO_X control alternatives considered for MRY Station Unit 1, data points for conventional gas reburn (Point D) and fuel-lean gas reburn (Point B) with advanced separated overfire air, and lignite reburn with ASOFA (Point C), lay distinctly left and above the other points of the control cost points' scatter plot of Figure 3-1. These control options are inferior and therefore were eliminated from further control cost-effectiveness analysis.

Average and incremental annual costs and NO_X emission reductions for the dominant least-cost control alternatives remaining after the elimination of the obviously inferior options are listed in Table 3-13. The annual NO_X control tons per year, divided by the total levelized annual cost, yields an average unit cost ($/ton). Incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. The additional tons per year of NO_X control relative to the previous apparent least-cost curve point, divided by the increase in levelized annual cost, yields an incremental unit cost ($/ton). Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the envelope of least-cost control alternatives, also called the dominant controls cost curve or DCCC) between successively more effective alternatives which are considered technically feasible for Milton R. Young Station boilers.

TABLE 3-13 – Dominant Controls Cost Curve Points for Feasible BACT NO_X Alternatives - MRY Station Unit 1

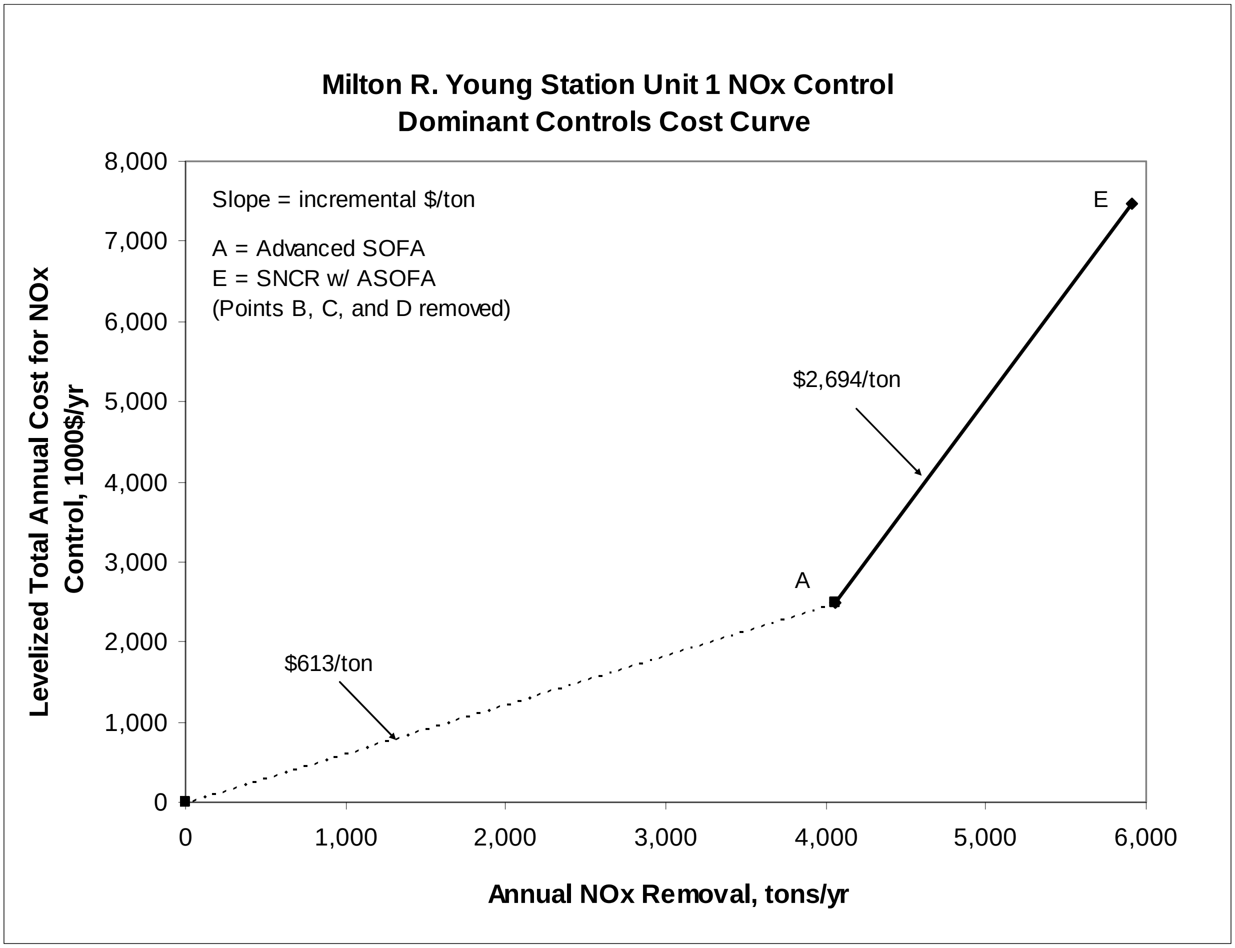
Alt. Label(1)	NOx Control Technique	Levelized Total Annual Cost(2),(3) ($1,000/yr)	Annual Emission Reduction(3) (tpy)	Incremental Levelized Total Annual Cost(2),(4) ($1,000/yr)	Incremental Annual Emission Reduction(4) (tpy)	Incremental Control Cost Effectiveness ($/ton)(2),(4)
E	SNCR w/ ASOFA	7,472	5,909	4,982	1,849	2,694
A	Advanced SOFA (ASOFA)	2,489	4,060	2,489	4,060	613

(1) – Dominant controls cost curve points from lowest (ASOFA) to highest (SNCR w/ ASOFA) are labeled the same as in Table 3-12, and on the graphs that accompany this table (Points B, C, and D were eliminated).
(2) – All cost figures in 2006 dollars.
(3) – Annual emission reduction and levelized control cost of these alternatives is relative to current costs and pre-control unit MCR baseline emission rate.
(4) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest, except as noted.

The incremental cost analysis indicates that from a cost effectiveness viewpoint, the SNCR with ASOFA alternative incurs a significant annual (levelized) incremental cost compared to the ASOFA NO_X control technique (slope from zero baseline to ASOFA, Point A was $613/ton for MRYS Unit 1; the incremental cost (slope) from ASOFA, Point A to SNCR with ASOFA, Point E was $2,694/ton for MRYS Unit 1.

Figure 3-2 contains a repetition of the levelized total annual cost and NO_X control information from Figure 3-1 for MRY Station Unit 1, with Point B (FLGR™ with ASOFA) , Point C (Lignite Reburn with ASOFA) and Point D (conventional gas reburn with ASOFA) removed. This is the dominant controls cost curve for MRY Station Unit 1 NO_X emissions alternatives.

Figure 3-2 – MRY Station Unit 1 NO_X Control Alternatives BACT Dominant Controls Cost Curve(1)



(1) - All cost figures in 2006 dollars. Numbers are listed and qualifiers are noted in Table 3-13.

In the U.S. EPA's NSR Manual, the EPA does not specify acceptable or unacceptable ranges for average (unit control costs) and incremental cost effectiveness values. As can be seen from a review of Table 3-14, the average levelized control cost effectiveness (called the unit control cost in this report) ranges from approximately $613/ton to $6,597/ton of MRYS Unit 1's NO_X emissions removed. It should be noted, however, that the highest estimated average control costs involve gas reburn technologies that were shown to be inferior options (not on the dominant controls cost curve) and thus were eliminated from further impacts analysis.

The incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the least-cost envelope of dominant control alternatives or dominant controls cost curve) between successively more effective alternatives. The economic impact analysis indicates that from a cost effectiveness viewpoint, the highest performing alternative is SNCR with ASOFA (Point E). This control option is considered technically feasible for Milton R. Young Station Unit 1 boiler but incurs a significant annual (levelized) incremental cost relative to the next highest feasible NO_X control technique, ASOFA (Point A) when ASOFA is compared against the pre-control baseline. The Advanced Separated Overfire Air alternative has an average unit control cost ($613/ton) approximately 48% of the highest performing feasible alternative on the dominant controls cost curve (SNCR with ASOFA, $1,265/ton). ASOFA also has a much lower incremental cost per ton relative to the pre-control baseline (slope from zero to Point A, $613/ton) compared to SNCR with ASOFA (Point E) versus ASOFA (Point A); the slope from Point A to Point E was $2,694/ton.

The other elements of the fourth step of a BACT analysis following economic impacts are to evaluate the following impacts of feasible emission controls:

- The energy impacts.
- The environmental impacts.

TABLE 3-14 – Estimated Emissions and Economic Impacts Summary for NO$_X$ Control Alternatives - MRY Station Unit 1

Summary of Estimated Annual Emissions and Economics for NOx Control Alternatives Evaluated for Milton R. Young Station Unit 1

		EMISSIONS(2)					ECONOMIC IMPACTS			
Alt. Label(1)	NOx Control Alternative	Emission Rate lb/mmBtu	Hourly Emission lbs/hr	Annual Emission tons/yr	Emission Reduction tons/yr	NOx Removal Efficiency(2) %	Installed Capital Cost(3) $1,000	Annual O & M Cost(4) $1,000	Levelized Total Annualized Cost(5) $1,000	Average Control Cost(6) $/ton
E	SNCR w/ ASOFA	0.355	975	4,025	5,909	58.1	8,113	5,417	7,472	1,265
D	Gas Reburn w/ ASOFA	0.374	1,025	4,275	5,659	56.0	18,006	28,641	37,334(7)	6,597
C	Lignite Reburn w/ ASOFA	0.385	1,058	4,343	5,591	54.6	46,656	5,862	11,388(7)	2,037
B	FLGR w/ ASOFA	0.460	1,261	5,260	4,674	45.9	10,639	12,863	16,990(7)	3,635
A	Advanced SOFA (ASOFA)	0.513	1,409	5,874	4,060	39.5	4,277	1,695	2,489	613
	Baseline	0.849	2,330	9,934	0	0.0	0	0	0	

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Estimated NO$_X$ control level reductions relative to average annual unit emission baseline of 0.849 lb/mmBtu at 2,744 mmBtu/hr MCR heat input. Emissions are calculated from unit emission rates, control percentage, hourly heat input, and annual hrs/yr operation compared to pre-control baseline based on annual operation at a gross unit electrical output of 244.5 MWg and assumes a 97.3% average annual availability. Values from reported emission data for the 12 month operating period during 2001-2005 with the highest rolling summation of NOx pounds.

(3) - Installed capital cost is estimated for determination of total capital cost for a particular technology or combination, assuming 257 MWg unit capacity rating. All cost figures in 2006 dollars. Costs for gas reburn options include high-pressure natural gas supply pipeline installed capital cost of $8,075,000 for CGR and $4,038,000 for FLGR. Costs for increased PM collection capacity included in lignite reburn option are $23,561,000 for installed capital cost.

(4) - Annual operating and maintenance cost for a particular technology or combination is compared to unit baseline operation at a gross unit electrical output of 244.5 MWg and assumes a 96.6% average running plant capacity factor compared to nominal unit gross electrical output capacity of 253 MWg. All cost figures in 2006 dollars. Costs for increased PM collection capacity included in lignite reburn option are $1,909,000/yr for annual O&M cost.

(5) - Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. Annualized capital cost = Installed capital cost x 0.08718 annualized capital cost factor. Levelized annual O&M cost = Annual O&M cost x 1.24873 annualized O&M cost factor.

(6) - Average Control Cost Effectiveness ($/ton) is the Levelized Total Annual Cost (1000$) divided by Annual Emission Reduction (tons). All cost figures in 2006 dollars.

(7) - LTAC for reburn options include high-pressure natural gas supply pipeline annualized capital cost of $704,000/yr for CGR and $352,000 for FLGR; LTAC for increased PM collection capacity included in lignite reburn option are $2,054,000 for annualized capital cost plus $2,384,000/yr for annualized O&M cost, for a total of $4,438,000/yr.

3.4.2 ENERGY IMPACTS OF MRY STATION NO_X CONTROLS

Operation of the most cost-effective NO_X control technologies considered feasible for potential application at the Milton R. Young Station impose direct impacts on the consumption of energy required for the production of electrical power at the facility. The details of estimated energy usage and costs for the various NO_X control alternatives are summarized in Appendix C3.

Control alternatives for reduction of NO_X emissions were reviewed to determine if the use of the technique or technology will result in any significant or unusual energy penalties or benefits. There are several basic kinds of energy impacts for NO_X emissions controls:

- Potential increase or decrease in power plant energy consumption resulting from a change in thermal (heat) energy to net electrical output conversion efficiency of the unit, usually expressed as an hourly unit heat rate (Btu/kW-hr) or the inverse of pounds of pollutant per unit electrical power output (MW-hr). This may or may not change the net electrical output (MW) capacity of the EGU, depending on if there are physical or imposed limits on the total heat input to the boiler or electrical power output.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in physical operational limitations imposed on the ability to sustain a fuel heat input rate (mmBtu/hr) which results in a potentially lower or higher unit net electrical output (MW) capacity. This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in auxiliary electrical power demand and usage (kW, kW-hrs). This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in reliability and availability to generate electrical power. This results in a change to the number of hours of annual operation, not necessarily a change in net electrical output (MW) capacity of the EGU.

3.4.2.1 ENERGY IMPACTS OF SOFA TECHNOLOGY

There should not be a major impact on energy consumption resulting from the operation of the advanced variation of a separated overfire air system. SOFA does not significantly change the total amount of air introduced into the boiler, only the location where it is introduced. Damper resistance and supply pressure impacts of the SOFA system on fan power consumption should be insignificant. The amount of flyash emitted from the boiler is expected to be reduced (less than five percent) from the baseline level when the SOFA system is in full operation. Slightly higher levels of unburned carbon in the flyash may occur with the operation of a SOFA system. This could have a small negative impact on the plant heat rate (higher Btu/kw-hr). These changes are expected to be within the typical range of current operation.

There is a potential reduction in reliability and availability of a lignite-fired cyclone boiler to generate steam for production of electrical power as a result of installing and operating a separated overfire air system. Typical SOFA operation on bituminous or western subbituminous coal-fired cyclone boilers does not carry a significant additional risk of causing insufficient or excessive accumulation of slag within the cyclone barrels or furnace bottom compared with non air-staged combustion. Reliable boiler operation depends on avoiding such adverse conditions in the cyclones and lower furnace, which could require a forced outage to remove the solidified slag prior to returning the boiler to generation production service.

The challenges of maintaining adequate slag layer development and flow while firing lignite in MRY Unit 1's cyclones under excess air conditions have been significant during the operating history of the powerplant. Minimizing forced outages resulting from cyclone slag issues have largely been successful through operational practices that do not affect day-to-day boiler reliability and availability. Due to the variability of combustion characteristics of lignite supplied from the Center mine, and the dependency of the slag flow on the temperature within the cyclone barrels or furnace bottom, conditions may occur during ASOFA operation that exceed the ability to adjust operational practices sufficiently to avoid forced outages to remove the solidified slag.

The potential impact on annual unit operating time due to cyclone slag issues associated with air-staged cyclones/ASOFA system operation was estimated to be approximately 2% reduction from the assumed pre-control baseline availability, i.e. 0.97-0.02=0.95. The estimated electrical generation production lost due to the reduction in MRY Unit 1's annual availability is shown in Table 3-16.

3.4.2.2 ENERGY IMPACTS OF SNCR TECHNOLOGY

For SNCR, the injection of a diluted urea solution will require some additional auxiliary power for heating and pumping the liquid and using compressed air for atomization and cooling the reagent injection nozzles/lances, on the order of 70 to 200 kW. The injection of water (used for urea dilution) into the boiler flue gas also will have a small negative impact on the plant heat rate (higher Btu/kw-hr), although the vendor of SNCR systems advises that the heat released from the oxidation of a portion of the injected urea compensates for this impact. The impact of additional flue gas created by operation of an SNCR-related system on fan power consumption should be small.

There is a potential reduction in reliability and availability of a lignite-fired cyclone boiler to generate steam for production of electrical power as a result of installing and operating a SNCR-related system. Typical SNCR operation with low ammonia slip when firing low-sulfur western subbituminous coal in cyclone-fired boilers does not carry a significant additional risk of causing excessive fouling of the tubular air preheater compared with non-SNCR operation. Reliable boiler operation depends on avoiding adverse fouling conditions in the air preheater, which could require a forced outage to remove the ash deposits prior to returning the boiler to generation production service.

The challenges of maintaining open passages through the air preheater tubes while firing lignite in MRY Unit 1's cyclones under typical conditions have been minor during the operating history of the powerplant. Minimizing forced outages resulting from ash deposits within the air preheater have largely been successful through operational practices that do not affect day-to-day boiler reliability and availability. Due to the variability of fouling characteristics of lignite supplied from the Center mine, and the dependency of the fouling within the air preheater on sodium, sulfur, and ammonia slip emission levels, conditions may occur during SNCR operation that exceed the ability to adjust operational practices sufficiently to avoid forced outages to remove the air preheater deposits.

The potential impact on annual unit operating time due to air preheater fouling and other potential issues associated with SNCR system operation was estimated to be an incremental 1% reduction from the assumed pre-control baseline or ASOFA availability. The estimated electrical generation production lost due to the reduction in MRY Unit 1's annual availability is shown in Table 3-16.

TABLE 3-15 – Expected Auxiliary Electrical Power Impacts for NO_X Controls - MRY Station Unit 1

Alt. Label(1)	NOx Control Technique	Estimated Annual Average Auxiliary Electrical Power Demand and Consumption for NOx Control Equipment	
		Gross Demand(2) kW	Power Usage(3) kW-hrs/yr
E	SNCR w/ ASOFA	73	582,411
A	Advanced SOFA (ASOFA)	1	8,058

(1) – Alternative number has been previously assigned from highest to lowest unit NOx emission rate.

(2) – The APC NOx equipment gross auxiliary electrical power demand of alternatives is the sum of individual technologies combined by simple addition. Actual power demands may differ from this due to positive or negative synergistic effects.

(3) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.

TABLE 3-16 – Expected Electrical Power Generation Availability and Capacity Impacts for NO_X Controls - MRY Station Unit 1

Alt. Label(1)	NOx Control Technique	Estimated Annual Average Availability(2)	Estimated Annual Average Operating Time Reduction, hrs/yr(3)	Estimated Annual Average Running Plant Capacity Factor(4)	Estimated Annual Average Electricity Generation Reduction kW-hrs/yr(5)
E	SNCR w/ ASOFA	0.956	273	0.965	67,660,606
A	Advanced SOFA (ASOFA)	0.952	188	0.966	46,586.546

(1) – Alternative number has been previously assigned from least removal to highest removal percentage.

(2) – Baseline availability is assumed at 97.3 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

(3) – Annual lost operating time resulting from the implementation of the individual NOx control technique is the difference between the baseline and expected annual outage times.

(4) – Baseline running plant capacity factor is assumed at 96.6 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

(5) – Annual electricity generation reduction is annual reduction of operating time multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the MCR capacity rating of 253 MW (MCR gross unit electrical output capacity).

TABLE 3-17 – Expected Total Electrical Power Generation Impacts for NO_X Controls - MRY Station Unit 1

Alt. Label(1)	NOx Control Technique	Power Usage(2) kW-hrs/yr	Estimated Annual Average Electricity Generation Reduction(3) kW-hrs/yr	Est. Total Annual Change in Net Electrical Power Generation Available for Sale(4) kW-hrs/yr
E	SNCR w/ ASOFA	582,411	67,660.606	68,243,017
A	Advanced SOFA (ASOFA)	8,058	46,586.546	46,594,605

(1) – Alternative number has been previously assigned from least removal to highest removal percentage.

(2) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.

(3) – Annual electricity generation reduction is annual reduction of operating time multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the MCR capacity rating of 253 MW (MCR gross unit electrical output capacity).

(4) – Annual change in net electrical power generation available for sale is arithmetic sum of annual power generation reduction due to a change in the auxiliary electrical power consumed plus the annual generation reduction from a decrease in annual operating time and average annual running plant capacity factor resulting from the implementation of the individual NOx control technique, compared with baseline.

3.4.3 ENVIRONMENTAL IMPACTS OF NOx CONTROLS - MRY STATION

Nitrogen oxides react with oxygen in the atmosphere to produce elemental nitrogen and ozone (O_3). This is one of the common causes of visible pollution in the atmosphere referred to as “smog”. Operation of the various NO_X control technologies considered for potential application at the Milton R. Young Station impose direct and indirect impacts on the environment. The most pronounced direct environmental impact expected from operation of any of the NO_X control options considered is the reduction of ozone and improvement in atmospheric visibility (i.e. reduced visibility impairment) downwind of the facility.

3.4.3.1 ENVIRONMENTAL IMPACTS OF SOFA TECHNOLOGY

The operation of a separated overfire air system is expected to slightly increase carbon monoxide concentrations in the stack flue gas. The advanced form of SOFA alternative is expected to slightly lower the amount of particulate matter emitted from the boiler and may raise the amount of unburned carbon in the flyash collected for land disposal and emitted to the atmosphere by small increments. Alternatives involving forms of gas reburn should experience lower particulate emissions, and a reduction in the amount of boiler bottom and flyash requiring disposal.

The environmental impact from potential reduction of annual unit operating time by approximately two percent due to cyclone slag issues associated with air-staged cyclones/ASOFA system operation will be to reduce the annual amount (tons) of nitrogen oxides emitted, and therefore the annual number of NO_X tons removed will increase, by approximately two percent.

3.4.3.2 ENVIRONMENTAL IMPACTS OF SNCR TECHNOLOGY

Operation of a conventional SNCR system is not expected to significantly impact emissions of CO or volatile organic compounds (VOCs).

Operation of an SNCR system will normally create a small amount of unreacted urea or ammonia to be emitted. The amount of ammonia slip produced by SNCR depends on the amount of reagent utilization and location of the injection points. Higher SNCR NO_X reduction performance involves greater amounts of reagent usage and ammonia slip. This is typically controlled to less than 10 ppmvd, especially when the possible formation of sulfates such as ammonium sulfate $[(NH_4)_2SO_4]$ and ammonium bisulfate $[NH_4HSO_4]$ will be more problematic at higher slip levels. Sulfur trioxide (SO_3) formed during combustion in the boiler can combine with ammonia during passage through the flue gas ductwork to form the sulfates.

Some of the unreacted ammonia from SNCR operation will be collected with the flyash in the electrostatic precipitator. Any remaining ammonia slip that is not collected or condensed in the air pollution control system will be emitted from the stack as an aerosol or condensable particulate. This has the potential to increase atmospheric visibility impairment downwind of the facility compared with a pristine condition. Although the predicted amount of such potential impact from ammonia slip emissions has not been determined, it is expected to be small in comparison with the significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NOx emission reduction.

Delivery of the urea reagent to the powerplant facility and storage of aqueous urea reagent on-site creates the potential for accidents, leaks, and subsequent releases to air, ground, and surface water immediately surrounding the facility. Urea is much less volatile than anhydrous or aqueous ammonia, and these risks are expected to be manageable. Emergency planning and community communications are part of the management plan requirements for such reagent usage.

The environmental impact from potential reduction of annual unit operating time by approximately one percent due to air preheater fouling issues associated with SNCR system operation will be to reduce the annual amount (tons) of nitrogen oxides emitted, and therefore the annual number of NO_X tons eliminated relative to the constant pre-control emission baseline will increase by approximately one percent.

3.4.4 SUMMARY OF ECONOMIC, ENERGY AND ENVIRONMENTAL IMPACTS OF MRY STATION NO_X CONTROLS

The economic, energy, and environmental impacts of each feasible BACT alternative evaluated for this study is summarized in this Section. Table 3-18 summarizes the various impacts discussed in Sections 3.4.1 through 3.4.3. The economic analysis examined the capital cost of each feasible BACT alternative evaluated and any other powerplant upgrade costs necessary to implement the alternative. In addition, the economic analysis examined the operating and maintenance cost associated with the highest-performing forms of each feasible BACT alternative evaluated. These costs were then combined into the levelized total annual cost for a comparative assessment of the total implementation cost of each alternative. Finally, as part of the top-down analysis, a dominant controls cost curve was plotted and the unit control cost for each alternative was evaluated. Two alternatives were on the dominant controls cost curve and thus were identified as the more cost effective alternatives. The two BACT NO_X control alternatives evaluated for incremental cost, energy, and environmental impacts applicable to Milton R. Young Station Unit 1 were:

- Selective Non-Catalytic Reduction (SNCR) combined with a special form of separated overfire air (SOFA) specifically for lignite-fired cyclone boilers (referred to as Advanced SOFA or ASOFA); and
- ASOFA alone.

TABLE 3-18 – Summary of Top-Down BACT Impact Analysis Results for Dominant NO_X Control Alternatives - MRY Station Unit 1

		EMISSIONS(2)				ECONOMIC IMPACTS					ENERGY IMPACTS		ENVIRONMENTAL IMPACTS	
Alt. Label(1)	**NOx Control Alternative**	**Emission Rate lb/mmBtu**	**Hourly Emission lbs/hr**	**Annual Emission tons/yr**	**Emission Reduction tons/yr**	**Installed Capital Cost(3) $1,000**	**Annual O & M Cost(4) $1,000**	**Levelized Total Annualized Cost(5) $1,000**	**Average Control Cost(6) $/ton**	**Incremental Control Cost(7) $/ton**	**Incremental Aux. Power Demand(8), kW**	**Incremental Annual Aux. Power Usage + Generation Reduction(8), kW-hrs/yr**	**Non-Air Increase**	**Toxic Air Increase**
E	SNCR w/ ASOFA	0.355	975	4,275	5,659	8,113	5,417	7,472	1,265	2,694	73	68,243,017	Flyash UBC	CO, NH_3
A	Advanced SOFA (ASOFA)	0.513	1,409	5,874	4,060	4,277	1,695	2,489	613	613	1	46,594,605	Flyash UBC	CO
	Baseline	0.849	2,330	9,934	0	0	0	0						

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Estimated NO_X control level reductions relative to average annual emission baseline of 0.849 lb/mmBtu at 2,744 mmBtu/hr heat input. Emissions are calculated from unit emission rates, control percentage, hourly heat input, and annual hrs/yr operation compared to pre-control baseline based on annual operation at a gross unit electrical output of 244.5 MWg and assumes a 97.3% average annual availability.

(3) - Installed capital cost is estimated for determination of total capital cost for a particular technology or combination, assuming 257 MWg unit capacity rating. All cost figures in 2006 dollars. Costs for increased PM collection capacity included in lignite reburn option are $23,561,000 for installed capital cost.

(4) - Annual operating and maintenance cost for a particular technology or combination is compared to unit baseline operation at a gross unit electrical output of 244.5 MWg and assumes a 97.3% average annual availability, which is the highest consecutive 12-months of operation from 2001-2005. All cost figures in 2006 dollars.

(5) - Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. Annualized capital cost = Installed capital cost x 0.08718 annualized capital cost factor. Levelized annual O&M cost = Annual O&M cost x 1.24873 annualized O&M cost factor.

(6) - Average Control Cost Effectiveness ($/ton) is the Levelized Total Annual Cost (1000$/yr) divided by Annual Emission Reduction (tons/yr). All cost figures in 2006 dollars.

(7) - Incremental Control Cost Effectiveness ($/ton) is the difference in LTAC between the next most stringent alternative divided by the emissions reduction. All cost figures in 2006 dollars.

(8) - Energy impacts are incremental auxiliary electrical power demand (kW) and annual power usage plus generation lost due to negative unit reliability (fewer hours per year of operation) resulting from each control alternative (kW-hrs/yr).

(9) - Environmental impacts summarize expected non-air effects and potential toxic air emissions resulting from control alternative. Flyash unburned carbon content may increase with air-staging cyclones; carbon monoxide concentrations likely will increase with air-staging cyclones. Excess unreacted ammonia (slip) expected from SNCR technology.

3.5 BACT RECOMMENDATIONS AND CONTROL LEVELS – MRY STATION UNIT 1

This report presents the analysis of control technologies for nitrogen oxides (NO_X) for Minnkota Power Cooperative's (MPC's) Milton R. Young Station Unit 1 using the EPA's "top-down" BACT approach. BACT is an emissions limitation for each pollutant from a source determined to be achievable using control technologies(s) that provide the "maximum degree of emission reduction…taking into account energy, environmental, and economic impacts"[30]. A BACT review does not result in a percent removal efficiency requirement. The generally accepted procedures for performing a BACT analysis are outlined in the EPA's draft NSR Manual. The BACT analysis for Milton R. Young Station NO_X emissions was performed in accordance with this procedure. The EPA's draft NSR Manual outlines five basic steps that are to be followed in the "top-down" BACT evaluation. These steps were as follows:

Step 1 – Identify All Control Technologies
Step 2 – Eliminate Technically Infeasible Options
Step 3 – Rank Remaining Control Technologies by Control Effectiveness
Step 4 – Evaluate Most Effective Controls and Document Results
Step 5 – Select BACT

The final result of this analysis is a recommendation of the BACT alternative and the associated NO_X emission rate for Minnkota Power Cooperative's Milton R. Young Station Unit 1. The emission limitations for a generation facility are expressed in a pounds per million British Thermal Units (lb/mmBtu) basis.

3.5.1 UNIT 1 NO_X BACT

In step one of the technology evaluation, three basic categories of NO_X controls for EGUs were-identified: pre-combustion, combustion, and post-combustion. Eleven basic types of NO_X control processes were identified within these three categories. Twenty four variations of these eleven processes were reviewed for availability and applicability to cyclone-fired EGUs burning North Dakota lignite. An "advanced" form of Separated Overfire Air, alone and in various combinations with Lignite Reburn, Selective Non-Catalytic Reduction (SNCR), Conventional Gas Reburn and

---

[30] Ibid, NSR Manual B.1

Fuel Lean Gas Reburn™, was evaluated for cost-effectiveness. The cost-effectiveness analysis indicated that ASOFA alone, and ASOFA with SNCR were cost effective alternatives for MRY Station Unit 1 NO_X control. The energy and environmental impacts analysis for MRY Station Unit 1's cost-effective NO_X control alternatives were generally insignificant.

Based upon the definition of BACT and the results of the BACT analysis, Selective Non-Catalytic Reduction (SNCR) in combination with a special form of separated overfire air (SOFA) specifically for lignite-fired cyclone boilers (referred to as Advanced SOFA or ASOFA) is recommended as the Best Available Control Technology for nitrogen oxides emissions from Minnkota Power Cooperative's Milton R. Young Station Unit 1. The unit BACT NO_X emissions rate for MRYS Unit 1 is 0.355 lb/mmBtu , determined as a rolling 12-month average. This is shown in Table 3-19.

TABLE 3-19 – NO_X Emission Control Technology and Rate Recommended as BACT for Milton R. Young Station Unit 1

Control Technology and Emission Rate Recommended as BACT

1	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.355

3.5.2 EMISSION RATE LIMITATION RECOMMENDATION

To complete the BACT determination process, the Consent Decree (CD) requires that "specific control technologies to be installed and a specific Phase II 30-day Rolling Average NO_X Emission Rate limitation (lbs/MMBtu)"[31] (pounds per million Btu) must be established for each subject emission Unit. The CD also states that "a "30-day Rolling Average Emission Rate" shall be determined by calculating an arithmetic average of all hourly emission rates in lbs/MMBtu for the current Operating Day and the previous 29 Operating Days. A new 30-day Rolling Average Emission Rate shall be calculated for each new Operating Day. Each 30-day Rolling Average Emission Rate shall include startup, shutdown, and Malfunction periods within each Operating Day"[32].

---

[31] Ibid footnote number 1, Paragraph 66, page 20.
[32] Ibid footnote number 1, Paragraph 5, page 4.

The Consent Decree also states that the North Dakota Department of Health's (NDDH) NO_X "BACT Determination shall address specific emission limitations during Unit startups"[33] at Milton R. Young Station. The type and duration of firing during startups, and the limited ability of available and feasible technologies to control startup NO_X emissions, both significantly influence the 30-day rolling average BACT NO_X emission rate limit recommended for Milton R. Young Station boilers. A 24-hour rolling average NO_X emission rate limit applied to startup periods is also recommended for Milton R. Young Station boilers.

The Consent Decree and the EPA's NSR Manual do not describe the method for determining a 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT applied to Milton R. Young Station Unit 1.

In keeping with the establishment of a specific CD Phase II 30-day Rolling Average NO_X Emission Rate limitation, a relevant precontrol baseline level of emissions and its basis must be determined. The EPA's NSR Manual states:

> "The baseline emissions rate represents a realistic scenario of upper boundary uncontrolled emissions from the source. The NSPS/NESHAP requirements or the application of controls, including other controls necessary to comply with State or local air pollution regulations, are not considered in calculating the baseline emissions. In other words, baseline emissions are essentially uncontrolled emissions, calculated using realistic upper boundary operating assumptions"[34].

Also stated in the EPA's NSR Manual:

> "Estimating realistic upper bound case scenario does not mean that the source operates in an absolute worst-case manner all the time. For example, in developing a realistic upper boundary case, baseline emissions calculations can also consider inherent physical or operational constraints on the source. Such constraints should accurately reflect the true upper boundary of the source's ability to physically operate and the applicant should submit documentation to verify these constraints"[35].

---

[33] Ibid footnote number 1, Paragraph 66, page 20.
[34] Ibid footnote number 2, NSR Manual page B.37
[35] Ibid footnote number 2, NSR Manual page B.37.

The BACT Analysis was conducted based upon the highest historical 12-month rolling NO_X emission summation operating conditions for Milton R. Young Station boilers during years 2001-2005. However, a baseline reflecting a realistic upper bound case scenario based upon the highest historical 30-day rolling NO_X emission operating conditions during years 2001-2005 was established prior to recommending enforceable permit conditions for BACT to be applied to each Milton R. Young Station boiler.

The approach taken in this analysis was to identify pre-control 30-day baseline operating conditions from the 30-consecutive day period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation between January 1, 2001 and December 31, 2005. This reflects unit NO_X emissions that were generated during periods of high unit operations, not affected by unit shutdowns, startups, or malfunctions. MRYS Unit 1's highest reported 30-day rolling average NO_X unit emission rate during years 2001-2005 was 0.884 lb/mmBtu for the period ending January 15, 2004. The corresponding MRYS Unit 1 30-day average hourly NO_X mass emission rate was 2,642 lb/hr. The average unit heat input rate for MRYS Unit 1 was 2,990 mmBtu/hr, and the average gross unit electrical power output was 246.7 MW_g for the same 30-day period.

The operating conditions during the highest historical 30-day rolling NO_X emission for years 2001-2005 were then compared to the highest 12-month historic pre-control baseline conditions. The average unit NO_X emission rate (lb/mmBtu) from the highest historic pre-control 30-day baseline period was compared with the average NO_X emission rate (lb/mmBtu) from the 12-consecutive month period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation during the same 5-year look-back period. An estimate of NO_X emission reduction for the proposed BACT NO_X alternative operating at the historic pre-control 30-day baseline average NO_X emission rate (lb/mmBtu) was made. This rate considered recognized operational factors and equipment designs applied to "steady state" conditions with sustained output close to maximum continuous capacity ratings. The potential impact of startups, recognizing operational and technical limitations on NO_X emission control performance, was then applied to the steady-state rate, to establish a recommended 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT for Milton R. Young Station Unit 1. This is explained below.

NO_X emissions for cyclone-fired boilers are typically higher in pounds per million BTUs during start up events than during steady-state operation at maximum continuous rating (MCR) conditions. This is because hourly heat and combustion air input rates required to establish adequate molten slag formation within the cyclone barrels and promote slag tapping are typically produced from firing conditions that create high flame temperatures. NO_X emissions are sensitive to peak furnace gas temperatures, thus uncontrolled NO_X emissions can be high during cyclone boiler startups. Furnace exit flue gas temperatures (FEGTs) during cyclone boiler startups are less than those occurring during conditions of steady state MCR firing rates due to the high heat absorption of the boiler metal and water being raised from ambient or near-ambient temperatures. Until sufficient FEGT exists for a feasible and available post-combustion technology, such as SNCR, to be effective, NO_X emissions will be basically uncontrolled. There is a practical lower limit of boiler heat input for conventional combustion-based NO_X emission control techniques, such as the advanced version of separated overfire air, to be operated beyond the amount required for cooling the SOFA injection nozzles when it can be diverted from the cyclone burners and significantly control NO_X emissions. These limitations of the effectiveness of BACT controls on Milton R. Young Station boilers during startups and other reduced-load operating periods influence the recommended 24-hour and 30-day rolling average NO_X emission rate limits.

Startup procedures for steam electric generating units (SEGUs) comprising a fossil fuel-fired boiler and steam turbine-generator are specified by the original equipment manufacturers to follow guidelines for heat and pressure increases to provide protection of boiler and turbine equipment. Initial start up duration after an outage may be dictated by the need to gradually warm up burner port/cyclone refractory materials, steam drum shell, steam headers, and other boiler metal surfaces exposed directly or indirectly to furnace gases, and the steam turbine’s multiple casings and rotor shafts. This is normally accomplished with easy-to-ignite fossil fuel firing (such as natural gas, distillate fuel oil, or propane) of the boiler combined with coal to gradually increase firing until recommended boiler steam outlet temperature and pressure are reached. This is followed by supplying the steam turbine with sufficient inlet steam flow to reach conditions that allow the coupled generator to be synchronized and electricity to be generated above zero megawatts. From this point, boiler fuel firing is increased within prescribed rates until the desired operating load is achieved.

The SEGU startup operating period is usually not defined in emission permits. Startup is the period beginning with initiation of fuel ignition, and continuing until the powerplant equipment has reached operating conditions that include continuous fuel firing and sustained operating steam pressure and temperature levels within the guidelines of the designs for the boiler and turbine and their auxiliary systems for minimum sustainable levels without causing damage to the equipment.

A recent SEGU proposed PSD permit has included a definition of startup as “the period beginning with ignition and lasting until the equipment has reached a continuous operating level and operating permit limits”[36]. Similarly, a shutdown is defined as “the period beginning with the lowering of equipment from base load and lasting until fuel is no longer added to the boiler and combustion has ceased”[37]. Based on the referenced definitions of a startup period and a shutdown period, the amount of time required for a SEGU’s load (boiler steam output or generator electrical output) to increase beyond such minimum sustainable operating levels can be considered part of startup events if the SEGU is typically base-loaded at full load or MCR output. This is the case with both MRY Station SEGUs.

Startups of SEGUs may be labeled as cold, warm, and hot to account for the amount of residual heat remaining in the boiler and steam turbine equipment. The various types of starts are dependent upon the amount of time the SEGU has been out-of-service (i.e. without boiler fuel firing or generator megawatt output). Cold starts have been defined as starts after the boiler has been without fuel firing for more than 72 hours, warm starts are more than 8 hours and less than 72 hours, and hot starts are less than 8 hours[38].

Although the definition of a startup event and the corresponding startup period is not required by the Consent Decree, defining start-ups is recommended. This helps to address the specific emission limitations during Unit startups at Milton R. Young Station and determine the impact of such operations on 30-day rolling average NO_X emissions. For the purpose of this NO_X BACT analysis, a Unit startup was defined as the period from initial fuel combustion to the point in time when:

- the measured Heat Input to the boiler on a 6-hour rolling average basis is greater than or equal to 2500 million BTU/hr for Unit 1; or
- the amount of time reported for the longest individual Unit 1 startup period during actual operation between January 1, 2001 and December 31, 2005 elapses, whichever occurs first; or
- fuel firing is discontinued prior to satisfying either previous criteria.

This startup definition for MRY Station Unit 1 accounts for conditions where cyclone refractory materials replaced during boiler overhauls must be cured by extended low-firing heating cycles,

[37] Ibid, page 7.
[38] Application for Prevention of Significant Deterioration Permit for the Desert Rock Energy Facility, Document Number 09417-360-250R1, May 2004, page 5-1.

unit controls are upgraded and must be adjusted during low-load operation, or for boiler feedwater quality to improve after boiler maintenance has been performed that affects the insides of the waterwall and superheated steam tubes. It also allows for a failed or interrupted start sequence which can require considerably less or more time to elapse than an average startup duration.

Analysis of MRY Station Unit 1 operations data from 2001 through 2005 revealed:

- There were 60 total startups in the five year period;
- Minimum startup was 10 hours for a "hot" start following a boiler master fuel interruption (Unit "trip");
- Maximum startup with an extended ramp-up period until full load was reached was 61 hours.

Unit 1 had a start-up that began on June 27, 2005 that lasted for 61 hours. This startup included initial firing in the 5th hour of 6/27 (0500 hours being the beginning of the startup period), and which ended at the end of the 17th hour (i.e. at 1800 hours) on June 29th, 2005 upon reaching a generator output of 245 MW (gross) rather than a 6-hour average heat input rate of more than 2500 million Btu per hour.

There are certain boiler operating conditions that need to exist before the BACT NOx control techniques and technologies can be effectively operated:

1. The furnace gas temperature in the region where a urea reagent solution is injected for SNCR-based NO_X control must be between 1700°F and 2100°F. This region is expected to be in the vicinity of the furnace exit, which is commonly defined as either the horizontal plane extending from the furnace rear wall arch ("nose") to the front wall of the boiler, or the vertical plane from the nose up to the furnace roof, upstream of the gas inlet to the superheater tube banks. The gas temperature (FEGT) range in this furnace region is dependent on boiler heat input rate and cleanliness of the firesides of the furnace walls, which affects the amount of radiant energy absorbed by the wall tubes and transferred to the water within.
2. The numbers of active cyclones and continuous coal firing rates must be enough to establish sufficient:
   a. coverage of molten slag on the actively-fired cyclone barrel surfaces and drainage of the slag from the bottom of the boiler; and

b. combustion airflow through the actively-fired cyclones to allow a portion to be diverted to the separated overfire air system above the amount required for idle cyclone cooling and SOFA nozzle cooling.

As previously discussed, furnace exit flue gas temperatures (FEGTs) will need to be measured or determined empirically during operation of the MRY Station boilers in order to be able to effectively control NO_X emissions using SNCR technology. The design and operation of the SNCR systems at MRYS for CD Phase II emissions control should include features that accommodate cyclone boiler startups and low-load operation with "clean" or "dirty" boiler heat transfer surfaces as soon as conditions occur that are technically practicable, i.e. within the SNCR system vendor's recommended operating guidelines, as well as full-load conditions in order to minimize NO_X emissions.

The amount and duration of sustained boiler heat input required to establish the operating conditions described in item 2 above is more difficult to precisely determine. Lignite heat content variability and inability to accurately determine the actual air/fuel ratio on a cyclone-by-cyclone basis in real-time, and the slagging and fouling characteristics of the lignite ash, cause (and are expected to continue to cause) difficulties with stable combustion performance. The minimum firing rates of the MRY Station boilers required to successfully initiate the effective operation of the SOFA system are specific to each individual boiler, and are not currently known. Due to such operating problems and emission control limitations, the ability to effectively limit NO_X emissions during startup periods and low-load operation following implementation of advanced SOFA (CD Phase I control) and/or an SNCR system (CD Phase II control) is uncertain.

Because there are expected to be minor short term variations in operating conditions during startups where Minnkota has not, in fact, materially changed any of their normal startup operating practices and criteria, a margin between the 30-day rolling average steady-state NO_X emission rate (which does not include the impacts of startups) and the proposed 30-day rolling average NO_X emission permit limit that includes startup emissions is recommended. This rate considered recognized operational factors and equipment designs applied to steady state conditions with sustained output close to maximum continuous capacity ratings. The recommended 30-day Rolling Average NO_X Emission Rate permit limitation excluding the impact of startups that reflects BACT for Milton R. Young Station Unit 1 is shown in the table below.

TABLE 3-20 – Recommended NO_X BACT Control Method and 30-Day Rolling Average NO_X Emission Rate Limit Without Startups

Unit	Pollutant	Control Method	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)
1	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.360

This recommended BACT 30-day NO_X emission rate limit is based upon a historic pre-control 30-day baseline average NO_X emission rate of 0.884 lb/mmBtu for Unit 1. The baseline emission was determined from the 30-consecutive day period with the highest historic unit NO_X emissions rate reported for actual operation between January 1,2001 and December 31, 2005.

A recommended BACT 30-day NO_X emission rate limit that includes the impact of startup emissions should be suitably higher such that operation consistent with the technological limitations, manufacturer's specifications, and good engineering and maintenance practices to the extent practicable for the MRY Station boilers would not result in an exceedance (violation) of an enforceable 30-day rolling average NO_X emission permit limit.

For MRYS Unit 1, the recommended 30-day rolling average NO_X emission permit limit rate that includes the impact of startups is based upon recognized operational factors and equipment designs that influence whether the startup emissions result in higher 30-day emissions compared to normal continuous operation without or excluding such startup periods:

1. The uncontrolled emission rate (i.e. without separated OFA or SNCR in operation) and its variability during operation from a cold, warm, or hot startup up to and including maximum continuous rated output;
2. The operating conditions that are required to exist for the selected NO_X BACT control techniques to be initiated and be effective; and
3. The effectiveness of these two particular control techniques if invoked at less-than-MCR steady-state operating conditions.
4. The number of startups and their range of typical durations per 30-day period time frame.

The June 27-29, 2005 startup was chosen for additional evaluation as the start-up for MRY Station Unit 1.

An incremental adjustment to the proposed 30-day rolling average steady-state unit NO_X BACT emission rate without startups of 0.36 lb/mmBtu for Unit 1 is recommended for the 30-day rolling average NO_X emission permit limit periods as defined and applied to Milton R. Young Station. This is summarized in the table below.

TABLE 3-21 – Recommended BACT 30-Day Rolling Average NO_X Emission Rate Limit and Startup Impact

Unit	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)	Impact on 30-day Rolling Average NOx Emission Rate Limit Due to Startups (lb/million Btu)
1	0.36	+0.041 per startup

This recommended adjustment to the proposed 30-day rolling average steady-state NO_X BACT emission rate limit without startups is based upon average historic pre-control NO_X emission rates of 0.766 lb/mmBtu for Unit 1 reported for the longest individual Unit 1 startup period during actual operation between January 1, 2001 and December 31, 2005. These emissions occurred during the 61-hour June 27-29, 2005 startup for Unit 1.

A 24-hour rolling average BACT NO_X emission rate limit applied to startup periods is also recommended for each of the Milton R. Young Station boilers.

This is summarized in the table below.

TABLE 3-22 – Recommended 24-Hour Rolling Average NO_X Emission Rate Limit During Startups

Unit	24-hour Rolling Average NOx Emission Rate Limit During Startups (lb/million Btu)
1	0.980

These emissions occurred during the 61-hour June 27-29, 2005 startup for Unit 1.

Compliance with these emission rates would be measured at the stack of the Unit, verified with Continuous Emission Monitoring (CEM) systems in accordance with the reference methods specified in 40 C.F.R. Part 75, and would be determined on a 30 consecutive Operating Day and 24-consecutive hour rolling average basis, respectively.

A trial demonstration operating period of 18 months after the completion of Consent Decree Phase II NO_X emission reduction system installation commissioning at Milton R. Young Station is recommended. It is proposed to allow Minnkota to demonstrate the actual control system capabilities of the combined NO_X BACT emissions reduction system. Operating experience during the trial period will:

- confirm steady-state control performance of the combined NO_X BACT emissions reduction system;
- allow determination of the ability to further control Unit start-up emissions;
- allow the determination of the permitted 30-day rolling average NO_X emission limit including startups, shutdowns, and malfunctions; and
- address the specific emission limitations during Unit startups at Milton R. Young Station and their impact on the proposed 30-day rolling average emission rate limit (without startups).

Based upon the information obtained during the trail period, final emission limits can then be determined.

The means that will be employed to minimize emissions during startup will primarily be based on operating procedures, both before and after the level of upper furnace gas temperatures and/or heat input rate are considered sufficient to start the NO_X controls and operating conditions are conducive for effective emissions reduction. These could be similar to Minnkota's current MRYS practices, or could be different, depending upon the capabilities of the NO_X controls and their impacts on Unit operations.

APPENDIX A

Technical Feasibility Assessment Details for NO_X Control Technologies (A1)

U.S. Coal Cyclone NO_X Reduction Projects Summary

With Retrofit NO_X Control Projects’ Technical Literature Summary (A2)

A.1 Technical Feasibility Assessment of NO_X Control Alternatives

A.1.1 Pre-Combustion Fuel Treatment/Switching

Fuel switching can be a viable method of NO_X emission reduction in certain situations. Often, coal combustion facilities are constructed to take maximum advantage of the particular combustion characteristics of a specific fuel. In the case of MRY Station, the Unit 1 and 2 boilers were designed and constructed specifically for firing North Dakota lignite, which has a fuel higher heating value (Btu/lb) approximately 20% lower than typical Powder River Basin (PRB) coal. A cyclone–fired boiler (Ottertail's Big Stone Unit 1) that is similar in geometry and steam generation design to MRY Station Unit 2 fires PRB coal. Based on a comparison of available emission data between Big Stone Unit 1 and MR Young Unit 2, there is no expected reduction in baseline (i.e. uncontrolled) NO_X emissions from switching to PRB from lignite at Milton R. Young Station.

Conversion of Milton R. Young Station Unit 1 boiler to fire PRB coal is technically possible. It is expected that major plant modifications will be required. Rail service is not presently installed at this site, so the additional operational and capital costs to bring in large quantities of PRB coal will be significant. Investigation of the specific source, distance, and costs for supplying necessary quantities of PRB coal via rail or trucks to M.R. Young station has not been performed. With zero baseline NO_X emissions reduction expected from application of fuel switching, this alternative will not be economically competitive with other NO_X control technologies that offer better results for a much lower combination of capital and operational costs. Although fuel switching is technically feasible, it has not been considered further as an effective NO_X emissions control option for MRY Station Unit 1 boiler.

A.1.2 Combustion Controls

Combustion controls comprise the most numerous category of NO_X emission reduction technologies. These techniques employ methods that reduce the amount of NO_X emissions created in the combustion zone of the boiler prior to exhausting the flue gases from the furnace (upstream of the convective heat transfer zones). These controls result in fewer emissions to atmosphere or that may require subsequent reduction from additional applicable combustion and/or post-combustion techniques.

As the boilers in question were designed for firing North Dakota lignite fuel, they were furnished with suitably-sized furnaces and limited back-end economizer heat transfer surfaces upstream of the air preheaters. This provides high temperature air to aid the evaporation of excess moisture from the crushed coal particles in the pre-combustion drying systems, and long residence times for solid and gaseous fuel particles to burn essentially to completion prior to leaving the furnaces. The latter feature is especially advantageous for applying various forms of combustion modifications which are conducive in reducing NO_X emissions.

A.1.2.1 Basic Combustion Improvements

Combustion improvements are commonly-applied techniques which may produce modest incremental NO_X emissions reductions. In their most basic form, these typically provide improvements to combustion air flow distribution, measurement, and pressure, together with fuel flow measurement and metering, to promote consistent combustion performance by burning fuel with more accuracy in maintaining a desired fuel/air ratio.

These improvements may allow, or be combined with, the practice of several other NO_X control techniques. Separated overfire air (discussed below), with or without “low excess air” (LEA), burners out-of-service (BOOS) and biased firing (BF) operation of the cyclones, cause a decrease in the ratio of combustion air to fuel supplied to the cyclones (burners), thus reducing the amount of thermal NO_X emissions produced during combustion. The amount of potential NO_X emission reduction achievable from these basic techniques is highly-dependent on the specific type of firing, fuel, and conditions which apply to the boiler(s) being reviewed.

Making lignite drying system air adjustments and adding improvements to the boiler combustion controls and reducing combustion air inputs have already reduced uncontrolled NO_X emissions at Milton R. Young Station boilers approximately 10%. Further incremental improvements from additional combustion controls that allow operation with modest amounts of cyclone air staging, similar to the effect of a separated overfire air system, are possible. Incremental NO_X emissions reductions are expected from such improvements being incorporated into another feasible alternative, such as separated overfire air. This alternative was not considered as a stand-alone option for additional NO_X reduction at Milton R. Young Station for the Unit 1 boiler.

A.1.2.2 Low NO_X Burners (LNB)

Low NO_X burners (LNBs) of various designs have been commonly applied to pulverized coal-fired utility and industrial boilers for more than ten years. However, they are not installed on cyclone-fired boilers. This technology is infeasible on cyclone boilers[1], and was eliminated from consideration for additional NO_X reduction at Milton R. Young Station Unit 1’s boiler.

A.1.2.3 Separated Overfire Air (SOFA)

Separated overfire air (SOFA) is a combustion-related NO_X emission reduction technology frequently-applied with and without low NO_X burners to utility and industrial boilers for more than twenty five years. Separated Overfire Air (SOFA) is an air-staging NO_X emission reduction combustion technique that is typically based on withholding 15 to 20 percent of the total combustion air conventionally supplied to the firing zone. The diverted combustion air is then injected in the upper furnace, where combustion is completed. For typical cyclone coal-fired boilers, this involves diverting approximately 20 percent of the secondary combustion air, forcing the cyclones to operate fuel-rich. Starved-air combustion causes fewer NO_X emissions to be produced.

At least thirty nine existing cyclone-fired boilers, firing eastern bituminous, midwestern bituminous, and western subbituminous (“Powder River Basin”) coals in units ranging in size from 50 to 1150 MW, have been retrofitted with commercial SOFA since 1998. A summary of several of the first SOFA (and reburn) retrofits to cyclone-fired boilers is described in published technical papers[1,2]. Cyclone boiler retrofit SOFA installations are included in the EPA’s BART technical support document[3] and listed later in Appendix A2.

A basic form of separated overfire air (SOFA) can be applied and installed on MRY Station Units 1. There are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application.

Key aspects of successfully applying and operating a separated overfire air system on a cyclone-fired boiler are the ability to:

- Accurately measure the fuel heat input rate (BTUs) and combustion air inputs on a real-time, individual cyclone by cyclone basis, to allow the ability to determine and control the desired air/fuel ratio, especially when “starved air“ (i.e. substoichiometric) combustion conditions are required.
- Maintain adequate molten coal ash (slag) formation and flow within the barrels and slag taps.

The degree to which the cyclone furnaces can be operated with less than theoretical (substoichiometric) combustion air directly contributes to less NO_X formation and further in-furnace emission reduction but also risks solidification of the molten coal ash. In the case of MRY Station Unit 1 boiler, cyclone combustion must be sufficiently air-staged to reduce NO_X emissions while releasing enough heat to continue to melt the fuel ash so that it flows effectively within and from the cyclone burners.

In the case of MRY Station boilers, there is a significant amount of variability in the combustible and ash components of North Dakota lignite supplied from the current mine near Center, ND. Analysis of several hundred coal feed samples taken simultaneously from multiple cyclones of MRY Station Unit 2's boiler revealed that the maximum differential of the lignite heating values from cyclone-to-cyclone was just over 12% of the average heating value of all the samples. Assuming an operating case occurred where the maximum cyclone-to-cyclone differential heating value was for two cyclones at the opposite ends of the fuel heat content range, there would be a plus or minus 6% variation in fuel heat content for either of the individual cyclones from the overall average. If the desired average cyclone air/fuel (stoichiometric) ratio was 0.95 when operating with air-staged cyclones associated with separated overfire air, and the amount of secondary combustion air to each cyclone was equal, there would be a stoichiometric ratio of approximately 1.01 in one cyclone and a stoichiometric ratio around 0.89 in another cyclone at the same time. The modestly air-staged cyclone would produce higher than average NOx emissions. The deeply staged cyclone would produce less than average NOx emissions and potentially insufficient amounts of heat release, and raise the risk of solidifying the fuel ash so that it accumulates within the cyclone barrel. This could result in firing auxiliary fuel oil in the deeply-staged cyclone or taking the boiler out-of-service to remove the pluggage. Neither of these conditions is desirable because they result in lower emissions removal performance and higher operating costs. Thus, due to the variability of the fuel heat content and the complex behavior of lignite ash when exposed to high temperatures, the extent of air-staging and thus the level of NO_X control in MRY Station boilers is expected to be modest while firing lignite coals.

In order to potentially achieve lower NO_X emission rates with modestly air-staged combustion for MRY Station boilers, additional combustion improvements can be installed. One potential improvement is to implement a unique form of SOFA for North Dakota-lignite–fired cyclone boilers. This includes relocated lignite drying system vent ports. This will be referred to as "Advanced SOFA" (ASOFA). There are several design challenges anticipated for implementing the advanced version (with the described port relocations) of separated OFA. These are believed to be solvable.

Both forms of separated overfire air as a combustion-related NO_X control technique are considered feasible for application to Milton R. Young Station cyclone boilers. Since the advanced SOFA is the highest-performing form of this technology, only this ASOFA version of the alternative was considered for additional NO_X reduction at Milton R. Young Station boilers.

Another form of separated overfire air being marketed commercially is “Rotating Opposed Fire Air” (ROFA). For utility applications in the United States, this has only been applied to pulverized coal-fired boilers, primarily tangentially-fired units[4]. It is different than basic SOFA in that it includes a hot air booster fan, and injects the overfire air in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row. The vendor (Mobotec USA) claims ROFA maximizes air-staged in-furnace combustion NOx reduction while minimizing negative impacts on carbon monoxide and flyash unburned carbon.

While this variation of separated overfire air could potentially be applicable to cyclone boilers, it has not been marketed to serve such applications. Because cyclone boilers do not require the addition of hot air booster fans for SOFA, this technique is not distinct enough from basic SOFA from functional and air-staged cyclone NO_X reduction performance standpoints to warrant individual consideration. ROFA technology lacks demonstrated cyclone-fired boiler experience, and thus was considered infeasible and not included in the control effectiveness and cost-effectiveness sections of the main report.

A.1.2.4 Oxygen-Enhanced Combustion

A supplier of liquid oxygen (Praxair) has developed a method of replacing some of the combustion air supplied to the burners with pure oxygen. Combustion air, which is normally input through the secondary air system ductwork downstream of the forced draft (FD) fan and air heater, is supplemented with pure oxygen directly injected into the burners. Oxygen-enhanced combustion (OEC) can reduce boiler NO_X emissions resulting from “ thermal NO_X“, a reaction of the nitrogen in the combustion air admitted to the burners with the available oxygen in the air in the flame or peak temperature regions of the fuel combustion process. The use of pure oxygen instead of air reduces the availability of nitrogen from the air to be oxidized in the high temperature regions, thus reducing formation of thermal NO_X. This technique has only been demonstrated in a boiler with pulverized fuel burners firing bituminous coal[5].

The lack of adequate experience on any cyclone-fired coal-burning boiler, on a temporary demonstration or permanent full-scale basis, and for a coal-fired facility of this size, precludes consideration of oxygen-enhanced combustion at MRY Station Unit 1’s boiler. This is deemed to be infeasible technology at this location at the present time.

A.1.2.5 Flue Gas Recirculation

Flue gas recirculation (FGR) has been commonly applied to coal-fired boilers, primarily to inject into the lower furnace, just above the burners, supplied from the boiler’s economizer flue gas outlet via a hot gas booster fan. This modifies the amount and temperature of hot furnace gas either in the lower-middle or upper furnace and convection heat transfer zones. As this flue gas typically has an oxygen content around 2-5%, it limits the availability of oxygen in a high temperature, possibly fuel-rich lower furnace zone. Flue gas recirculation for NO_X control is most commonly applied with gaseous or liquid fossil fuels to reduce the high temperatures which convert nitrogen in the combustion air to nitrogen oxides. No examples of using or installing FGR on cyclone-fired boilers strictly for NO_X emissions control were found in available technical literature.

For MRY Station Unit 1’s boiler, FGR was originally supplied from the outlet of the induced draft fans, but has since been discontinued and removed. Since it is not operational on Unit 1, and therefore does not affect the potential performance of separated overfire air (in an “advanced” form), it would not be expected to reduce NO_X emissions if reinstalled alone or in combination with SOFA. Although FGR is technically feasible, it has not been considered further as an effective NO_X emissions control option for MRY Station Unit 1’s boiler.

A.1.2.6 Water/Steam Injection (Combustion Tempering)

When applied to older gas-fired and oil-fired utility and industrial boilers, water and/or steam injection adds moisture into the lower furnace, concurrent with or near (to the side or slightly above) the burners, supplied from the boiler’s treated feedwater or auxiliary steam systems via a metering pump or valve. There has been some limited testing of water injection for NO_X emissions control on natural gas-fired and coal-fired cyclone boilers[6,1]. For coal-fired cyclones, this technique is most effective on boilers burning bituminous coal; however, it has not been permanently installed and continuously operated in such applications. Successful long-term operation of water injection would be difficult for lignite-fired cyclone boilers, due to the high moisture levels in the coal and the need to readily ignite and sustain stable combustion and molten slag formation in the cyclone furnaces. For these reasons, water/steam injection is considered technically infeasible for NO_X control application at Milton R. Young Station.

A.1.2.7 Fuel Reburn

Another combustion technology that may be applicable to control NO_X emissions from the Milton R. Young Station units is fuel reburn. In a similar manner that overfire air diverts a portion of the combustion air input to the main firing zone, the reburning process involves supplying a portion of the fuel heat input to the boiler at a higher elevation in the furnace. This creates an upper furnace atmosphere where the reburn fuel's combustion products causes some of the NO_X formed in the main burner combustion zone and reburn zone to be converted into molecular nitrogen. Depending on the amount of reburn fuel added and the amount of oxygen available in the furnace gases to combine with the reburn fuel introduced, additional combustion air may be supplied as supplemental or overfire air. Downstream of the air injection elevation, the intention is to complete the reaction of any remaining carbon monoxide (CO) to carbon dioxide (CO_2), plus reduce the amount of combustible matter remaining in the entrained flyash.

The most common forms of reburn technology applied to utility powerplant boilers are:

- Pulverized or micronized coal reburn (PCR or MiCR); and
- Gas reburn (GR).

Pulverized coal reburning and micronized coal reburning have been applied to pulverized coal and cyclone-fired boilers. NO_X reduction efficiencies of 50 to 60 percent have been demonstrated on eastern bituminous coal and midwestern bituminous and Powder River Basin (PRB) western subbituminous coals while supplying up to approximately 20-30% of the boiler's total fuel heat input to the reburn zone[7,8].

For utility powerplant boiler applications, natural gas has been utilized as reburn fuel most often, demonstrated in two basic approaches:

- Conventional gas reburn (CGR); and
- Fuel-lean gas reburn (FLGR™).

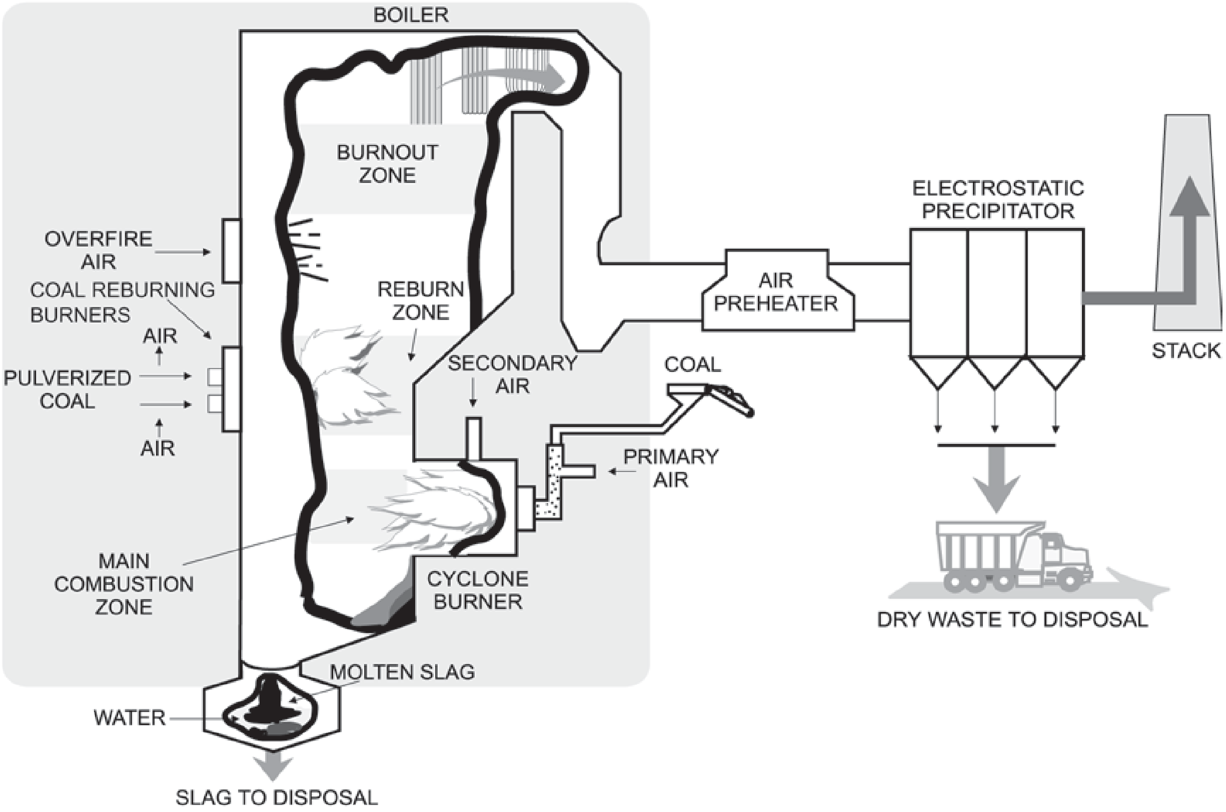
Either natural gas or pulverized coal (lignite) can be used as the reburn fuel. A sufficient quantity of natural gas is not currently available at the Milton R. Young Station plant site. Supplying enough natural gas to provide 6 to 25% of the total heat input to either or both boilers at MRY Station is expected to be technically feasible, although transport pipeline installation capital costs, and current and predicted unit natural gas costs and operating economics, are likely to be unfavorable.

Various forms of fuel reburning have been demonstrated and operated routinely on cyclone boilers for NO_X emission controls. This has been applied to units firing eastern bituminous coal, and western subbituminous or PRB/bituminous coal blends, using pulverized or micronized coal or natural gas as the most common reburn fuel. Reburning for NO_X emissions reduction has not been demonstrated on a unit firing high moisture, low heat content North Dakota lignite. Pulverized/micronized coal, along with conventional and fuel lean gas reburn technologies, are discussed below.

A.1.2.7.1 Coal Reburn

In the case of applying conventional coal reburn to cyclone boilers, the existing cyclones are supplied with the majority of the fuel, with either natural gas or pulverized coal (lignite) used as the reburn fuel such that the total heat input to the boiler is essentially the same as without fuel reburn. Separated OFA ports are located above the reburn fuel injection section of the furnace. These SOFA ports provide sufficient oxygen in a conventional fuel reburn installation to complete the combustion process that begins in the main combustion zone and is supplemented in the reburn and burnout zones. This is shown schematically for a pulverized coal reburn application on a cyclone-fired boiler with SOFA in Figure A.1-1.

Figure A.1-1 Pulverized Coal Reburn Application on Cyclone Boiler With Overfire Air[8]



In the United States, pulverized coal reburning and micronized coal reburning techniques for utility powerplant NO_X emissions reduction have been applied on a very limited full-scale, full-time basis to cyclone-fired boilers in field demonstration tests and longer-term demonstration operation, respectively. There have been only two known pulverized or micronized coal reburn installations in the United States on cyclone boilers, one on a utility boiler in Wisconsin, and one on a small industrial-size cyclone boiler in New York state[7,8,9,10,11,12,13,14]. NO_X emissions reduction efficiencies of 57 percent have been demonstrated on cyclone boilers firing eastern bituminous coal, or midwestern bituminous and Powder River Basin (PRB) western subbituminous coals while supplying up to approximately 20-30% of the boiler's total fuel heat input to the reburn zone. With the exception of the U.S. Department of Energy's (DOE) Clean Coal Technology Program demonstration projects[7,8,9], no known commercially-available coal reburn systems have been installed and are routinely operated on cyclone boilers in the United States to date. The DOE-CCTP projects for coal reburn applied to cyclone boilers are described below.

Pulverized coal reburning for NO_X emissions reduction in a cyclone-fired boiler was demonstrated on the 110 MW Nelson Dewey Unit 2 for Wisconsin Power & Light in 1991-1992. Reburn fuel preparation and handling, reburn burners with flue gas recirculation, and a separated overfire air system were added. Coal reburn tests were conducted on this unit while firing bituminous and PRB coals. NO_X emission control efficiencies of 50 to 60 percent, with reductions from 0.75-0.83 lb/mmBtu baselines to around 0.38 lb/mmBtu, but as low as 0.29 to 0.32 lb/mmBtu, with PRB coal at full load with approximately 25-30% of the total fuel heat input from reburn fuel were demonstrated[9,11,12]. The reburn system is no longer operated on Nelson Dewey Unit 2.

Micronized coal reburning has been demonstrated in 1997-1998, and continues to operate year-round on a small industrial cyclone boiler (400,000 lb/hr steam output, 50 MW gross equivalent) for Eastman Kodak Company at their Kodak Park facility in Rochester, NY. This unit (Boiler #15) achieves a NO_X reduction efficiency of approximately 57 percent on eastern bituminous coal, involving limited cyclone air-staging (cyclones believed to be slightly above 0% excess air) and a modest amount of overfire air injection downstream of the micronized reburn fuel input nozzles. Approximately 17% of the boiler's total fuel heat input is typically supplied to the reburn zone. This coal reburn system continues to operate routinely at this facility. This installation is reported to use a Fuller MicroMill to produce micronized coal with 80% passing through a 325 mesh screen[7,9,13].

If a coal reburn system was applied to MRY Station boilers, the existing cyclones would be supplied with the majority of the fuel in the form of crushed coal, and the balance of fuel would be supplied to a pair of dedicated pulverizers to feed the reburn injection ports, such that the total heat input to the boiler is essentially the same as without fuel reburn. In a conventional fuel reburn installation, OFA ports located above the reburn section of the furnace provide sufficient oxygen to complete the combustion process that begins in the main combustion zone and is supplemented in the reburn and burnout zones.

Similar to the application of separated overfire air, there are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. As a reburn fuel, lignite is expected to behave appropriately upon introduction in the lower middle furnace to help reduce NO_X emissions. The concerns are that the diversion of a significant amount of heat input from the cyclone barrels to use as a source of reburn fuel in the form of pulverized or micronized lignite may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction as part of this reburn technique will further risk slag “freezing” in the barrels and lower furnace. Reducing the number of active cyclones which are air- and fuel-staged to accommodate reduced firing rates while operating a coal-fired boiler with reburn and separated overfire air is the typical approach to avoid slag tapping problems.

Potential NO_X emissions reduction performance is expected to be limited on lignite-fired cyclone boilers with a basic form of separated overfire air system, since the reburn fuel injection location is expected to coincide with the existing lignite pre-drying system vent ports. The amount of oxygen introduced by the vent ports will be disruptive to any conventional reburn process in that it would require much higher reburn fuel injection rates to create a substoichiometric atmosphere in the lower secondary furnace that is conducive to promoting in-furnace NO_X reduction.

Significant additions to the fuel preparation equipment in the existing plant facilities will be required. The coal reburn system expected to be applied to MRY Station boilers may use two new fine-grind pulverizers and dynamic classifiers to achieve the level of coal particle size distribution required.

Higher unburned carbon levels in the flyash exhausted from the boiler may occur, especially when the reburn fuel is coal, and the regular burners are fired with less than theoretical amounts or combustion air commonly practiced with the use of overfire air. Lowering the reburn fuel injection elevation, decreasing the amount of reburn fuel, and grinding the reburn coal to a greater degree of fineness can help to offset some of the increase in flyash unburned carbon content. Flue gas opacity from the stack may increase if the particulate removal equipment is an electrostatic precipitator, due primarily to reduced resistivity and smaller particle sizes of the flyash.

An issue that affects the feasibility of lignite reburning is the uptime required for the lignite reburn fuel pulverizing system, and impact of the reburn system on effectiveness in reducing NO_X emissions during load changes and lower loads. Typically, one new pulverizer is dedicated to prepare reburn fuel in existing pulverized fuel-fired boiler applications. Cyclones may be fired with less fuel or deactivated during boiler operation in order to accommodate changes in fuel combustion characteristics, boiler load, and for scheduled or unscheduled individual crusher maintenance. Milton R. Young Station Unit 1 has seven crushers for cyclone coal grinding, each dedicated to one of the seven cyclone furnaces. Diverting as much as 30% of the total heat input as reburn fuel could require two of the existing cyclones to be deactivated, and two new MPS-89 pulverizers to be dedicated to reburn fuel preparation. As each of these mills requires periodic maintenance, boiler emissions and/or load could be negatively impacted during individual reburn mill outage periods while the boiler remained in service. A high level of fineness of coal particles from the reburn mills is important to achieve and maintain in order to limit increases in flyash combustibles. A minimum of 60 percent passing through 200 mesh fineness is recommended by one of the reburn technology vendors (B&W) for pulverized lignite reburn. Micronized coal reburn requires even greater fineness: 70-80 percent passing through a 325 mesh screen.

Pulverized or micronized coal reburn with the advanced form of separated overfire air (ASOFA) can be applied and installed on MRY Station Unit 1's boiler. These combined techniques are expected to reduce NO_X emissions approximately 54% from current pre-control baseline levels (down to 0.385 lb/mmBtu) for the MRY Station Unit 1 boiler. These levels of NO_X reduction depend on the advanced form of separated overfire air technique to achieve the expected NO_X reduction percentages when applied to lignite-fired cyclone boilers, which may not be successful given the concerns expressed about the potential impacts of this technique. Using finely pulverized lignite for reburn fuel is considered technically feasible for NO_X emissions control under evaluation for application to MRY Station Unit 1's boiler.

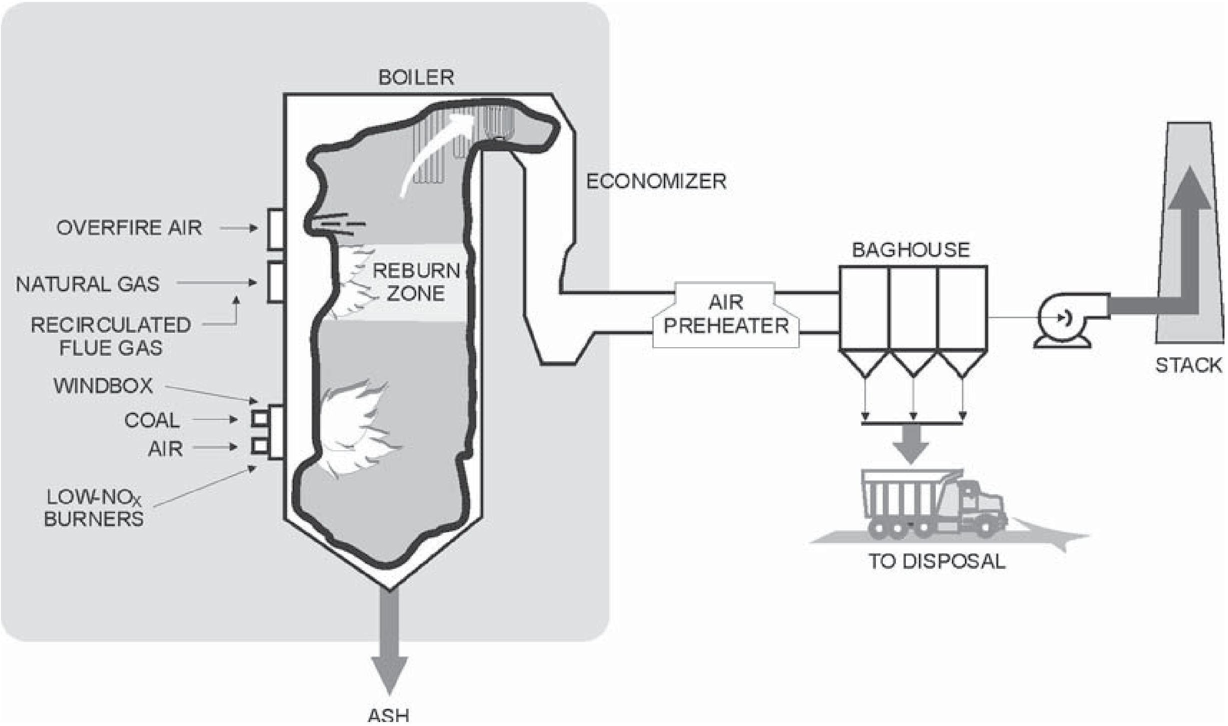
A.1.2.7.2 Conventional Gas Reburn

Natural gas has been preferred as the reburn fuel of choice. Natural gas has been utilized for reburn fuel in two basic approaches: conventional reburn and fuel-lean gas reburn. In the conventional approach, up to 30% of the boiler's total fuel heat input is supplied to the reburn zone, followed by a significant amount of overfire air for completion of combustion prior to flue gases exiting the boiler.

Conventional gas reburning in a cyclone-fired boiler has been available at Tennessee Valley Authority's Allen Station Boiler #1 (300 MW) since 1998. The reburn technology provider (vendor) claims NO_X emissions were reduced 67% from a full-load baseline of 1.29 (down to 0.42) lb/mmBtu when firing a blend of western bituminous and PRB coals[14]. Conventional gas reburn fuel input rates were not available from the technology vendor's literature. Another reference source of information stated NO_X emissions were reduced 65% from a full-load baseline of 0.86 (down to 0.30) lb/mmBtu with 7 percent of the total fuel heat input supplied as reburn fuel[9].

A schematic graphic of conventional gas reburn on a pulverized coal-fired boiler is shown in Figure A.1-2.

Figure A.1-2 Natural Gas Reburn Application on
Wall-Fired Pulverized Coal Boiler with Overfire Air[8]



Similar to the application of separated overfire air, there are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. For the most effective NO_X reduction by applying the various available forms of fuel reburn, the injection of fuel is usually performed using recirculated flue gas as a diluent and carrier media to aid dispersion and avoid completely oxidizing the carbon and nitrogen components in the fuel and furnace gases from staged burners/cyclones. Improved gas reburn designs have reduced or eliminated FGR with higher gas injection pressures. For lignite-fired cyclone boilers, reburn fuel firing with a basic form of separated overfire air is expected to be much less effective in reducing NO_X emissions than previously demonstrated elsewhere. This is related to the likelihood that the injection of reburn fuel will be near the elevation of the existing lignite drying system vent ports, and that the oxygen introduced with the lignite drying system's vented moisture will disrupt the desired in-furnace nitrogen oxides reduction process.

It should be recognized that application of air-staged cyclones with basic or advanced forms of SOFA with reburn techniques will require the overfire air injection ports to be located at a somewhat lower elevation of the furnace compared with air-staged cyclones without reburning. This means that less air-staging of the cyclones may be practiced, or that less residence time will be available for the in-furnace NO_X reduction process to occur.

Similar to coal reburning, there are concerns that withholding a significant amount of heat input from the cyclone barrels to use natural gas as a source of reburn fuel may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Air-staging the cyclones for use of separated overfire air to further complement combustion NO_X reduction as part of this reburn technique will further risk slag "freezing" in the barrels and lower furnace. Reducing the number of active cyclones which are air- and fuel-staged to accommodate reduced firing rates while operating a coal-fired boiler with conventional reburn and separated overfire air systems is the typical approach to avoid slag tapping problems. Natural gas reburn with the advanced form of separated overfire air (ASOFA) can be applied and installed on Milton R. Young Station's Unit 1 boiler.

Although the unit operating and capital costs to supply large quantities of gaseous fuel not currently available at this site are economic disadvantages, using high-pressure natural gas for reburn fuel is considered technically feasible for NO_X emissions control under evaluation for application to MRY Station Unit 1's boiler.

A.1.2.7.3 Fuel Lean Gas Reburn

Another approach to gas reburning is “fuel-lean gas reburn” (FLGR™) technology, which injects limited amounts of natural gas (approximately 3-10 percent of the total fuel heat input) above the burners (or cyclones) with or without significant air-staging of the burners (cyclones) or the addition of overfire air upstream of the fuel injection elevation. FLGR’s first field-test on a cyclone-fired boiler was at Commonwealth Edison’s Joliet Unit 6 (327 MW), a 9-cyclone-furnace boiler[15]. NO_X emissions reduction with FLGR (without SOFA) was believed to be approximately 35-40% with 7% of the boiler’s total fuel heat input supplied in the reburn zone. This test yielded 0.59 lb/mmBtu NO_X emissions from a baseline of 0.98[16]. One other cyclone boiler has been modeled using computational fluid dynamics (CFD) as part of a study looking at applying FLGR at Owensboro Municipal Utilities’ Elmer Smith Station Unit 1 (150 MW single-wall, eastern bituminous coal-fired boiler). This model predicted that NO_X emissions could be reduced by 25-30% over that achievable from overfire air and SNCR[17].

More commonly, FLGR™ has been applied on medium to large pulverized coal wall-fired boilers burning eastern bituminous or western subbituminous coals. On Wisconsin Electric Power Company’s (WEPCO’s) Pleasant Prairie Unit 1, a 620 MWg Riley turbo-fired wet-bottom (slagging) boiler, FLGR™ alone was predicted to reduce NO_X emissions by 35-39 percent at a gas reburn rate of 7-8 percent but only achieved 20% from a baseline of 0.45 lb/mmBtu[16,18]. This is presumably without burner air-staging or SOFA. It has also been applied in combination with SNCR at this WEPCO site.

A potential advantage of FLGR™ over conventional gas reburn is that the former is generally compatible with, but does not require, the installation and operation of SOFA. The staged reburn fuel is introduced into an oxygen-rich atmosphere downstream of the burners and any OFA injection points. The amount of reburn fuel injected is typically limited by acceptable carbon monoxide levels in the boiler exit flue gas.

There are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. This is significant, especially for alternatives with FLGR™ technology when combined with basic or advanced SOFA to allow the natural gas introduced above the SOFA ports to burn completely prior to the furnace exit plane. In either case, the amount of additional potential NOx reduction possible with FLGR™ is limited, since the reburn fuel injection location is expected to coincide with the existing lignite pre-drying system vent ports. The amount of oxygen introduced by the vent ports will be disruptive to the fuel-lean reburn process in that it would require much higher reburn fuel injection rates in the lower secondary furnace to promote in-furnace NO_X reduction. There are reduced concerns that the withholding of a modest amount of heat input from the cyclone barrels to use natural gas as a source of reburn fuel may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction is an optional part of this reburn technique which will further risk slag "freezing" in the barrels and lower furnace.

Fuel lean gas reburn can be applied and installed on MRY Station Unit 1's boiler with or without SOFA/ASOFA. This technique is considered technically feasible for application to MRY Station Unit 1's boiler. Expected NO_X reduction will be modest for FLGR™ without SOFA and FLGR™ with a basic form of SOFA. Unit operating and capital costs to supply large quantities of gaseous fuel not currently available at this site are economic disadvantages. Because of these factors, these variations of this technology will not be cost-effective compared to other alternatives with similar control effectiveness. FLGR™ without SOFA and FLGR™ with a basic form of SOFA were not included in the control effectiveness and cost-effectiveness sections of the main report.

Other demonstrated forms of fuel lean gas reburning in combination with post-combustion technologies, such as amine-enhanced fuel lean gas reburn (FLGR™ with SNCR), are discussed under the layered technologies section.

A.1.2.7.4 Fuel Oil Reburn

Fuel oil has been substituted for natural gas in a conventional reburn application. This is much less common in the United States than using natural gas as a reburn fuel, due to the general lack of demand and difficulties in supplying the volume of fuel oil which would be required. It has been installed commercially on three 350 MW oil-fired boilers in New Brunswick (Canada) at the Coleson Cove plant. NO_X emissions reduction with reburn and SOFA was 78% with 25% of the boiler's total fuel heat input supplied in the reburn zone. This yielded 0.22 lb/mmBtu NO_X emissions from a baseline of 1.0 lb/mmBtu[9]. No examples of conventional fuel oil reburn applied to a coal-fired cyclone boiler were found in available literature.

Fuel oil reburn could potentially be considered for application to MRY Station Unit 1 and Unit 2 boilers. Investigation of the specific source, distance, and costs for supplying significantly increased quantities of fuel oil via transport trucks hauling tanker trailers or underground pipeline to M.R. Young station has not been performed. The unit operating and capital costs to supply large quantities of high-volume liquid fossil fuel at this site are economic disadvantages. The concerns regarding potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application are similar to those expressed for conventional gas reburn. It is believed that potential NO_X control with oil reburn would be slightly less than comparable conventional gas reburn systems.

Although fuel oil reburn could potentially be considered for application to MRY Station Unit 1's boiler, the lack of any distinct potential NO_X reduction advantages and demonstration on cyclone-fired boilers does not appear to support its consideration. This alternative was not included in the NO_X control and cost-effectiveness analysis.

A.1.3 Post-Combustion Controls

Post-combustion controls deal with techniques that thermally or chemically-treat the flue gases to reduce NO_X emissions after they have exited the boiler's lower furnace. In the case of Milton R. Young Station Unit 1, this primarily involves forms of selective catalytic reduction (SCR) and selective non-catalytic reduction (SCR) technologies. Another emerging technology that has recently entered the commercial market is Powerspan's Electro Catalytic Oxidation®, which treats utility boiler flue gas for removal of nitrogen oxides, sulfur oxides, and mercury. Another emerging technology that has recently entered the commercial utility air pollution control market is Powerspan's Electro Catalytic Oxidation®, which treats boiler flue gas for removal of nitrogen oxides, sulfur oxides, and mercury.

A.1.3.1 Selective Non-Catalytic Reduction (SNCR)

Selective Non-Catalytic Reduction (SNCR), and variations such as hydrocarbon-enhanced SNCR (sold under the trade name of NOxStar™), and Rich Reagent Injection (RRI), are all post-combustion types of boiler NO_X emission controls. While these technologies are insensitive to the specific fuel types whose combustion products are being treated, the large majority of boiler applications to date have been on pulverized coal-fired units burning eastern bituminous fuels. SNCR has been used to reduce NO_X emissions on numerous utility boilers burning eastern bituminous coal, midwestern bituminous coal, and, to a lesser extent, western subbituminous coal. SNCR has also been used with fuel oil and natural gas-fired units. SNCR (and hydrocarbon-enhanced SNCR) technologies can each be applied to cyclone boilers with or without the use of a SOFA system. SNCR does not appear to be dependent directly on the type of burners (wall-fired, tangentially-fired, and cyclone-fired) employed in the boilers where it has been installed, with or without overfire air in full operation. Operation at these plants has demonstrated that SNCR can decrease NO_X emissions as much as 15-40% at full load, most typically between 25-35 percent[19].

In the conventional SNCR process, urea or ammonia is injected into the boiler in a region where the combustion gas temperature is in the 1700 to 2100 degrees F range. Under these temperature conditions, the urea reagent [$CO(NH_2)_2$] or ammonia [NH_3] reacts with the NO_X, forming N_2 and water, reducing NO_X emissions.

Long-term examples where SNCR has been used to reduce NO_X emissions on two cyclone-fired boilers are on a 138 MW unit and 160 MW unit burning eastern bituminous coal at Conectiv's B.L England Station (Units 1 and 2) since 1995 and 1996, respectively. Tests at these plants demonstrated that SNCR can decrease NO_X emissions as much as 30-36% at full load, from around 1.3-1.4 lb/mmBtu respectively to as low as 0.85 lb/mmBtu (without overfire air)[18,19,20]. These boilers, located near Atlantic City, New Jersey, continue to operate SNCR (with OFA) for annual NOx emissions around 0.55 and 0.45 lb/mmBtu, respectively.

SNCR can be applied and installed on MRY Station boilers. Estimated NO_X emission rates for using SNCR with North Dakota lignite considered published levels achieved by cyclone-fired units firing western subbituminous coal, and vendor predictions. SNCR alone is expected to reduce NO_X emissions approximately 37% from MCR baseline levels (down to around 0.5 lb/mmBtu) for the MRY Station Unit 1 boiler with ammonia slip limited to approximately 5 ppmvd. Because of the operating costs of the consumed reagent, this technology will not be cost-effective compared to other alternatives with similar control effectiveness (i.e. SOFA), SNCR alone was not included in the control effectiveness and cost-effectiveness sections of the main report.

Other demonstrated forms of SNCR-related technologies, such as Rich Reagent Injection with SNCR, and amine-enhanced fuel lean gas reburn (FLGR™ with SNCR), are discussed under the layered technologies section.

A.1.3.2 Hydrocarbon-enhanced SNCR (NOxStar™)

Hydrocarbon-enhanced SNCR technology, commercially marketed as NO_XStar™, is offered by a single vendor (Mitsui Babcock) as a post-combustion type of enhanced SNCR technology, whereby an ammonia-based reagent is continuously injected into the superheater/reheater pass of an operating boiler with small amounts of gaseous hydrocarbon (typically either natural gas or propane) and air or steam to provide lance cooling and aid reagent dispersion. The targeted combustion gas temperature range is between 1500°F and 2000°F. The amount of gaseous hydrocarbon introduced is small enough (0.1 to 0.2% of total fuel heat input) that this is not intended to act as a form of reburn or staged fuel combustion. An array of permanently-installed injection lances are located within the boiler convection pass, divided into numerous discrete zones across the full width and height of the duct. The hydrocarbon auto-ignites, forming hydroxyl (OH) radicals which react with the NO_X and ammonia to produce elemental nitrogen (N_2) and water vapor (H_2O).

NO_XStar™ was demonstrated at Tennessee Valley Authority's Kingston Power Station Unit 9 (tangentially-fired 200 MW twin-furnace boiler firing eastern bituminous coal) in 2002[21]. This technology was subsequently permanently-installed at TVA's Colbert Station Unit 4 in late 2003 on a 192 MW wall-fired boiler burning eastern bituminous coal[22]. NO_X reduction was stated as 68-80% for these applications, which included the impact of overfire air and air-staged combustion upstream of the ammonia and propane injection locations.

An example of a hydrocarbon-enhanced SNCR installation on a wall-fired pulverized fuel boiler is shown as a sectional side elevation view of the upper furnace in Figure A.1-3.

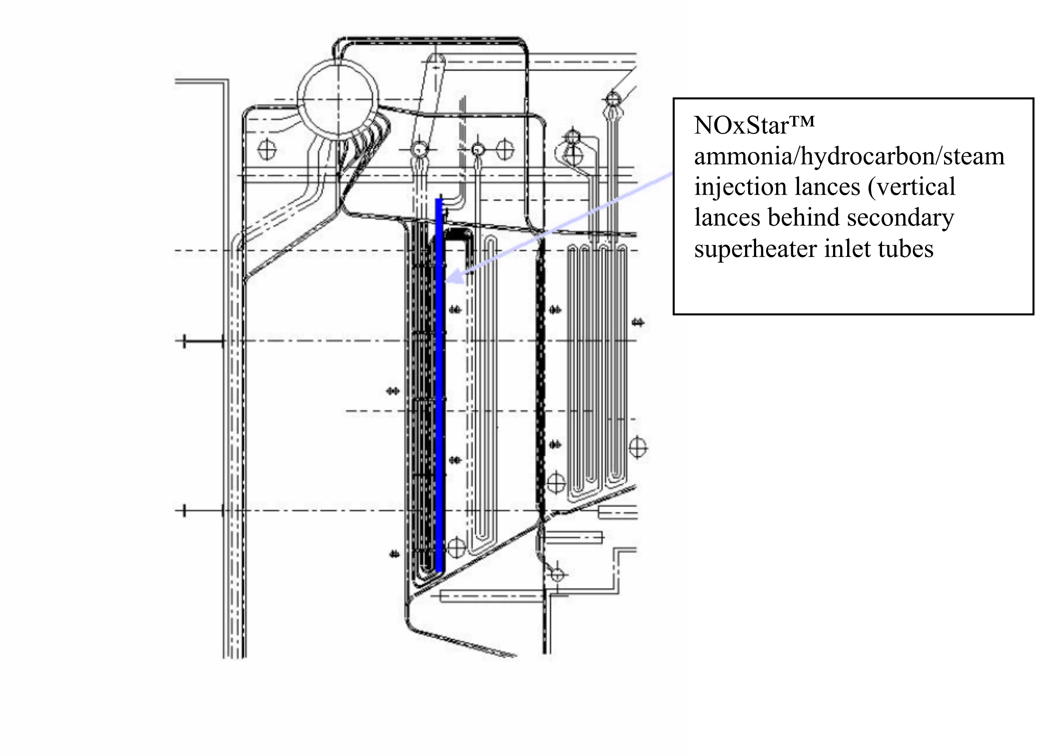


Figure A.1-3 Hydrocarbon-enhanced SNCR Application on PC-fired Boiler[22]

The supplier (Mitsui Babcock) of hydrocarbon-enhanced SNCR technology claims there is little sensitivity to the type fuel (coal) or burners this technique can be potentially applied to in order to reduce NO_X emissions. The chemical reagent injection for hydrocarbon-enhanced SNCR (NO_XStar™) NO_X control technology must be precisely located and carefully controlled to be effective. Operation outside of the required operating ranges can even result in increased NO_X emissions. Extensive computational fluid dynamic (CFD) model simulations are needed to determine the optimum injection points and spray patterns. Boiler operating conditions change with unit load and varying fuel characteristics. The NO_XStar™ process control system must be able to adjust for these changing conditions in order to be effective throughout the intended load range and firing conditions encountered. Non-retractable ammonia injection lances arranged in a parallel-series manner are permanently mounted inside the upper furnace zone, attached to convective tube elements. Different sections of the injection "grid" can be turned off or on, depending on load and firing conditions and amount of NO_X reduction required. Injection nozzles are continuously purged and cooled by extracted superheated steam from the boiler's main steam outlet, whether ammonia reagent is being introduced into the flue gas stream or not. Ammonia slip can be minimized by injecting less reagent, although NO_X control performance will be reduced.

There are a number of issues with firing North Dakota lignite that make the applicability of hydrocarbon-enhanced SNCR infeasible compared to previous experience in other coal-fired powerplants. These issues include:

- Hydrocarbon-enhanced SNCR (NOxStar™) technology has not been applied to cyclone boilers (with or without the use of a SOFA system). It has been only applied to date on pulverized coal-fired boilers burning eastern bituminous fuels.
- There is no successful demonstrated full-scale experience in continuous service of hydrocarbon-enhanced SNCR (NO_XStar™) technology on units firing high-slagging coals such as western subbituminous (PRB) and lignite. The heat transfer surfaces in the convective heat transfer zone where the reagent mixture is injected are prone to severe fouling from flyash constituents common in North Dakota lignite coals. Flyash deposit accumulation on the outside of the NO_XStar™ lances in Milton R. Young Station Unit 1 boiler's upper furnace is expected to be significant, potentially occurring within a matter of a few weeks from startup and nearly impossible to prevent or remove effectively during boiler operation. Such buildup is expected to cause maldistribution of the NO_X reduction chemical reagent from the injection nozzles. Effective on-line removal of these deposits from the injection nozzles is anticipated to be insufficient to maintain effective injection distribution and volume control. It is anticipated that this would significantly reduce the NO_X emission reduction performance consistently achieved on a sustainable basis.

The lack of experience with cyclone boilers, especially those firing coal with severe deposition characteristics such as North Dakota lignite, makes this technology technically infeasible for application on the Milton R. Young Station Unit 1 boiler.

A.1.3.3 Rich Reagent Injection (RRI)

Rich Reagent Injection (RRI) is a NO_X control process that has been developed and demonstrated specifically for use on cyclone boilers. Rich Reagent Injection is an SNCR process that involves the injection of aqueous urea into the lower furnace between the cyclones and the SOFA ports. RRI targets a high temperature, fuel-rich zone within the boiler-furnace environment immediately adjacent to the cyclone burners, and requires temperatures in the range of 2400 to 3100 degrees F.

The three zones of a Rich Reagent Injection SNCR application on a boiler with separated overfire air are shown as a sectional side elevation view of the furnace in Figure A.1-4.

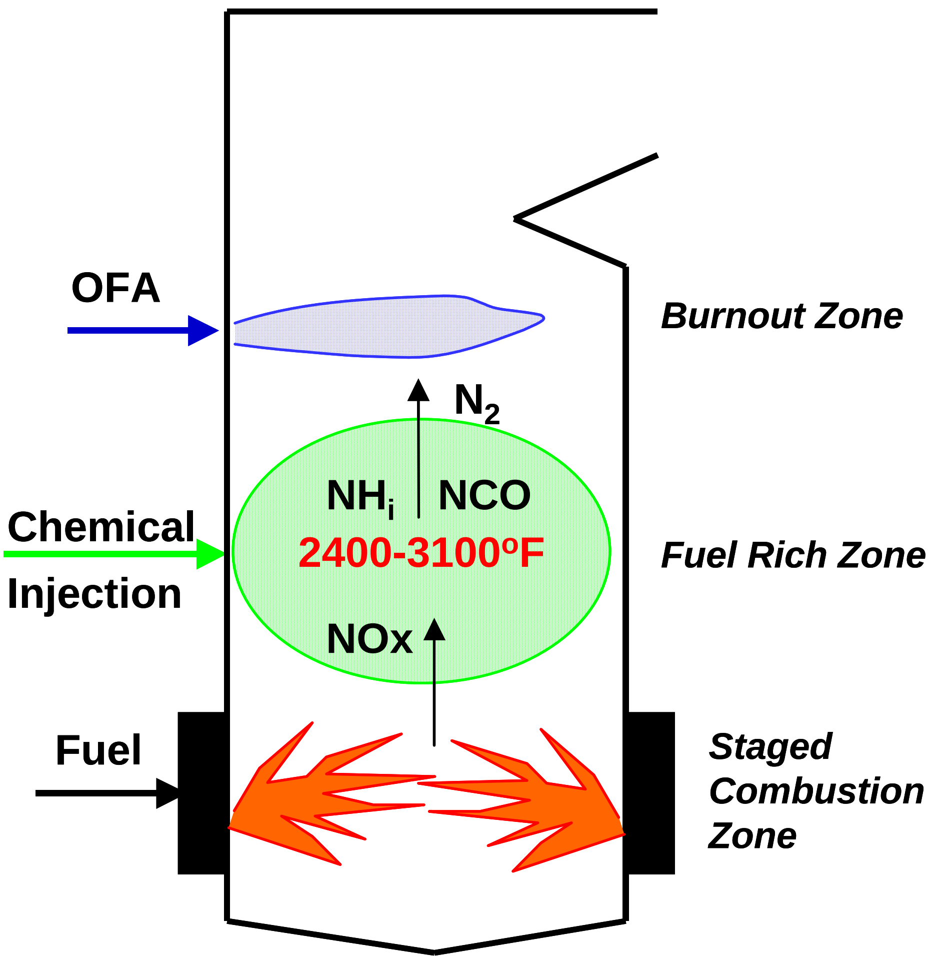

Figure A.1-4 Rich Reagent Injection Application on Boiler With Overfire Air[23]

The Rich Reagent Injection (RRI) process has been successfully demonstrated on at least two cyclone-fired boilers, with the most recent installation at Ameren's Sioux Unit 1, a 500 MW boiler firing a blend of PRB and midwestern bituminous coals. Generally, the heat content of these coals typically varies very little. Short-term testing of the RRI process has been performed alone and in combination with SNCR on B.L. England Unit 1 in 1999[24,25], and more recently at Ameren's Sioux Unit 1 in 2002[23,25], in 2004[26] (alone), and in the first half of 2005[27] (alone, and with SNCR).

The RRI process is intended to be used only with air-starved (substoichiometric staged-air) cyclone combustion, in conjunction with the installation and operation of an OFA system. The RRI process has not been demonstrated on any unit that fires North Dakota lignite. As of May 2006, no commercial installation of a permanent Rich Reagent Injection system has been made at any cyclone-fired boiler.

There is only one holder of a commercial license for modeling and conceptually designing RRI (Reaction Engineering International), with two vendors sub-licensed to design and sell RRI equipment (Fuel Tech and Combustion Components Associates). Since these license agreements are in place, and considering that successful demonstration testing has been performed at two cyclone-fired boiler powerplants, this technology is considered to be applicable and commercially available for potential application on cyclone boilers which burn coals with heat contents that are relatively constant. However, due to the variable heat content of lignite coal, RRI is considered to be technically-infeasible for application on North Dakota lignite-fired boilers. Technical feasibility and expected NO_X emissions from RRI for application on the Milton R. Young Station Unit 1 boiler are included in the "Layered NO_X Reduction Technologies" section.

A.1.3.4 Selective Catalytic Reduction (SCR)

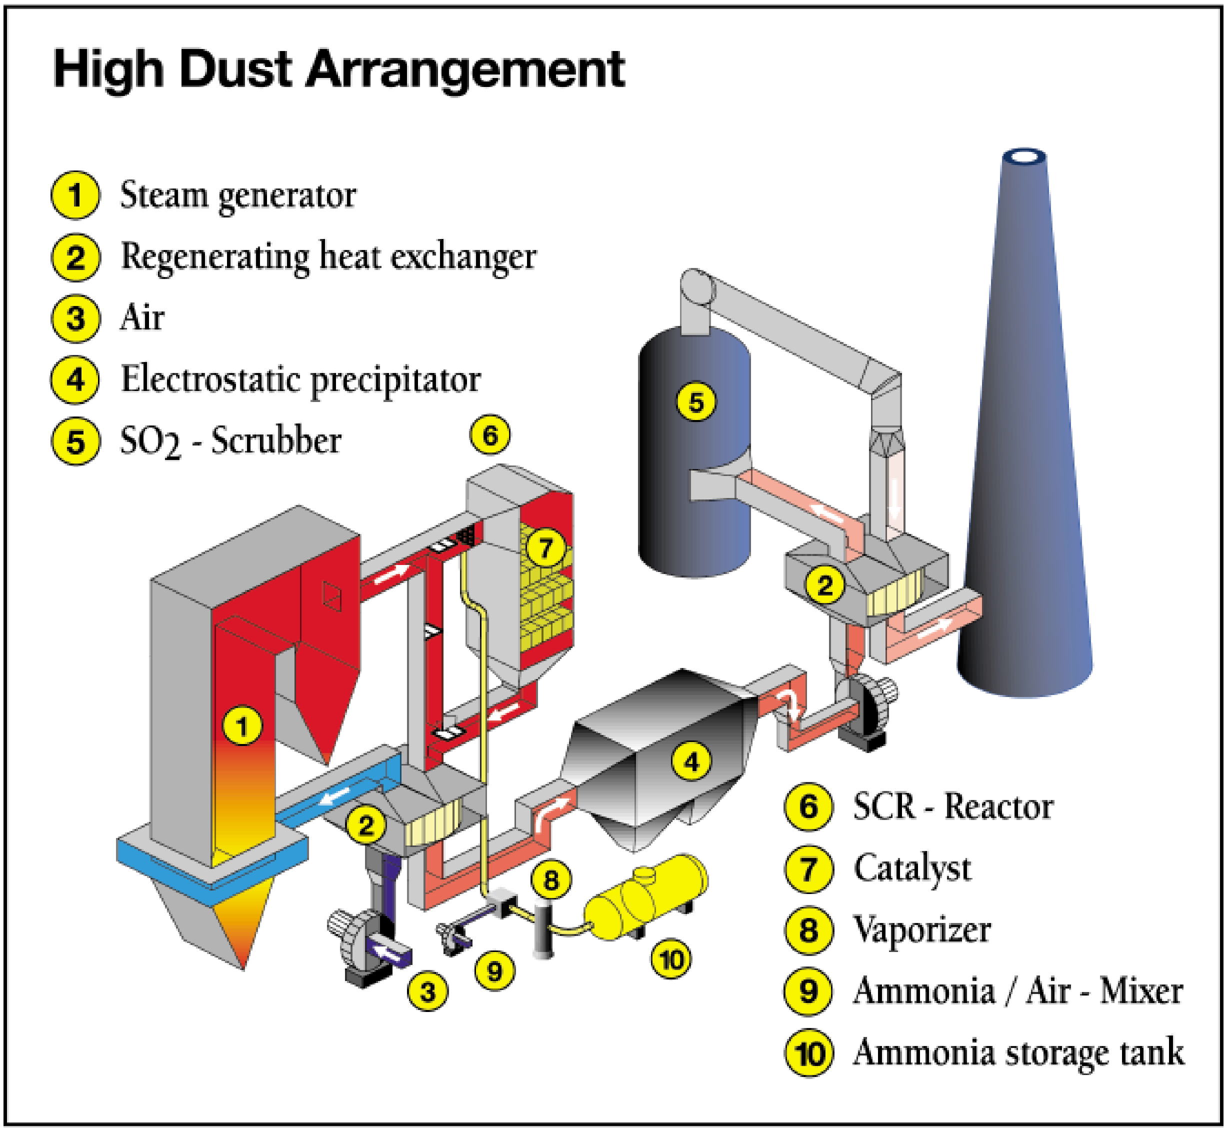
The lowest NOx emission levels from coal-fired utility boilers are typically achieved by installing and operating selective catalytic reduction (SCR) technology. In the SCR process, the gas stream is passed through a catalyst bed in the presence of ammonia to reduce NO_X to molecular nitrogen and water. The process is termed "selective" because the ammonia preferentially reacts with the NO_X rather than with the oxygen in the flue gas. A catalyst is used to enhance NO_X reduction and ammonia utilization at appropriate flue gas temperatures. SCR is usually applied to flue gas in the 600°F to 750°F temperature range. There are variations in the SCR process for coal-fired boilers that mostly involve locations in the flue gas path where the catalyst is placed in order to promote the desired NO_X emission reduction effect. These are described below.

A.1.3.4.1 High-Dust Selective Catalytic Reduction (HD-SCR)

For coal-fired boilers, a conventional SCR reactor utilizes readily-available catalyst materials and reagent in the form of ammonia. A conventional SCR reactor is commonly installed in a high-dust, hot-side arrangement, located between the economizer outlet and air heater inlet, where the flue gas temperature is within the desired operating range for the SCR catalyst. The conventional SCR reactor arrangement is preferred for most coal-fired applications in utility boilers because it avoids the added expense of reheating the flue gas if placed after the air heaters which cool the flue gas, and downstream of any flue gas treatment to remove acid gases. Conventional SCR technology uses an ammonia injection grid (AIG), which consists of multiple nozzles, for distributing the reagent into the flue gas at the boiler's economizer flue gas outlet.

A schematic graphic diagram for a conventional high-dust, hot-side SCR system on a boiler with a flue gas desulfurization system and stack gas reheat is provided in Figure A.1-5.

Figure A.1-5 Conventional High-Dust SCR Arrangement with FGD Scrubber Outlet Reheat



(figure copied from Wheelabrator Air Pollution Control literature)

Conventional high-dust, hot-side SCR technology has been installed on several pulverized coal and cyclone boilers firing bituminous and subbituminous coal in the United States. There are also a limited number of European SCR installations on steam electric generating units (SEGUs) firing lower grade (brown) coal. There are, however, no existing full-scale SCR installations on units that fire North Dakota lignite. There are approximately 50 cyclone-fired units located in the states affected by EPA's NO_X SIP call. Over half of these units are planning to install conventional high-dust, hot-side SCR systems in response to the SIP call. The installation of conventional high-dust, hot-side SCR systems has been completed on approximately 22 of these units. Appendix A2 lists several conventional high-dust hot-side U.S. SCR installations on pulverized coal and cyclone-fired utility boilers, along with measured NO_X emissions. Initial data from these units indicate that conventional high-dust, hot-side SCR systems operated on suitable cyclone-fired units may be able to reduce NO_X emissions to as low as 0.07 lbs/mmBtu. Several SCR installations have been retrofit on existing cyclone-fired boilers burning western subbituminous coal (or PRB blended with midwestern bituminous coal). For cyclone coal-fired utility boilers retrofitted with SCR technology, all were originally designed to burn bituminous coal.

The EPA NO_X SIP call only applies to units in the eastern United States. There are no facilities firing North Dakota lignite in the EPA NO_X SIP call region. SCR system operation is currently only needed during the ozone season (June – September) for units installing control equipment solely to meet the EPA NO_X SIP call requirements. Limited annual operation is a significant factor with respect to SCR equipment reliability, maintenance, operational costs, and catalyst life. The demands on the SCR system are much more severe if the equipment is required to operate on a full-time, annual basis.

Two byproducts from the high-dust, hot-side SCR process are ammonia slip and SO_3:

- Ammonia Slip: Slip is ammonia that is unreacted in the NO_x emission reduction process. Maximum ammonia slip for a gas fired unit is usually 10 ppmvd whereas, on a coal fired unit, ammonia slip below 5 ppm is desired. For certain applications, this concentration can be problematic, therefore requiring more catalyst to reduce slip. Most new SCR applications have ammonia slip guaranteed at a 2 ppmvd maximum for an initial operating period.
- SO_3: Due to the composition of typical SCR catalysts, a small percentage of inherent SO_2 will be oxidized to SO_3. This oxidation can be controlled by catalyst selection and can be less than one percent. SO_2 to SO_3 oxidation must be carefully controlled to avoid creating SO_3 levels sufficiently high to raise the possibility of air heater fouling. A unit firing high-sulfur coal with SCR technology is especially vulnerable to SO_3 oxidation and ammonia slip-related fouling problems. The deposition and fouling is due to formation of solid ammonium sulfate ($(NH_4)_2SO_4$) and liquid ammonium bisulfate (NH_4HSO_4). The most important design variable is optimizing the catalyst selection and amount of catalyst that will reduce NO_X emissions, control ammonia slip, and minimize SO_2 oxidation.

Recent technology has allowed catalyst suppliers to make more rigorous and lengthy guarantees. A reasonable initial operating period for conventional catalysts in high-dust reactor arrangements on boilers firing eastern or midwestern bituminous coal is around 24,000 active operating hours (i.e. when ammonia reagent is being injected). Factors that need to be taken into account in design of a high-dust, hot-side SCR application that affect the need for catalyst replacement are:

- Pressure drop: The amount of restriction to flue gas flow through the SCR inlet, ammonia injection grid, SCR reactor, and downstream ductwork directly increases induced draft fan horsepower required to maintain adequate boiler draft. This is an important parameter to consider and minimize during the design stage. Pressure drop is a function of the average and maximum SCR reactor duct velocities, the amount of restriction caused by flow distribution correction devices (baffles or vanes), and the number and geometrical aspects of the catalyst layers. Many retrofit SCR installations require a booster fan or upgraded induced draft fan to overcome the added flow resistance. This increases operating cost for the increase in auxiliary power consumption and loss of saleable electric power. The type and pitch of the catalyst are factors most influential in determining the amount of pressure drop.
    - Catalyst type: The most common types or forms of catalyst material are honeycomb or plate. The former offers more surface area per volume, but can be more restrictive and prone to pluggage from ash deposits. The latter is usually less restrictive but requires more catalyst per layer or more layers to achieve the active surface needed to achieve the intended NO_X emission reduction.
    - Catalyst pitch: The pitch of the catalyst, a term used to describe the size of the gas path openings through the catalyst, varies depending on the manufacturer and design dust loading. Pitch is generally on the order of 5 to 7 millimeters. Potential pluggage of flow channels within the catalysts layers is therefore an issue that must be dealt with during design.
- Catalyst performance: The amount of NO_X emission reduction expected is a function of the specific activity level of the catalyst material and the amount of catalyst installed, over a given period of time. Catalyst formulation selection and features of construction have a significant impact on long-term NO_X emission reduction and subsequent costs for reagent and catalysts replacement. The frequency of catalyst replacement is influenced strongly by:
    - Catalyst erosion: Erosion of the catalyst material in coal fired units from entrained flyash or sootblowing action reduces the amount of active surface available for reacting with the reagent and flue gas, and can cause distortions in gas distribution (“channeling”) through the

SCR reactor. Catalyst material is fragile and can be easily damaged. Some catalyst is provided with erosion-resistant top edges to mitigate this tendency.

- Moisture absorption: Many types of catalyst are damaged by absorption of moisture. The reactor must be kept above ambient dewpoint temperatures or protected from freezing during outages in order to protect the catalyst from moisture damage. Spare catalyst must be carefully packaged to keep it dry and must be handled delicately to prevent damage.
- Thermal degradation: The specific active elements of the catalyst surface, or the matrix structure itself upon which the catalyst material is applied, can degrade when exposed to flue gas temperatures greater than the intended design of the formulation. High flue gas temperatures within the reactor causes sintering, leading to a permanent loss of catalyst activity due to a change in the pore structure of the catalyst. Proper selection and manufacturing control of the catalyst structure and formulation can minimize thermal degradation.
- Catalyst poisoning: The loss of performance or activity of the catalyst over time can be due to chemical damage or poisoning. Two elements especially detrimental to the life of common titanium-supported vanadium pentoxide SCR catalyst are arsenic and zinc. Vanadia/tungsten-based catalysts are particularly susceptible to rapid deactivation due to gaseous arsenic poisoning. In some German SCR installations, a 50% loss of activity has been reported within 10,000-15,000 operating hours. Addition of molybdenum to a vanadia-titanium SCR catalyst on similar applications shows relative activity reductions of 20-25%. Progressive loss of SCR NO_X reduction performance from catalyst deactivation due to poisoning is not possible to restore without effective cleaning to remove the deposits, or eventual replacement.
- Catalyst fouling: The surface area potentially exposed to the reagent (ammonia) and nitrogen oxides in the flue gas can become fouled with flyash or sulfur-related compounds. The presence of excess calcium oxide in the presence of sulfur in the flue gas can form a calcium sulfate surface coating that can be extremely dense, masking the pores of the catalyst. Progressive loss of SCR NO_X reduction performance from catalyst deactivation due to fouling is difficult to restore without effective cleaning to remove the deposits, or eventual replacement.

SCR technology has been installed on numerous coal-fired utility boiler facilities around the world and there are a large number of manufacturers that market the catalysts. The question is whether SCR is a feasible technology for a unit firing North Dakota lignite. There are serious concerns whether installation of SCR technology on a North Dakota lignite-fired unit can be successful, especially in a conventional "hot-side, high-dust" configuration. The effectiveness of the SCR process is highly dependent upon the ability of the nitrogen oxides in the flue gas being able to contact the active sites within microscopic pores of the catalyst in the presence of ammonia reagent with minimal interference from contaminants.

A recent technical paper "Ash and Mercury Behavior in SCR Catalysts When Firing Subbituminous and Lignite Coals" by the Energy & Environmental Research Center (EERC) of the University of North Dakota was published in the February 2005 issue of Fuel Processing Technology magazine[28]. This paper summarized the results of SCR slipstream testing at two PRB-fired plants and one North Dakota lignite-fired powerplant. The evaluation included determination of impacts of ash on SCR plugging and blinding. Flue gas was isokinetically extracted from the convective pass of the boiler upstream of the air heater. Pressure drop across the catalyst was measured during the initial two-month test period, and the two consecutive two-month test periods following the initial trial, while holding flue gas flow and temperatures constant. Ammonia was injected downstream of a screen, upstream of a flow straightener and air pulse section. Compressed air was injected ahead of the reactor, and was periodically pulsed to simulate sootblowing to minimize ash deposit accumulation.

This slipstream SCR testing examined the significance of ash accumulations on SCR catalyst on both the macroscopic and microscopic levels. Very small flyash particles were found bonded together by a matrix of sodium-, calcium-, and sulfur-rich materials, likely in the form of calcium sulfate. North Dakota lignite coal contains many alkali and alkaline-earth elements, and sulfur. The firing of lignite coal which produces fine (less than 5-µm diameter) flyash particles creates conditions that enter the pores of the catalyst, react with SO_3 in the flue gas, and form sulfates which bind other ash particles into the matrix.

As posted on Electric Power Research Institute Inc.'s (EPRI's) website regarding the impact of coal type on SCR catalyst life and performance, a recent EPRI study[29] produced field data analyzed from an "In-Situ Mini SCR Reactor" system installed in a typical "high-dust" location at seven different test sites, including four firing PRB coal, one firing Texas lignite, one firing high-sulfur eastern bituminous coal, and one firing a PRB/eastern bituminous coal blend. The PRB/bituminous coal blend test was performed at AmerenUE's Sioux Station, on one of the two 500 MW cyclone-fired boilers. This study found that the cyclone unit firing the PRB/bituminous coal blend exhibited the fastest rate of catalyst activity degradation. Also, the higher deactivation rates seen at this site were due to economizer exit flue gas temperatures being significantly higher than at the other sites. A comparison of the Texas lignite and one of the PRB-fired sites with two different catalysts, deactivation was more a function of trace elements in the flue gas and flyash than the specific catalyst type or formulation.

North Dakota lignite produces an ash that is very sticky and creates severe ash deposition problems. There have been no installations of SCR systems (full-scale) on units that fire North Dakota lignite. A technical assessment was conducted for the installation of SCR technology on a North Dakota lignite unit. In order to further evaluate the feasibility of installing a conventional SCR system on a North Dakota lignite fired unit, the Energy & Environmental Research Center (EERC) at the University of North Dakota was consulted. EERC has extensive experience investigating the deposition characteristics of North Dakota lignite ash.

Technical difficulties and anticipated operating problems that are unresolved with respect to installing conventional SCR technology at Milton R. Young Station include the impacts of erosion, severe ash deposition, and "popcorn ash" on the catalyst. According the EERC's study (see Appendix B), "the most significant problems that prohibit the successful operation of SCR catalysts to lignite coal is the formation of low-temperature sodium-calcium-magnesium sulfates and phosphates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency". For these reasons, application of available conventional high-dust SCR technology is considered technically infeasible for Milton R. Young Station Unit 1 and Unit 2 boilers. These concerns can be divided into four categories. Each category is addressed below. An explanation of the factors that make conventional SCR technology infeasible for these boilers follows:

1. Ash Deposition: North Dakota lignite contains a variable and complex variety of inorganic compounds that contribute to ash deposition. This fuel produces ash with severe deposition characteristics that are not typical with other coals. When exposed to the heat of the combustion process inside the cyclone burners, the majority of the fuel ash becomes molten and flows into the bottom of the furnace. A significant portion of the fuel ash is entrained into the flue gas exiting the cyclone barrels at high velocity, where it comes into contact with the lower furnace waterwalls. The portion that is carried with the rising flue gas cools and some is deposited on heat transfer surfaces in the upper furnace and boiler convection pass. Ash deposition on heat transfer surfaces is a substantial problem for units that fire North Dakota lignite. The problem is so severe at Milton R. Young that the Unit 1 boiler must be shut down at 120-day intervals to

allow for cleaning of ash deposits from the boiler heat transfer surfaces in order to restore reasonable furnace exit gas velocities and temperatures.

Sodium is a significant contributor to the "stickiness" of the ash produced from firing North Dakota lignite. Sodium content of the lignite ash averages approximately 4.4%, and can nearly double this value for some of the lignite produced from the Center mine. PRB coal typically averages around 1.5% sodium content. Boilers firing North Dakota lignite typically have a 2.5% higher heat rate (million Btu per kilowatt of electric generation) than a typical boiler firing PRB coal, thus requiring more heat input and firing more fuel per megawatt of electricity output. A cyclone boiler firing North Dakota lignite also converts approximately 50% of the fuel ash to flyash, compared with a 35% conversion rate for PRB coal-fired cyclone boilers. Overall, this results in an amount of sodium emitted from a cyclone boiler firing North Dakota lignite of approximately 7.3 lbs/MW-hr compared with 0.9 lbs/MW-hr for a PRB-fired cyclone boiler.

The catalysts in coal-fired boiler SCR reactors are highly susceptible to ash deposition. In a typical conventional high-dust SCR reactor, the flue gas typically passes through two to four layers of catalyst modules. The catalyst modules have numerous narrow passages to provide intimate contact between the flue gas, ammonia and catalyst. The clearance (pitch) in these passages is typically 6-10 millimeters. A typical catalyst layer is approximately 1 to 1.5 meters deep. The catalysts in coal-fired boiler SCR reactors must be cleaned frequently using soot blowers and/or sonic horns. This is true even on units firing fuels that do not produce a sticky ash that contributes to ash deposition. Ash deposition on the catalyst in a high-dust SCR application would be severe for a unit firing North Dakota lignite.

Sulfur in the coal is oxidized during excess air combustion to form sulfur dioxide (SO_2), and a small amount of sulfur trioxide (SO_3). Some of the ammonia-based reagent injected upstream of the SCR reactor will combine with SO_3 to form ammonium bisulfate. The catalyst in the SCR reactor will also oxidize a portion of the SO_2 to SO_3. Excess unreacted ammonia reagent carryover ("ammonia slip") from the SCR reactor will also react with these sulfuric acid compounds in a similar fashion. The deposition characteristics for a unit burning North Dakota lignite will create difficult-to-remove ash deposits and pluggage of a conventional high-dust catalyst, and increase the probability that the air preheater downstream and flue gas ductwork will be prone to accumulations which could be severe. High-dust SCR performance and catalyst life will be severely impacted. It is anticipated that a high-dust SCR's catalyst life will be shortened from 3-6 years (typical) to as little as 2-12 months, requiring extended, frequent outages for replacement.

Hot-side air preheaters are susceptible to fouling. Tubular air pre heaters originally supplied with all cyclone boilers also tolerate moderate dust loadings, since their height and size make them difficult to maintain cleanliness. Leak tightness of the air preheater is important on cyclone-fired boilers with relatively high forced draft fan discharge (combustion air supply) pressures. A high-dust SCR installation will be prone to air preheater tube fouling and pluggage, requiring extended, frequent outages for cleaning.

2. "Popcorn Ash": A second consideration in the application of conventional high-dust SCR technology on a lignite-fired unit is the potential of the SCR reactor catalyst pluggage resulting from carry over of "popcorn ash" from the boiler. Boilers firing North Dakota lignite have severe problems with ash deposition on boiler surfaces. North Dakota lignite has a high propensity to form deposits on the boiler's furnace and convection pass fireside surfaces. For lignite-fired units, the boiler's heat transfer surfaces must be cleaned by sootblowing and other methods (e.g. water lances) frequently to maintain satisfactory boiler operation. Some of the removed deposits released by the cleaning action within the boiler and convection passes form "popcorn ash", which will be entrained in the flue gas. Carry over of boiler ash deposits will contribute to pluggage of the "popcorn ash" screen ahead of the top layer of SCR reactor catalyst. This can cause distortions in gas distribution ("channeling") through the SCR reactor, which will aggravate erosion in the high velocity areas and ineffective performance of the catalyst.

3. Temperature: A third issue that impacts the feasibility of installing high-dust SCR technology on the North Dakota lignite-fired units is catalyst operating temperature. The performance of any SCR catalyst is highly dependent on the temperature of the flue gas passing through the reactor. Typically, a temperature of 600 – 750 degrees F is required to obtain satisfactory operation of an SCR reactor. Operation of commonly supplied catalyst suitable for a high-dust SCR reactor at temperatures above 750 degrees results in severe and rapid deterioration of the catalyst and SCR reactor's NO_X emission reduction performance. For bituminous and sub-bituminous coal-fired units, boiler flue gas passing between the economizer outlet and air heater inlet is generally

within a temperature range acceptable for conventional SCR catalysts without additional heating or cooling of the flow stream.

North Dakota lignite-fired cyclone boilers, including those at Milton R. Young Station, have high temperatures at the economizer's flue gas outlet by design. The highest gas temperatures downstream of the convection pass economizer sections and upstream of the air heater inlets in Milton R. Young Unit 1's boiler are much higher than 750 degrees.

High gas temperatures at the air heater inlet are required to produce the high air temperatures (700°F) needed for the pre-combustion lignite drying system, along with primary and secondary combustion air supplied to the cyclones. Such air preheater arrangements and capabilities have been taken into account in the design of the North Dakota lignite-fired cyclone boilers. Reducing this high gas temperature to accommodate conventional catalysts for a conventional high-dust SCR reactor would result in pre-combustion air temperatures that are too low to provide satisfactory drying and rapid ignition of the high-moisture fuel. This will seriously impact reliable combustion, slag formation and tapping in the cyclone burners. Consequently, it is not feasible to modify the Milton R. Young Unit 1's boiler to operate with the lower economizer outlet flue gas temperature.

Catalysts for a conventional high-dust, hot-side SCR system have not been installed nor successfully demonstrated in a full-scale installation of an operating solid fuel-fired unit that are designed to continuously operate at the high temperatures (above 750 degrees F) that exist between the convection pass economizer and air heater on the Milton R. Young Unit 1's boiler.

4. Erosion: A final consideration on whether hot-side, high-dust SCR technology can be successful on a North Dakota lignite-fired unit is the potential for erosion of the SCR catalyst. North Dakota lignite supplied from the Center mine has an average fuel ash content of 10.5%, and can have an ash content up to 25.5 percent. PRB coal fuel ash content typically averages approximately 5 percent. As previously stated, a cyclone boiler firing North Dakota lignite converts a significantly greater amount of flyash than a PRB-fired cyclone boiler. Overall, this results in a flyash output rate from a cyclone boiler firing North Dakota lignite of approximately 83 lbs/MW-hr compared with 21 lbs/MW-hr for a PRB-fired cyclone boiler. High ash contents in the flue gas stream can result in physical erosion of the catalyst. In addition, effective on-line cleaning of the

high-dust catalyst will likely require steam or compressed air sootblowing. Cleaning cycles of the catalyst will be required much more frequently than a typical conventional SCR installation due to the ash deposition characteristics of the North Dakota lignite and the expected buildup and pluggage resulting from the carry over of "popcorn ash". Frequent sootblowing of the catalyst to remove fouling deposits and ash accumulations will contribute to erosion and decreased catalyst life. There is some European experience with high ash brown coals that catalyst manufacturers will be able to draw upon. This experience, however, will not be directly applicable to these United States units because of the severe deposition characteristics of the North Dakota lignite ash compared to brown coal.

The EPA's NSR Manual states that for a technology to be feasible it must "available and applicable". SCR technology is an available technology which has been installed on numerous powerplant facilities around the world and there are a large number of manufacturers that market the technology. The question is whether SCR technology is "applicable" for a unit firing North Dakota lignite.

In accordance with EPA's NSR Manual, a technology is "applicable" if it has been installed on a "similar unit". Hot-side, high-dust SCR technology has been retrofit on coal-fired units featuring cyclone boilers. However, there are no SCR installations in operation or planned on units that include cyclone burners firing North Dakota lignite with severe slagging and fouling tendencies combined with such high boiler economizer outlet gas temperatures (over 750°F) required for high-moisture fuel pre-drying systems and tubular air preheaters.

The EPA's NSR Manual also states a technology may be determined to be not applicable if "a technical assessment considering physical, chemical and engineering principles and/or empirical data showing the technology would not work on the emissions unit under review or that unsolvable technical difficulties would preclude the successful deployment of the technique." In this SCR technology application, it appears that a facility utility powerplant firing North Dakota lignite would experience extended time delays or be required to devote significant internal resources and engage outside research, followed by extended field trials to learn how to apply a conventional high-dust, hot-side SCR technology on a such a fuel source.

Based upon this technical assessment that looked at the various design and operational issues associated with the installation of hot-side, high-dust SCR technology on a North Dakota lignite-fired steam-electric generating unit, this control option is considered technically infeasible for Unit 1's boiler at Milton R. Young Station.

A.1.3.4.2 Low-Dust Selective Catalytic Reduction (LD-SCR)

Low-dust SCR (LD SCR) technology could potentially be applicable to North Dakota lignite-fired boilers for NOx emission control. Low-dust SCR refers to the location of the SCR system downstream of a particulate collection system, such as an electrostatic precipitator or a fabric filter. If the low-dust SCR is downstream of a hot-side electrostatic precipitator and prior to the air preheater, flue gas reheating is unnecessary. This has been the prevalent form of alternative retrofit SCRs in the United States for coal-fired utility boilers. There are ten known hot-side low-dust SCR installations (without flue gas reheat) operating in the United States as of July 2005. These are listed in Appendix A2. If applied to MRY Station Unit 1's boiler, the low-dust SCR equipment would be downstream of a cold-side electrostatic precipitator; flue gas reheat prior to the LD SCR reactor inlet would be required for proper NO_X emission reduction performance.

For a cold-side LD SCR, the ESP outlet flue gas passes through a low-dust gas-to-gas heat exchanger (LD GTG-HE), prior to passing to the low-dust SCR reactor. After the LD GTG-HE, the flue gas will travel through the new duct, receiving hot flue gases from a direct-fired gas burner or set of high-pressure steam coils, leading to an ammonia injection grid, turning vanes and then into the LD SCR reactor. The flue gas entering the inlet to the LD GTG HE is expected to be near the air heater outlet temperature (330-340°F) in a cold-side LD SCR application. The supplemental heat added downstream of the LD GTG-HE can be supplied from high temperature steam coils (indirect heat exchange) or directly from natural gas-fired duct burners. The flue gas must be heated to a minimum of approximately 600°F for the LD SCR NO_X–ammonia reaction to be effective. The LD gas-to-gas heat exchanger is used to recover part of that supplied heat, prior to exhausting to the FGD system (if applicable) and stack. The use of rotary regenerative-type heat exchangers has been applied in European LD SCRs. With this design, there will be leakage between the untreated and treated gas streams such that the exit flue gas has higher NO_X concentrations than the LD SCR outlet gas. The direct-fired flue gas reheat duct burners will also create NO_X emissions, which will add to the amount emitted from the boiler and input into the LD SCR reactor. The LD SCR reactor, GTG HE, and connecting ductwork will increase the pressure drop through the flue gas system. This normally requires an induced draft fan upgrade or a booster fan addition.

The factors that make low-dust SCR technology infeasible for the Milton R. Young Station Unit 1's boiler with existing particulate collection via electrostatic precipitators are as follows:

- Catalyst Fouling and Deactivation: An existing electrostatic precipitator upstream of a low dust SCR reactor will still expose the catalyst to the acid gas content and fine particulate containing trace metals and the high alkali mineral content of the entrained lignite flyash not removed by the ESP upstream. Although the total amount of flyash carryover into the LD-SCR reactor is greatly reduced compared with a high-dust design, it is anticipated that the low-dust SCR catalyst life will still be unacceptably short. The small particle flyash passing into the reactor will be sufficient to cause pluggage of the catalyst pores, resulting in deactivation of the catalyst. The firing of lignite coal produces fine (less than 5-µm diameter) flyash particles, which are also least likely to be removed by the existing particulate collection equipment (e.g. ESP) upstream of a low-dust SCR. This creates conditions that allow these small flyash particles to enter the pores of the catalyst, react with SO_3 in the flue gas, and form sulfates which bind other ash particles into a matrix of sodium-, calcium-, and sulfur-rich materials (likely in a form of calcium sulfate). Once such a matrix forms within the catalyst, it can be extremely tenacious and difficult to remove. One catalyst vendor's has stated it is their "experience that low-dust catalyst is more difficult to clean than that from high-dust"[30]. Low-dust SCR performance and catalyst life could be severely negatively impacted. Shortened lifespans of the LD SCR catalyst will require premature, extended, frequent outages for replacement.
- Site Space Constraints: The installation of a low-dust SCR system with flue gas reheat requires a substantial amount of space for installation and operation. A low-dust SCR system will likely use a regenerative gas-to-gas heat exchanger (reheater) to raise the temperature of the flue gas at the SCR inlet. A GTG HE will transfer heat from the flue gas at the SCR reactor outlet to the flue gas entering the SCR reactor in order to minimize the supplemental SCR energy usage. The gas-to-gas heat exchanger dictates the footprint of the cold-side low-dust SCR system. Space is required for the GTG HE and for ductwork in and out of the reheater. Sufficient free space around the reheater and SCR is also required for maintenance.

  The area around Units 1 and 2 at the M.R. Young station is extremely congested in the areas where low-dust SCR systems must be located. The situation is particularly severe for Unit No. 2. Equipment that impacts the feasibility of installing a low-dust SCR system on Units 1 and 2 includes the Unit 2 absorbers, Unit 2 flue gas desulfurization (FGD) dewatering equipment, fly ash handling equipment, fuel storage and transfer equipment, stacks, fans and ductwork. It would be extremely disruptive to the continued economic operation of both boilers to relocate all the mentioned equipment to create space for the low-dust SCR systems at the M.R. Young Station. Stacks, fans and ductwork and the Unit 2 FGD system cannot be readily relocated due to adjacent structures and the need to continue operation while constructing the retrofit installations. The fuel handling equipment includes a coal storage barn and the main conveyors supplying lignite to the units. Relocating the coal handling equipment currently occupying space needed for the low dust SCR systems would be quite difficult given the site configuration. It is conceivable that the fly ash equipment located west of Unit 1 could be relocated to provide some of the space needed for the low-dust SCR. However, the availability of this space is doubtful, since avoiding the likelihood of severe SCR catalyst sulfate fouling will require a new Unit 1 FGD system to be installed. If a new FGD system is installed for Unit 1, the FGD system would need to occupy the space that can be made available by relocating ash handling equipment. This space subsequently would not be available for a low-dust SCR system.

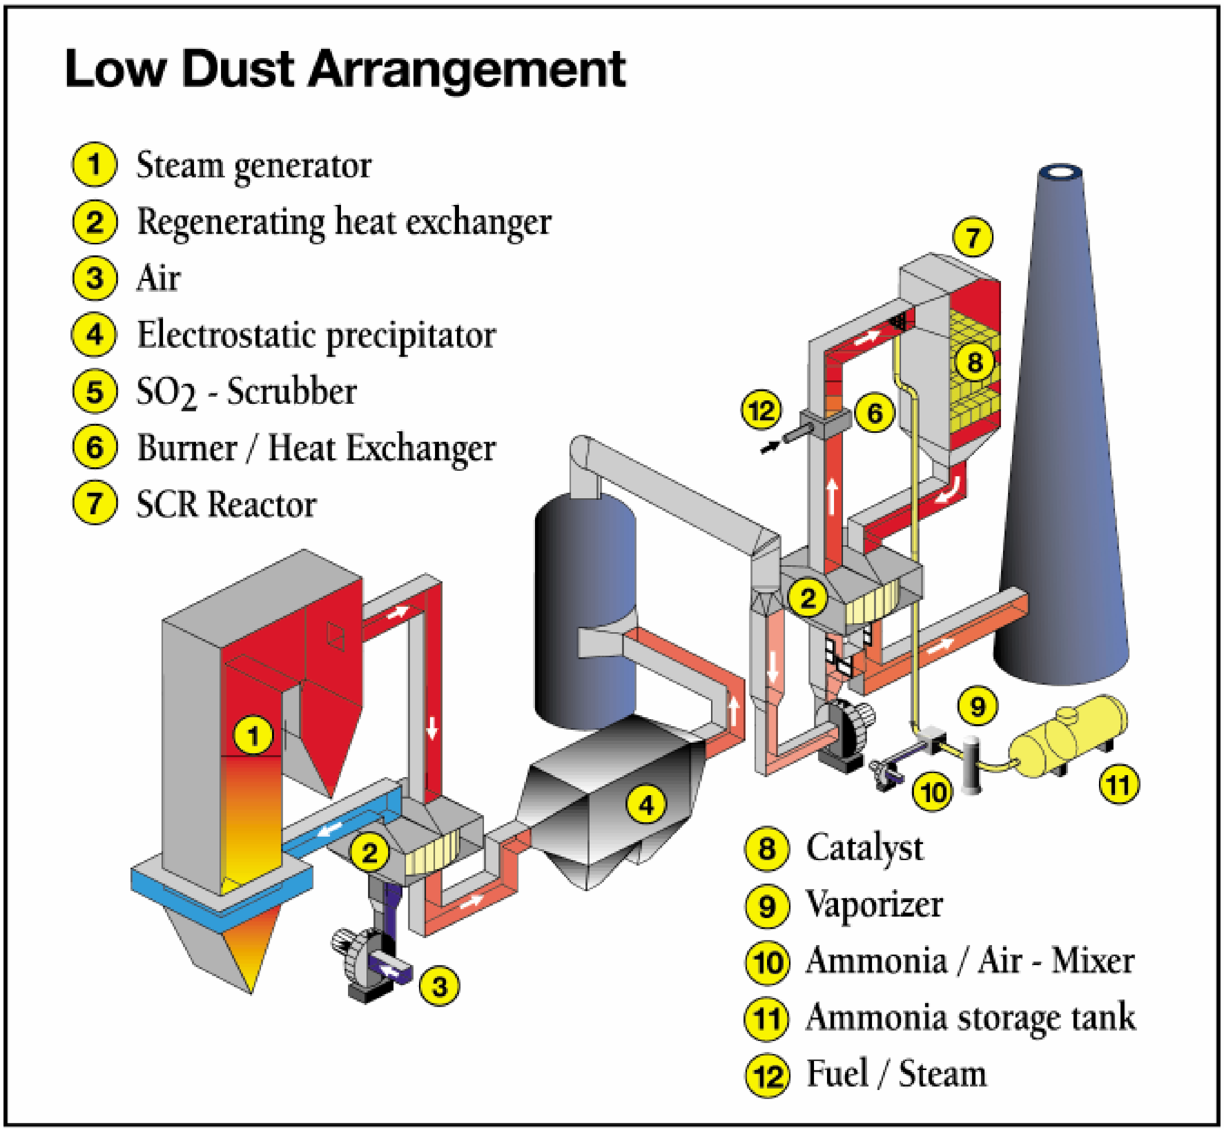
Based upon a technical assessment that looked at the various design and operational issues associated with the installation of low-dust SCR technology on a North Dakota lignite-fired steam-electric generating unit, this control option is considered technically infeasible for the Milton R. Young Station Unit 1’s boiler.

A.1.3.4.3 Tail-Gas Selective Catalytic Reduction (LD-SCR)

A tail-gas (TG) SCR is a low-dust SCR system where the LD SCR reactor is installed downstream of a FGD scrubber. The FGD outlet flue gas passes through a gas-to-gas heat exchanger (GTG-HE), prior to passing to the tail-gas SCR reactor. The flue gas will travel through new or modified ductwork leading to an ammonia injection grid, turning vanes and then into the TG SCR reactor. The TG SCR reactor, GTG HE, and connecting ductwork will increase the pressure drop through the flue gas system. This normally requires an induced draft fan upgrade or a booster fan addition.

A schematic graphic diagram for a low dust arrangement is shown in Figure A.1-6.

Figure A.1-6 Tail-Gas SCR Arrangement



(figure copied from Wheelabrator Air Pollution Control literature)

The flue gas from a wet FGD scrubber outlet entering the inlet to the gas-to-gas heat exchanger is expected to be near the saturation temperature (140°F) in a cold-side TG SCR application. The supplemental heat added downstream of the TG GTG-HE can be supplied from high temperature steam coils (indirect heat exchange) or directly from natural gas-fired duct burners. The flue gas must be heated to a minimum of approximately 600°F for the TG SCR NO_X– ammonia reaction to be effective. The TG gas-to-gas heat exchanger is used to recover part of that supplied heat, prior to exhausting to the stack. With a rotary regenerative-type gas-to-gas heat exchanger, there will be internal leakage between the untreated and treated gas streams such that the stack exit flue gas has higher NO_X concentrations than the

TG SCR reactor outlet gas. Using direct-fired flue gas reheat duct burners will also create NO_X emissions, which will add to the amount emitted from the boiler and input into the TG SCR reactor.

There is limited technical information published in English for coal-fired steam-electric generating units (SEGU) with low-dust/tail-gas SCR technology in applications requiring full flue gas reheat prior to the reactor inlet. There is no experience with TG SCR on eastern bituminous, western subbituminous coal or lignite-fired SEGUs in the United States. As of 1997, there was one low-dust/tail-gas SCR on a 220 MWe German cyclone-fired boiler with a 1988 retrofit installation. This boiler was reported to be operating without combustion controls or FGD, burning low sulfur, low ash, moderate moisture bituminous coal with an average pre-SCR NO_X emission rate of approximately 1.07 lb/mmBtu, and was meeting a 30-day rolling average emission limit of approximately 0.16 lb/mmBtu (85% reduction)[31].

Milton R. Young Station Unit 1 does not currently incorporate any flue gas desulfurization equipment, which would place the reactor catalyst in a low-dust SCR configuration, which is considered infeasible when burning North Dakota lignite. A new FGD system for Unit 1 would be required in order to avoid or significantly reduce expected sulfate formation within the catalyst and gas-to-gas heat exchanger when combined with ammonia required for the TG SCR. Unit 2 currently employs a wet scrubber which currently treats approximately 83% of the total flue gas flow from the boiler. Flue gas reheat is currently provided by the FGD bypass (i.e. warm, untreated flue gas is mixed with the cool scrubbed gas).

The factors that make tail-gas SCR technology infeasible for both Milton R. Young Station boilers with existing particulate collection via electrostatic precipitators are as follows:

- Catalyst Fouling and Deactivation: The TG SCR reactor downstream of a flue gas desulfurization (FGD) scrubber will still be susceptible to fouling, contamination, pluggage, and catalyst deactivation.
    - An existing electrostatic precipitator (ESP) upstream of a tail-gas SCR reactor will still expose the catalyst to fine particulate containing trace metals and the high alkali mineral content of the entrained lignite flyash not removed by the ESP upstream. Although the total amount of flyash carryover into the TG-SCR reactor is greatly reduced compared with a high-dust design, it is anticipated that the tail-gas SCR catalyst life will still be unacceptably short.
    - The firing of lignite coal produces fine (less than 5-µm diameter) flyash particles, which are also least likely to be removed by the existing particulate collection equipment (e.g. ESP) upstream of

a TG-SCR. Flue gas with entrained fine particulate matter, including some involving sodium and sulfur-containing compounds, will pass through and be carried-over from a wet FGD scrubber. This treated gas stream will carry sodium sulfate particles, formed by homogenous condensation after exiting the boiler and not removed by the FGD system, into the catalyst layers of the TG-SCR reactor. A dry FGD system followed by a fabric filter upstream of the TG-SCR will still allow sulfur-bearing flue gas and fine particles to enter the catalyst. There is serious concern that fine particles passing into the reactor will accumulate within the catalyst, and be resistant to removal by conventional sootblowers and other cleaning technologies. This creates conditions that allow these small flyash particles to enter the pores of the catalyst, react with SO_2 and/or SO_3 in the flue gas, and form sulfates which bind other ash particles into a matrix of sodium-, calcium-, and sulfur-rich materials (likely in a form of calcium sulfate). Once such a matrix forms within the catalyst, it can be extremely tenacious and difficult to remove. Catalyst that is exposed to such conditions will be ineffective at maintaining adequate activity upon which the performance of the TG-SCR's NO_X removal is based.

  - These entrained particles will also deposit on the gas-to-gas heat exchanger ahead of the tail gas SCR reactor. This deposition will decrease heat transfer between the incoming (cool) flue gas and the outgoing (warm) flue gas. Sootblowers could be used to remove the accumulated deposits from the GTG HE, but the SCR reactor could still suffer catalyst fouling from the deposits dislodged from the GTG HE cleaning cycle becoming reentrained in the reheated flue gas. Tail-gas SCR performance and catalyst life could be severely negatively impacted. Shortened lifespans of the TG SCR catalyst will require premature, extended, frequent outages for replacement.

- Site Space Constraints: The installation of a tail-gas SCR system with flue gas reheat requires a substantial amount of space for installation and operation. A tail-gas SCR system will likely use a regenerative gas-to-gas heat exchanger (reheater) to raise the temperature of the flue gas at the SCR inlet. A GTG HE will transfer heat from the flue gas at the TG SCR reactor outlet to the scrubbed flue gas entering the SCR reactor in order to minimize the supplemental SCR energy usage. The gas-to-gas heat exchanger dictates the footprint of the TG SCR system. Space is required for the GTG HE and for ductwork in and out of the reheater. Sufficient free space around the reheater and SCR system is also required for maintenance.

  The area around Units 1 and 2 at the M.R. Young station is extremely congested in the areas where TG SCR systems must be located. A flue gas desulfurization system will be needed for Unit 1 in the near future to comply with the Consent Decree. When a new FGD system is installed for Unit 1, the FGD system would need to occupy the space that can be made available by relocating ash handling equipment. This space subsequently would not be available for a tail-gas SCR system. Thus, the availability of adequate space for all the new FGD and TG-SCR system equipment and structures while accommodating existing coal storage and handling needs for both existing boilers at Milton R. Young Station is doubtful.

The challenges for installation of new ductwork, SCR reactors, and flue gas reheating equipment and the lack of pertinent experience with all aspects of design, construction, operation and maintenance of tail-gas SCRs on such high-fouling coals as North Dakota lignite are significant. The flue gas conditions that the TG-SCR catalyst will be exposed to will create unresolvable fouling and blinding that makes successful application of this technology difficult, expensive, and uncertain.

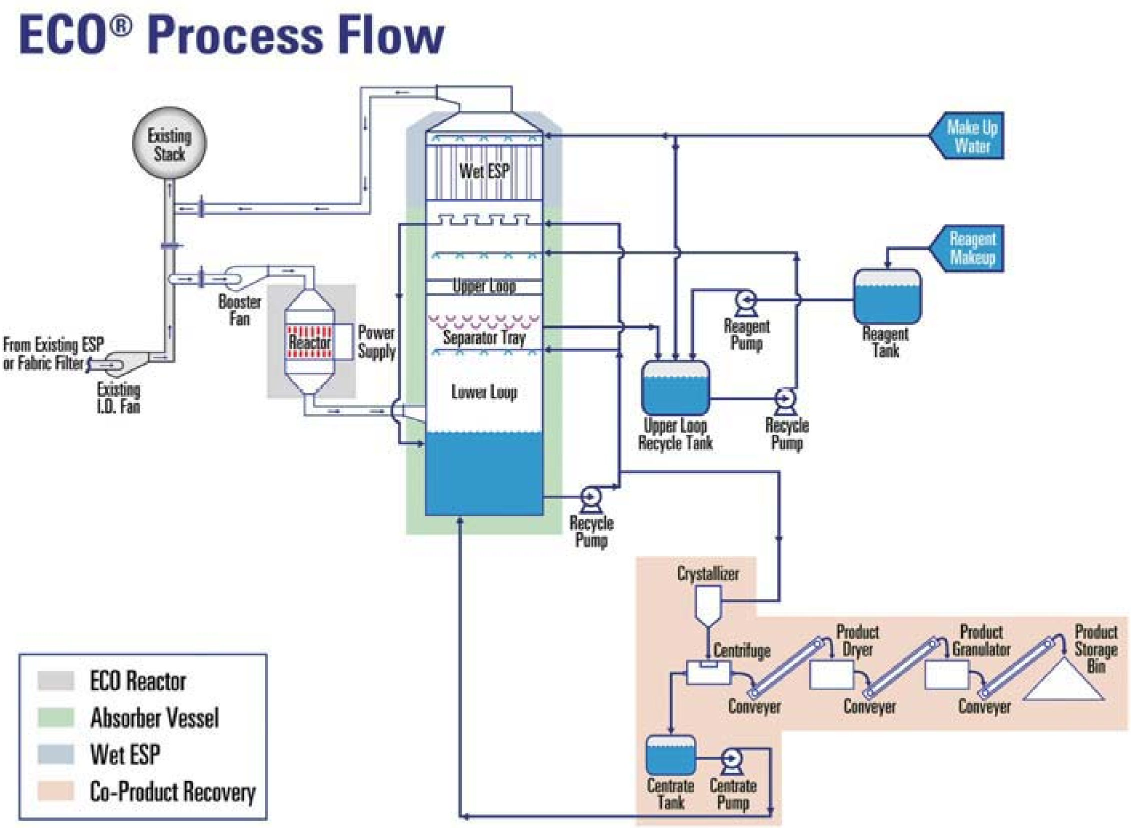
The risk of failure and uncertainty of successfully applying low-dust, tail-gas SCR technology to a cyclone-fired utility powerplant firing North Dakota lignite appear substantial.

Based upon a technical assessment that looked at the various design and operational issues associated with the installation of tail-gas SCR technology on a North Dakota lignite-fired steam-electric generating unit including a cyclone boiler, this control option is considered technically infeasible for the Milton R. Young Station Unit 1's boiler.

A.1.3.5 Electro-Catalytic Oxidation (ECO®)

Powerspan's Electro-Catalytic Oxidation (ECO®) system is a multi-pollutant technology designed to control emissions of NO_X, SO_2, fine particulate, mercury and certain Hazardous Air Pollutants (HAPs). The ECO® process has two main process vessels, a barrier discharge reactor, and a multi-level wet scrubber. The barrier discharge reactor utilizes an electrical discharge to create oxygen and hydroxide radicals which then react with NO_X, and other constituents in the flue gas stream. The flue gas stream then enters the bottom of the ECO® scrubber where the lower loop cools the flue gas and removes a portion of the acid gasses [sulfur trioxide (SO_3), sulfuric acid (H_2SO_4), nitric acid (HNO_3)] produced in the barrier reactor and oxidized metals such as mercury, with a low pH aqueous ammonia reagent. A second scrubbing loop is then entered where additional SO_2, NO_2, acid gases and oxidized metals are removed with an aqueous ammonia reagent, though at a higher pH. Above the second scrubber loop is an absorber section for absorbing fugitive ammonia from the first and second scrubbing loops. The final step in the ECO® process is a wet electrostatic precipitator (WESP) which collects fine particulate matter, aerosols generated in the scrubber and additional mercury. An updated schematic process flow diagram for the basic ECO® process is shown in Figure A.1-7.

Figure A.1-7 – Electro-Catalytic Oxidation (ECO®) Process Flow Diagram
(copied from http://www.epa.gov/appcdwww/aptb/EPA600R03110.pdf)



Powerspan has been involved in an extended ECO® process demonstration using a 28 MW Commercial Demonstration Unit (CDU) at R.E. Burger Station Units 4&5. The ECO® CDU project treated a slipstream and demonstrated performance, reliability and economics for approximately one year. The demonstration program started in January, 2004. NO_X removal is stated to be up to 90% with a claimed 0.05 lb NO_X/mmBtu outlet condition achievable for the front-end of the ECO® process. Further sustained operational tests of the ECO® CDU are underway during the second and third quarters of 2005.

As this is a post-combustion multi-pollutant control technology, it is claimed that there is little sensitivity to the type boiler or burners that Powerspan's Electro-Catalytic Oxidation (ECO®) process can be potentially applied to in order to reduce NO_X emissions. The effectiveness of this ECO® process for NO_X control has been demonstrated on a slip-stream commercial demonstration unit (CDU) associated with pulverized fuel boilers firing midwestern or eastern bituminous coal.

Powerspan's published data from the commercial demonstration unit's performance of up to 90% when treating flue gas with an inlet NO_X concentration around 0.5 lb/mmBtu. This would result in a stack NO_X emission around 0.05 lb/mmBtu.

The ECO® process has not been demonstrated in a full-scale configuration on any unit, nor tested in a slipstream configuration on any boiler that fires western subbituminous coals or North Dakota lignite. It has also not been applied to emissions from a cyclone-fired boiler. According the EPA's Draft NSR Manual, "Technologies which have not been applied to (or permitted for) full scale operations need not be considered available: an applicant should be able to purchase or construct a process or control device that has already been demonstrated in practice".

There are a number of issues with firing North Dakota lignite that make the applicability of the ECO® process technically infeasible for MRY Station boilers. These issues include:

- Deposits and Pluggage: The flyash deposition characteristics of the North Dakota lignite are extremely severe. Anything that contributes to flyash deposition and pluggage within the barrier reactor is expected to have a detrimental impact on the multi-pollutant control performance of the ECO® process, and thus could have a serious impact on MRY Station operations. The lack of demonstrated operation on treating the emissions from a boiler firing coal with a high slagging index precludes the use of the ECO® process as technically feasible for BACT as applied to a boiler firing North Dakota lignite.
- Reliability and Availability: Milton R. Young Station's major planned outages for each unit are scheduled to occur once every three years. Any NO_X control technology selected as BACT will need to operate year-round, year in and year out, on a routine basis, while performing at high levels of pollutant reduction. The Powerspan ECO® system is a new technology and is not as highly developed as other more common NO_X and SO_2 control technologies such as SCR or SNCR plus wet or semi-dry flue gas desulfurization (FGD). It is expected to require a full-time, full-scale application with sustained continuous operation to confirm levels of currently demonstrated reliability and availability from the ECO® CDU are acceptable to meet the

expectation of infrequent major outages over long time periods while maintaining high levels of control.

There are additional factors that make the application of the ECO® process potentially more difficult than other established emission control technologies available for coal-fired powerplants:

- There is a lack of experience with the ECO® downstream ammonia scrubber's coproduct crystallization and granulization equipment design, operation, and maintenance, which was not included with the initial commercial demonstration unit. The coproduct stream that would normally feed into the crystallization and granulation processes was collected and transported offsite for this process step during CDU operation. Because crystallization and granulation of ammonium sulfate from an ammonia scrubber solution is not a new technological process, this was not considered a technical feasibility deficiency. For instance, the Dakota Gasification Company (DGC) in Beulah, ND currently operates an SO_2 scrubber utilizing ammonia as a reagent. Following the generation of ammonium sulfate, DGC crystallizes and granulates a fertilizer product on site. However, at MRY Station, considerable costs would be incurred for interim storage and shipment of the ECO® process scrubber's liquid bleedstream until sufficient experience has identified and eliminated potential failures and repairs for the crystallization and granulation equipment should it prove to be unreliable.

- Size of the barrier reactor: Powerspan recently indicated that they would scale the reactor for optimum cost and space arrangement based upon lessons learned from the CDU plant operation. The number of individual passages within a barrier reactor sized for either of MRY Station boilers' maximum flue gas flow and gas stream constituents is expected to require a cross-sectional area comparable to half of a large electrostatic precipitator. Although this has not been closely examined for all aspects of design, construction, operation and maintenance, the amount of physical space required to hold the barrier reactor and inlet and outlet ductwork is believed to not be available for potential retrofit to MRY Station units. Site space constraints are considered to be a barrier to technical feasibility for potential application of the ECO® process at Milton R. Young Station for Unit 1 and Unit 2's boilers.

- Additional station auxiliary power consumption: The barrier reactor, plus the ammonia scrubber and wet electrostatic precipitator additions by an ECO™ system, require an increase in station auxiliary power consumption. For NO_X control, this includes more horsepower required by the booster fan needed to compensate for the flue gas pressure drop created across the barrier reactor. It also includes the power consumed by the electrodes of the barrier reactor itself.

Because of the technical feasibility issues and lack of commercial availability and full-scale experience, especially on such high fouling coals, the ECO® system was considered technically infeasible as a BACT alternative for Milton R. Young Station for Unit 1's boiler.

A.1.4 "Layered" NOx Reduction Technologies

Many of the NO_X emission reduction technologies which involve furnace or convection pass areas for their introduction into the flue gas stream have been, or can potentially be, applied in combinations so as to result in an overall higher level of removal. Separated overfire air, various types of fuel reburn, and various forms of SNCR could potentially be combined in series to reduce NO_X emissions prior to boiler's flue gas exit. However, all the possible NO_X control technology combinations have not been installed on coal-fired powerplants, so actual feasibility of some combinations have not been demonstrated as viable, particularly in consideration of the special challenges posed by cyclone boilers firing lignite coal.

A.1.4.1 SOFA Combined With Other NO_X Reduction Technologies

Separated Overfire Air can be favorably combined with every other method in order to reduce the amount of reagent or reburn fuel required to achieve the resulting level of NO_X emission reduction. Some control technologies, especially conventional fuel reburn systems, require overfire air to complete the combustion of the staged fuel admitted to the upper furnace. Fuel lean gas reburn can be applied with or without SOFA, as this limited amount of staged fuel is introduced into an oxygen-rich atmosphere downstream of the cyclone burners and any overfire air injection points.

A.1.4.1.1 SOFA with SNCR

Selective non catalytic reduction technologies are post-combustion, in-furnace NO_X control alternatives that have been installed in numerous boilers of various designs, fuel types, with and without overfire air. It is usually advantageous to apply overfire air so that the amount of chemical reagent consumption can be minimized in order to achieve the targeted NO_X emission rate from the boiler outlet.

Tests at Conectiv's B.L England Station (Units 1 and 2) demonstrated that SNCR can decrease NO_X emissions as much as 31% at full load, from 0.55 to 0.38 lb/mmBtu, over and above the reduction possible from overfire air alone (approximately 60% drop, from 1.3 to 1.4 down to 0.55) in full operation. This is an overall NO_X emission reduction of 72% from pre-retrofit baseline[24].

SNCR can be applied alone or combined with either the basic or the advanced forms of separated overfire air (ASOFA) on MRY Station boilers. Air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction is an optional part of this technique. However, as previously explained in the discussion of SOFA alternatives, this will risk slag "freezing" in the barrels and lower furnace. Estimated NO_X emission rates for using SNCR techniques with North Dakota lignite considered published levels achieved by cyclone-fired units firing western subbituminous coal, and vendor estimates. SNCR with ASOFA is expected to reduce NO_X emissions approximately 31% below NO_X levels predicted for ASOFA operation, and potentially 58% overall from current baseline level for the MRY Station Unit 1 boiler with ammonia slip limited to approximately 5 ppmvd. This highest performing basic SNCR system is potentially able to achieve a NO_X emission rate of 0.355 lb/mmBtu, when combined with the advanced form of SOFA on MRY Station Units 1 boiler during operation at the pre-control baseline (near MCR load). These levels of NO_X reduction depend on the advanced form of separated overfire air technique to achieve the expected NO_X reduction percentages when applied to lignite-fired cyclone boilers.

Another form of SNCR is combined with separated overfire air. This is currently being marketed commercially as "Rotating Mixing" (Rotamix). In the United States' utilities industry, this has only been applied to pulverized coal-fired boilers. It is different than basic SNCR in that it includes a hot air booster fan and a small ambient air fan, and injects the ammonia (or urea) reagent into the high-pressure overfire air flow stream ahead of the ROFA nozzles' outlets. This mixture is imparted into the boiler in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row. This vendor (Mobotec USA) claims that Rotamix (rotating opposed fire air or ROFA + SNCR) helps to distribute the reagent across the furnace cross section, which maximizes in-furnace NOx reduction while minimizing negative impacts on carbon monoxide and flyash unburned carbon. Three tangentially-fired utility boilers burning eastern bituminous coal or Illinois bituminous coal were retrofitted with Rotamix, each achieving a NO_X reduction of approximately zero to 55 percent beyond the levels produced by ROFA alone, from pre-SNCR baselines of 0.22 to 0.28 lb/mmBtu down to 0.10 to 0.23 lb/mmBtu without low-NO_X burners[4,32,33,34].

While this variation of SNCR combined with separated overfire air could potentially be applicable to cyclone boilers, it has not been marketed to serve such applications. Since cyclone boilers do not require the addition of hot air booster fans for SOFA, and optimum injection locations for both SOFA and SNCR reagent may not coincide, Rotamix may not perform as well as, or significantly better than, a well-designed combination of conventional SOFA and SNCR. This technique is not distinct enough from basic SNCR from functional and air-staged cyclone NO_X reduction performance standpoints to warrant individual consideration for Milton R. Young Station boilers. Because of a lack of cyclone-fired boiler experience with ROFA and Rotamix, the latter was considered infeasible and thus was not included in the control effectiveness and cost-effectiveness sections of the main report.

A.1.4.1.2 SOFA with RRI

Rich Reagent Injection must be used in an oxygen-deprived atmosphere in order to effectively reduce nitrogen oxide emissions. This requires air-staged cyclones and separated overfire air operation.
The NO_X emission reduction reagent injection for RRI processes must be precisely located and carefully controlled to be effective. Operation outside of the required operating ranges can even result in increased NO_X emissions. Extensive computational fluid dynamic (CFD) simulations are needed to determine the optimum injection points. Boiler operating conditions will change with unit load and varying fuel characteristics. The RRI process control systems must be able to adjust for these changing conditions.

RRI has the potential to provide a moderate degree of NO_X reduction on coal-fired boilers. Data from B.L. England and Sioux plants show this technology can reduce NO_X emissions between zero and 39 percent beyond the amount attributable to overfire air system operation[23,24,25,26,27]. During initial demonstration testing of RRI at Ameren's Sioux Unit 1 boiler, a 500 MW unit firing a blend of PRB and midwestern bituminous coals (without SNCR), with SOFA in August 2001 at a lower furnace SR of approximately 0.99, NO_X emissions were reduced approximately 55% to 0.55 lb/mmBtu w/ SOFA only, with zero to 15% additional NO_X reduction from RRI (down to 0.47 lb/mmBtu) with zero ammonia slip[25]. Results of this initial RRI testing at Sioux plant were poor at cyclone stoichiometric ratios close to 0.99 because inconsistent, sporadic, and non-repeatable NO_X emissions reductions between zero and 15% were measured. Subsequent RRI testing at Sioux Unit 1 in March 2002 with SOFA at an average cyclone stoichiometric ratio around 0.95 showed NO_X emissions reduction of 29 percent (down to 0.27 lb/mmBtu) beyond those achieved with a modest amount of cyclone air-staging with SOFA (68% drop down to 0.38 lb/mmBtu from SOFA alone), for an 80% overall decrease from uncontrolled baseline; RRI CFD model predictions for these conditions were NO_X emissions reduction of 31% with FGR and 37% without FGR operation. Tested NO_X emissions with RRI+SOFA in 2002 were with a reagent normalized stoichiometric ratio (NSR) of 3 (lbs NH_3 per lb NO_X)[25].

Parametric testing at Sioux Unit 1 in May 2005 reduced NO_X emissions between 15-38% with RRI, down to 0.15 to 0.20 lb/mmBtu. Reagent NSR between 1.0 and 4.0 and low ammonia slip levels less than 2 ppm from an established baseline condition of 0.20 to 0.285 lb/mmBtu level achieved NO_X emissions as low as 0.12 lb/mmBtu with deep cyclone air-staging and SOFA operation firing an 80:20 PRB/Illinois coal blend at 480 MWg unit output[27].

The intent of the RRI process for NO_X reduction is that it must be used in conjunction with air-starved (substoichiometric staged-air) cyclone combustion resulting from the installation and operation of an OFA system, with or without SNCR. The cyclones' air/fuel stoichiometry must be carefully controlled to maintain fuel-rich conditions for the RRI process to be effective. The combustion gases in the vicinity of the RRI urea injection ports must be essentially devoid of free oxygen, in order to avoid oxidizing the nitrogen contained in the injected reagent, which will increase NO_X emissions. For lignite-fired cyclone boilers, the basic form of separated overfire air (without relocated lignite drying system vent ports) is incompatible with RRI. Reagent injection will be near the elevation of the existing lignite drying system vent ports in the lower front and rear walls of a lignite-fired cyclone boiler located immediately above the top rows of cyclones. The oxygen introduced with the lignite drying system's vented moisture-laden airstreams will cause the urea to be oxidized, creating NO_X emissions.

The advanced form of SOFA relocates these lignite drying system vent ports from the lower to the middle furnace, enhancing the desired in-furnace nitrogen oxides reduction process. Therefore, in order for RRI to be even moderately effective in reducing NO_X emissions from a lignite-fired cyclone boiler, this technology must be combined with an advanced form of separated overfire air, whether installed with or without SNCR.

As mentioned in the feasibility discussion of applying separated overfire air to lignite-fired cyclone boilers, the degree to which each and every individual cyclone furnace can be successfully operated with less than theoretical (substoichiometric) combustion air directly impacts potential NO_X formation and further in-furnace emission reduction. Because the heat content of lignite from the Center mine is not consistent from hour to hour, there can be substantial deviations in air/fuel ratios for individual cyclones from the overall average.

In the case of MRY Station boilers, Minnkota has simultaneously sampled the unprepared lignite feed to several cyclones' lignite drying systems in order to determine the variability in the combustible and ash components of North Dakota lignite. This investigation found that fuel quality variations can result in individual samples' heating values to have a maximum differential of over 12% of the lignite samples' average.

TABLE A1-1 – Lignite Heating Values and Variations for Milton R. Young Station (Unit 2)

M.R. Young Station Individual Cyclone Lignite Samples		Differences Between Individual Cyclone Lignite Samples	
Higher Heating Values, Btu/lb	Percentage of Average HHV	HHV Differential, Btu/lb	Percentage of Average HHV
Minimum HHV: 5,852	88.9%	Minimum : 4	0.06%
Maximum HHV: 7,101	1.08%	Maximum : 797	12.1%
Average HHV: 6,584	100%	Average: 165	2.51%

When operating with air-staged conditions associated with separated overfire air, any individual cyclone with lignite heat input lower than average can allow significant amounts of oxygen to oxidize the urea reagent at high temperatures, thus increasing NOx emissions in that zone at that time. Cyclones with lignite heat inputs higher than average would produce lower stoichiometric air/fuel ratios and less NOx emissions. Less complete combustion in the deeply staged cyclones may release insufficient amounts of heat, thus raising the risk of solidifying the fuel ash so that it accumulates within the cyclone barrel. This could result in firing auxiliary fuel oil or taking the boiler out-of-service to remove the pluggage. Neither of these conditions is desirable because they result in increased emissions, lower performance, and higher operating costs.

The MRY Station Unit 1 boiler's cyclone air/fuel ratios vary in real-time based on significant changes in combustible content on an individual cyclone by cyclone basis. Adjustment of individual cyclone combustion air inputs to compensate for the variability in individual cyclone lignite heat input rates for Unit 1's boiler would be necessary to maintain consistent substoichiometric operation of every cyclone during air-staged combustion. This places great emphasis on achieving tight control over the air/fuel ratios on each cyclone during air-staged combustion operation in order for ASOFA to be successful in producing significant additional NOx emissions reduction on lignite-fired cyclone boilers.

There is no equipment available for coal-fired boilers that can measure the fuel heat input at the prepared feed injection point on such a variable fuel to allow the determination of reasonably accurate air/fuel ratios on individual cyclones in real time. Without being able to measure the cyclone air and heat inputs to allow for control of air/fuel proportions and emissions, the stoichiometric ratios of individual cyclones can not be established accurately to produce combustion products essentially devoid of free oxygen. This requirement is especially necessary when employing RRI to avoid increasing, rather than reducing, NO_X emissions on the Milton R. Young Station Unit 1 boiler.

Because of the significant insurmountable problems discussed above which would increase NOx emission rates, RRI is considered technically infeasible for application on the Unit 1 cyclone boiler at the Milton R. Young Station.

A.1.4.1.3 SOFA with RRI and SNCR

When RRI is combined with separated overfire air and SNCR, it has demonstrated very high NO_X emissions reduction at Conectiv's B.L. England Unit 1 boiler during short-term testing firing eastern bituminous coal, on the order of 80% from an uncontrolled baseline around 1.2 lb/mmBtu[24]. In May 2005, testing RRI+SNCR+SOFA at Ameren's Sioux Unit 1 boiler firing a high PRB-blend coal demonstrated NO_X emissions as low as 0.12 lb/mmBtu. This was from an established baseline condition of 0.20 lb/mmBtu level achieved with deep cyclone air-staging and SOFA operation. These testing results when firing an 80%:20% PRB/Illinois coal blend at 480 MWg unit output with a reagent NSR of 4 and ammonia slip limited to less than 5 ppmvd, showed an overall 90% reduction with no apparent adverse short-term impacts of deeper air-staged combustion together with overfire air, RRI and SNCR applications[27].

Because of the significant insurmountable problems regarding RRI as mentioned above, RRI with SNCR and ASOFA is considered technically infeasible for application on the Unit 1 cyclone boiler at the Milton R. Young Station due to the variable heat content of the lignite fuel which allows the creation of oxygen-rich conditions in the boiler.

A.1.4.2 SNCR and Reburn

Various forms of SNCR could potentially be installed downstream of separated overfire air and various types of fuel reburn, to reduce NO_X emissions prior to a boiler's flue gas exit. Several of these examples were already described[7,8,9,10,11,1213,14]. Conventional gas (CGR) or coal reburn systems, by and large, have not been combined with forms of SNCR, although at least one vendor (GE Energy) has promoted a combination of conventional gas reburn with SNCR and overfire air systems as "advanced" gas reburn. Only one example of permanent installation of SNCR with conventional gas reburn (and overfire air) on a tangentially-fired boiler was found in available technical literature[10] and vendor experience lists[14]. The vendor (GE Energy) that provided the advanced gas reburn system at 120 MW NRG Somerset Station claimed NO_X emissions were reduced by 44% from a baseline of 0.45 down to 0.25 lb/mmBtu with overfire air alone; an additional reduction of 20% resulting from conventional gas reburn with overfire air, down to 0.20 lb/mmBtu; and further decrease of 45% down to 0.11 lb/mmBtu using gas reburn with SNCR with an unstated amount of ammonia slip, for an overall reduction of 75% from uncontrolled baseline[14].

No examples of actual demonstration or permanent installation of SNCR with conventional gas or coal reburn (and overfire air) on cyclone-fired boilers were found in a search of published and proprietary technical literature. The lack of experience with these combinations on a cyclone-fired boiler, especially for lignite-firing, makes the application for MRY Station's boilers infeasible.

FLGR™ has been installed with SNCR for NO_X emission reduction on several pulverized coal boilers, as discussed in the following subsection. A potential advantage of FLGR™ over conventional coal or gas reburn techniques is that the former is generally compatible with, but does not require, the installation and operation of SOFA.

Rich Reagent Injection would appear to be less capable of being combined with fuel reburn, especially conventional fuel reburn alternatives with high amounts of reburn fuel injection. This is due to the expected need to idle (e.g. not fire) up to two of the seven cyclones when operating the reburn system at full boiler load. In this case, the cooling air introduced into the idle cyclones, and any conveying air injected with pulverized reburn coal (or if natural gas is injected with recirculated flue gas), are expected to counteract the fuel-rich conditions of the air-and fuel-staged cyclones operating substoichiometrically. This will cause a portion of the amine reagent to be oxidized in the lower furnace, creating NO_X emissions instead of converting them to nitrogen and water. No example of actual demonstration or permanent installation of RRI with reburn (and overfire air) on cyclone-fired boilers was found in available technical literature or vendor experience lists. This combination is considered infeasible at the present time.

Hydrocarbon-enhanced SNCR (e.g. NO_XStar™) may potentially be combined with all types and forms of reburn previously discussed, since the location of the enhanced ammonia injection nozzles will be above (beyond) the elevation in the middle furnace where any reburn fuel should be reacted. No example of actual demonstration or permanent installation of HE-SNCR with reburn (and overfire air) on any coal-fired utility boilers, especially cyclone-fired units, was found in available technical literature or vendor experience lists. The advantage that HE-SNCR presents is the potential for greater-than-SNCR-levels of NOx reduction without significant amounts of gaseous hydrocarbon being required. Because of a lack of experience with HE SNCR applied to cyclone boilers, and none with significant amounts of fuel reburn, this combination has not been investigated further, and was not included in the control and cost-effectiveness analysis for NO_X controls.

A.1.4.2.1 Amine-Enhanced FLGR™ (AEFLGR™) or FLGR™ + SNCR

Fuel-lean gas reburn has been combined with SNCR as a hybrid form of amine reagent technologies on at least five pulverized coal-fired utility powerplants retrofit installations within the United States. This combination of technologies allows the boiler to be operated with FLGR™ alone, FLGR™ and SNCR simultaneously, or SNCR only (without SOFA) for the specific level of control desired or required.

No examples of actual demonstration or permanent installation of FLGR™ + SNCR (with or without overfire air) applied to a cyclone-fired boiler were found in available technical literature or vendor experience lists. The vendor (Fuel Tech) that provided the AEFLGR™ system at Mercer Station claimed NO_X emissions were reduced by 60% (from a baseline of 1.4 down to 0.56 lb/mmBtu) with 5 ppm ammonia slip without overfire air. A technical paper provides more details[18]. Another technical paper stated that FLGR™ alone only reduced NO_X emissions approximately 27% from the 1.4 lb/mmBtu baseline, down to 1.03 lb/mmBtu[35].

An AEFLGR™ system (with or without SOFA or ASOFA) may be potentially applied to a cyclone-fired boiler. The high capital and operating costs associated with applying fuel lean gas reburn is expected to make this economically unattractive, and the existing lignite pre-drying vent ports will likely limit the NO_X emission reduction potential of the FLGR™ component if installed without the advanced form of

SOFA. The lack of experience with this combination on any cyclone-fired boiler, especially for lignite-firing, makes this combination infeasible for MRY Station Unit 1 boiler.

A.2.1 - U.S. Cyclone NOx Reduction Projects Summary

SELECTIVE NON-CATALYTIC REDUCTION/ RICH REAGENT INJECTION
Cyclone-Fired Boilers

Conectiv (formerly Atlantic Electric)
BL England Unit 1 Crushed Coal, single-wall cyclone-fired 1962 vintage
138 MW B&W boiler aqueous urea SNCR, 1995 startup eastern bituminous coal
Boiler has only 3 cyclone burners, arranged “1 over 2” style.
RJM implemented commercial Fuel Tech urea-based SNCR system installation in 1995 after short-term (3-month demonstration test) in 1993-1994. 31 % NOx reduction claimed, from 1.31 lb/mmBtu NOx baseline(1) for SNCR only; RJM claimed 35% reduction from 1.31 lb/mmBtu down to 0.85 lb/mmBtu (without overfire air) with urea-to-NOx NSR = 0.85 (RJM experience list).

Added eight temporary RRI ports (three nozzles on each lower sidewall, and two nozzles on the upper rear wall, and performed one month demonstration parametric testing of overfire air only (without SNCR or RRI), at 120 MW nominal boiler load and cyclone S.R. = 0.90 in 1999. REI claimed 55% NOx reduction from a 1.2 lb/mmBtu uncontrolled NOx baseline to 0.55 lb/mmBtu with OFA only, with stack CO emissions below 50 ppm. For Rich Reagent Injection; REI claimed 25-30% NOx reduction for RRI down to 0.38 lb/mmBtu from controlled baseline w/ OFA alone of 0.55 lb/mmBtu NOx and a RRI urea-to-NOx NSR = 2; also showed RRI+SNCR w/ OFA reduced NOx 55% to 0.25 lb/mmBtu (34% beyond RRI w/ OFA), for an overall 79% NOx reduction with a SNCR urea-to-NOx NSR = 1. Measured less than 1 ppm ammonia slip during RRI testing, < 5 ppm slip for RRI + SNCR. No significant increase in CO emissions during RRI testing(2).
Source: (1) ICAC White Paper; RJM experience list; (2) REI 2001 Technical Paper.

Conectiv (formerly Atlantic Electric)
BL England Unit 2 Crushed Coal, cyclone-fired, single-wall-fired 1964 vintage
160 MW B&W boiler SNCR, 1996 startup eastern bituminous coal
RJM implemented commercial Fuel Tech urea-based SNCR system in 1996, claimed 36% reduction from 1.36 lb/mmBtu down to 0.85 lb/mmBtu, urea-to-NOx NSR = 0.85 (without overfire air) (1).
An OFA system was added in 1998, resulting in NOx emissions of 0.33 lb/mmBtu, for an overall NOx reduction of 76%.
Source: RJM experience list. (Also listed in (1) ICAC White Paper).

AmerenUE (formerly Union Electric Co.)
Sioux Unit 1 Crushed Coal, opposed-wall cyclone-fired 1969 vintage
500 MW B&W boiler Rich Reagent Injection demonstration testing in 2001
Boiler has 10 cyclone burners, arranged “2 over 3” style, on opposite walls, and fires a blend of 85% to 50% western subbituminous (PRB) coal, with Illinois bituminous coal, petroleum coke, and tire-derived fuel.

Installed twenty temporary RRI ports (six nozzles on each lower sidewall, and four nozzles on each front and rear wall), and performed one month demonstration parametric testing of overfire air only and initial testing with RRI in August 2001, followed by additional testing in March 2002, and the second quarter of 2004. Added 8 RRI ports (1 in each sidewall, 4 in each front and rear wall) and 14 SNCR ports (5 on upper front wall, 9 on upper rear wall) to the furnace in early 2005, followed by three weeks of parametric testing and 3 days of continuous testing of RRI with SNCR and deeper-staged OFA.
Tested in August 2001 at lower furnace SR approx.=1.0, 0.55 lb/mmBtu w/ OFA only, only 15% NOx reduction w/ RRI, zero ammonia slip.

Tested in March 2002 at lower furnace SR approx.=0.95, from 0.38 lb/mmBtu baseline w/ OFA only, achieved 29% NOx reduction w/ RRI down to 0.27 lb/mmBtu, NSR=3, zero ammonia slip(3).
(assume blend of PRB and Illinois bituminous coal w/ tire-derived fuel and petroleum coke)(3).
Operation in the second quarter 2004 showed actual stack NOx averaged around of 0.30 lb/mmBtu with OFA only and lower furnace at a cyclone SR around 0.88 burning a 85% PRB, 15% Illinois #6 bituminous coal blend, presumably at 440 MW. This is a 75% NOx reduction from a 1.19 lb/mmBtu pre-control baseline. REI using CFD modeling predicted NOx down to 0.18 lb/mmBtu with RRI+OFA, and below 0.15 with RRI+SNCR under similar deep cyclone air-staging (1.19 to 0.28 lb/mmBtu is 76% reduction, 0.18 vs 0.28 is an additional 36% reduction w/ RRI, and 0.14 vs 0.28 is a 50% reduction w/ RRI+SNCR, for an overall reduction of 88%)(4).
Tested in May 2005 at 480 MWg with lower furnace SR approx. = 0.85-0.88, 76-83% reduction from 1.2 lb/mmBtu baseline down to as low as 0.20 lb/mmBtu w/ SOFA only firing 80% PRB, 20% Illinois #6 bituminous coal blend; additional 15-39% NOx reduction w/ RRI, to as low as 0.15 lb/mmBtu from 0.20-0.28 lb/mmBtu baseline w/ SOFA only at urea NSR varied between 1 and 4, with one ppm ammonia slip; achieved additional NOx reduction w/ RRI +SNCR down to 0.12 lb/mmBtu, NSR=4, ammonia slip10 ppm or less. RRI+SNCR w/ SOFA NOx reduction percentage varied from 15% to 50% below SOFA-only levels, with NSRs between 1 and 4.5. SNCR alone had 13% (NSR=1) to 32% (NSR=1) NOx reduction with ammonia slip around 1-2 ppm*.

REBURN – GAS, CONVENTIONAL

Cyclone-Fired Boilers

Constellation Energy (formerly Baltimore Gas & Electric)
C.P. Crane Station, Units 1 & 2 (MD)   Crushed Coal, cyclone-fired, eastern bituminous coal
2 x 200 MW B&W boilers   (four cyclones each)   1961, 1963 vintage
GE-EER Conventional Gas Reburn, 1999 startup
Added gas supply piping, metering, hangers, supports; reburn injectors and cooling air ductwork, OFA ductwork, injection nozzles and wall ports, field (assume eastern bituminous coal)
GE-EER claimed Gas Reburn with OFA lowered NOx between 60% and 65% from baselines of 1.50 lb/mmBtu to between 0.60 and 0.52 lb/mmBtu, at full load with reburn operation. No claims of percent reburn fuel or percent OFA included in GE-EER's experience list.
Another technical paper showed this installation of CGR operated with 25 percent reburn fuel(5).
Source: Sept. 2005 GE-EER experience list; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

City Water, Light & Power
Lakeside Unit 7   Crushed Coal, front-wall cyclone-fired, midwestern bituminous coal
300,000 lb/hr steam B&W boiler (approx. 33 MWe equivalent, two cyclones)   1961 vintage
Springfield, IL   DOE Clean Coal demonstration project (included sorbent injection)
GE-EER conventional gas reburn w/ OFA   1992 startup (CGR not currently operating)
Vendor claimed to lower NOx by 66% from 0.95 lb/mmBtu baseline to 0.32 lb/mmBtu. A GE-EER 2004 technical paper showed 25% reburn fuel yielded minimum NOx emissions(6).
A DOE NETL technical paper showed this demonstration of CGR from 5/93-10/94 (assume with OFA) with 23 percent reburn fuel reduced NOx 60% from 0.97 to 0.39 lb/mmBtu (5).
Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL 2004 Reburn Conference Technical paper.

Eastman Kodak Company
Kodak Park Boilers 41 & 42   Crushed Coal, front-wall cyclone-fired, 1964 & 1966 vintage

400,000 lb/hr steam B&W boilers (approx. 50 MWe equivalent, two 8-ft dia. cyclones)
Rochester, NY eastern bituminous coal
B&W conventional gas reburn w/ OFA December 1998, July 1998 startups (still operating)
Commercial installation of CGR, with (1) gas burner added to each sidewall + (2) large and (2) small OFA ports added to front wall above cyclones, utilizing higher reburn gas pressure (vs. Boiler #43) requires no flue gas recirculation; {Very small furnace w/ cyclone SR not <1.0}.
B&W claimed reburn with OFA lowered NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. B&W graph shows 10-12% percent reburn fuel to achieve 0.6 lb/mmBtu and 23-24% reburn gas input to reach 0.33 lb/mmBtu NOx (73% reduction) (7).
Another technical paper showed NOx lowered by 52% from 1.25 lb/mmBtu baseline to 0.60 lb/mmBtu with 18 percent reburn fuel(5).
Source: (7) B&W Technical Paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – GAS, CONVENTIONAL
Cyclone-Fired Boilers, continued
Eastman Kodak Company
Kodak Park Boiler 43 Crushed Coal, front-wall cyclone-fired 1968 vintage
600,000 lb/hr steam B&W boiler (approx. 60 MWe equivalent, two cyclones)
Rochester, NY eastern bituminous coal
B&W conventional gas reburn 1995 startup (still operating)
Commercial installation of CGR, with flue gas recirculation (FGR) for injection mass momentum w/ (1) FGR fan; (1) gas burner added to each sidewall + (2) OFA ports added front wall above cyclones. {Very small furnace/low residence time w/ cyclone SR not <1.0}
B&W claimed reburn with OFA & FGR lowered NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. B&W graph shows 18% percent reburn fuel to achieve 0.6 lb/mmBtu and 29% reburn gas input to reach 0.36 lb/mmBtu NOx (70% reduction) (7).
Another technical paper showed NOx lowered by 56% from 1.35 lb/mmBtu baseline to 0.60 lb/mmBtu with 18 percent reburn fuel(5).
Source: (7) B&W Technical Paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Tennessee Valley Authority (TVA)
Allen Station Unit 1 (TN) Crushed Coal, cyclone-fired (seven cyclones) 1959 vintage
300 MW B&W boiler PRB &western bituminous coal blend fired
GE-EER Conventional Gas Reburn, 1998 startup
Commercial installation added gas supply piping, metering, hangers, supports; reburn injectors and cooling air piping, OFA ductwork, injection nozzles and wall ports, field I&C devices.
Reburn with OFA claimed to lower NOx 65% from baseline 1.20 lb/mmBtu to 0.42 lb/mmBtu) at full load with reburn operation. No claims of percent reburn fuel included. (TVA also installed duplicate OFA systems on Allen Units 2 & 3 boilers).
Another technical paper showed NOx lowered by 65% from 0.86 lb/mmBtu baseline (to 0.30 lb/mmBtu) with 7 percent reburn fuel(5).
Source: Sept. 2005 GE-EER experience list; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – COAL, CONVENTIONAL
Cyclone-Fired Boilers
Alliant Energy (formerly Wisconsin Power & Light)
Nelson Dewey Station Unit 2 Crushed Coal, cyclone-fired, PRB coal 1962 vintage

110 MW B&W boiler 3-cyclones across front wall, 4 reburn burners +
4 OFA ports across rear wall, aligned vertically in columns.
US DOE Clean Coal Demonstration project of B&W's Conventional Coal Reburn, 1991 startup (since discontinued) added coal supply piping, reburn burners with flue gas recirculation, OFA ductwork + dual zone ports; coal feeder, pulverizer & PA fan, tested with PRB and bituminous coals. (western subbituminous coal)
B&W claimed reburn operation lowered NOx by 57% from baseline of 0.83 mmBtu to 0.38 lb/mmBtu at full load(7). Approx. 30% percent of total fuel input supplied as reburn fuel. Increased unit output by 10 MW, increased flyash unburned carbon by 4% (13-22% vs 9-18%), decreased furnace exit gas temperature (FEGT). OFA ports listed in B&W experience list.
B&W shows full load NOx w/o reburn was 0.75 lb/mmBtu, and 0.29-0.32 lb/mmBtu w/ PRB fuel during reburn operation (57% decrease). At 75% load, 0.64 vs 0.29-0.32 lb/mmBtu. At 55% load, 0.62 vs 0.29-0.31 lb/mmBtu without and with reburn activated(8).
Another technical paper showed NOx lowered by 52-55% from 0.82 lb/mmBtu baseline (to 0.39-0.34 lb/mmBtu) with 25-30 percent reburn fuel(5).
Source: (7) 2004 B&W Technical Paper; (5) DOE-NETL 2004 Reburn Conference Technical paper;
(8) B&W case history (from website, dated 1997).

REBURN – COAL, MICRONIZED, CONVENTIONAL

Cyclone-Fired Boilers

Eastman Kodak Company
Kodak Park #15 Boiler Crushed Coal, front-wall cyclone-fired, 1956 vintage
400,000 lb/hr steam B&W boiler (approx. 50 MWe equivalent, two cyclones)
Rochester, NY eastern bituminous coal
GE-EER micronized coal reburn1996 initial startup (operating since 1997)
Demonstration project performed with Dept. of Energy's US Clean Coal Technology Program. Project added flue gas recirculation for injection mass momentum, FGR fan and two micronized coal pulverizers; (6) reburn coal injectors added to rear wall + (1) reburn coal injector on each of the sidewalls, with (4) OFA ports added across front wall above cyclones(9). GE-EER designed and fabricated the coal injectors and OFA ports. {Extremely small furnace and low residence time}.
GE-EER claimed reburn + OFA w/ FGR reduced NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. No claims of percent reburn fuel included.
Another technical paper showed this demonstration of micronized coal reburn from 4/97-10/98 lowered NOx by 57% from 1.36 lb/mmBtu baseline (to 0.59 lb/mmBtu) with 17 percent reburn fuel(5).
Source: (9) DOE Topical Report Number 14 (May 1999); GE-EER experience list;(5) DOE-NETL 2004 Reburn Conference Technical paper.

REBURN – FUEL LEAN GAS REBURN

Cyclone-Fired Boilers

Midwest Generation (formerly Commonwealth Edison)
Joliet Station 9, Unit 6 Crushed Coal, opposed-wall cyclone-fired (nine cyclones)
340 MW B&W boiler 1959 vintage, 1997 startup (FLGR has since been decommissioned)
Energy Systems Associates demonstrated 25-30% NOx reduction using 5-10% of total heat input as reburn natural gas injected (without OFA)(5).
Another technical paper showed this demonstration in collaboration with Gas Research Institute of FLGR lowered NOx by 28-43% from 1.36 lb/mmBtu baseline (to 0.59 lb/mmBtu) with 7 percent reburn fuel(10).
Source: (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference);
(10) NGB Technologies Technical Paper.

REBURN – FUEL LEAN GAS REBURN w/ SNCR continued

Cyclone-Fired Boilers

Owensboro Municipal Utilities (KY) Crushed Coal, front-wall cyclone-fired
Elmer Smith Unit 1 (three cyclones) 1965 vintage
150 MW B&W boiler

CFD model study only predicted NOx reductions from 1.59 to 0.39 lb/mmBtu with OFA only (75% reduction, 0.90 SR); 25-30% NOx reduction using 6% of total heat input as reburn natural gas injected above OFA; 40-45% NOx reduction from SNCR with <5 ppm ammonia slip$^{(11)}$.
Source: $^{(11)}$ REI Technical paper.

Separated OVERFIRE AIR

Cyclone-Fired Boilers

Tennessee Valley Authority (TVA) Crushed Coal, cyclone-fired, 1959 vintage
Allen Station Units 2 & 3 (TN) (seven cyclones)
300 MW B&W boilers PRB &western bituminous coal blend
GE-EER Overfire air (duplicate of Allen 1), 1999 startup
GE-EER claimed to lower NOx with OFA alone up to 29% from baseline 1.20 lb/mmBtu to 0.85 lb/mmBtu on Units #2 and 3 at full load.
Source: Sept. 2005 GE-EER experience list.

AmerenUE (formerly Union Electric Co.)
Sioux Unit 1 Crushed Coal, opposed-wall cyclone-fired 1969 vintage
500 MW B&W boiler PRB/Illinois Coal blend
Boiler has 10 cyclone burners, arranged “2 over 3” style, on opposite walls, and fires a blend of 85% to 50% western subbituminous (PRB) coal, with Illinois bituminous coal, petroleum coke, and tire-derived fuel.
A ten-port OFA system (five ports on each front and rear wall) began operation in mid-2001, which reduced NOx emissions approx. 40-50% reduction from 1.1-1.3 (assume average of 1.19) down to 0.7 lb/mmBtu with moderate cyclone air-staging (cyclone SR from 1.19 to 1.0). $^{(3)}$ Subsequent testing and full load operation at deeper cyclone air-staging (SRs ≤ 0.90) has dropped NO_X with SOFA alone to around 0.3 lb/mmBtu in 2004$^{(4)}$.
Source: $^{(3)}$ REI 2002 and 2003 Technical Papers; $^{(4)}$ REI 2004 Technical paper;* REI 2005 Technical paper

Coal burning cyclone-fired utility boilers in the United States that have been retrofitted with Separated Overfire Air CR technology are listed in Table A.2-1. A large majority of the cyclone-fired boilers listed burn western subbituminous coal (or PRB blended with midwestern bituminous coal).

TABLE A.2-1 – Cyclone-Fired Boiler Overfire Air Retrofit Installations(12)

Facility Name	Installation Date	Comments
Allen Station Units 1	Installed 1998*	OFA w/ CGR retrofit; has SCR
Allen Station Unit 2	Installed 1999*	(Similar to Unit 1, w/o CGR) have SCR
Allen Station Unit 3	Installed 1999*	(Similar to Unit 1, w/o CGR) have SCR
Asbury Unit 1	Installed 5/10/1999	Empire District, BART-eligible
Bailly Unit 7	Installed 2003(13)	SCR to be installed in 2006-7
Bailly Unit 8	Installed 5/31/2000	SCR retrofit 5/11/2004
Baldwin Unit 1	Installed 12/31/1999	SCR retrofit 4/28/2003
Baldwin Unit 2	Installed 5/8/2000	SCR retrofit 4/12/2002
Big Stone Unit 1	Installed 10/22/1997	part of conversion to PRB
BL England Unit 2	Installed 1998*	previous SNCR retrofit in 1996
CP Crane Unit 2	Installed 2/1/1999	OFA w/ CGR retrofit
Coffeen Unit 1	Installed 2/1/2001	SCR retrofit 4/21/2003
Coffeen Unit 2	Installed 2/9/2000	SCR retrofit 4/09/2002
Edgewater Unit 3	Installed 11/2001(13)	
Edgewater Unit 4	Installed 6/19/2001	
Joliet 9 Unit 6	Installed 2000(13)	
Kincaid Unit 1	Installed 4/28/2000	SCR retrofit 12/17/2002
Kincaid Unit 2	Installed 5/24/2000	SCR retrofit 6/07/2002
Allen S. King Unit 1	Installed 11/30/1999	
LaCygne Unit 1	Installed 2/28/2000	
Lake Road Unit 6	Installed 6/01/2002	
Michigan City Unit 12	Installed 4/1998(13)	SCR retrofit 5/01/2003
Nelson Dewey Unit 1	Installed 2002(13)	
Nelson Dewey Unit 2	Installed 2002(13)	
Paradise Unit 1	Installed 11/14/1998	SCR retrofit 5/01/2001
Paradise Unit 2	Installed 12/8/1999	SCR retrofit 5/01/2000
Paradise Unit 3	Installed 5/4/2000	SCR retrofit 3/10/2004
Powerton Unit 5-1	Installed 6/1/2003	
Powerton Unit 5-2	Installed 6/1/2003	
Powerton Unit 6-1	Installed 6/1/2002	
Powerton Unit 6-2	Installed 5/4/1999	
Schahfer Unit 14	Installed early 2000(13)	SCR retrofit 5/11/2004
Sibley Unit 2	Installed 5/24/2002	
Sibley Unit 3	Installed 5/4/1999	
Sioux Unit 1	Installed 4/30/2001	SNCR demo May 2005
Sioux Unit 2	Installed 4/30/1997	
State Line Unit 4	Installed 11/2001(13)	Similar to Joliet 9 Unit 6
Tanners Creek Unit 4	Installed 5/12/2002	
Thomas Hill Unit 1	Installed June 2004(13)	
Thomas Hill Unit 2	Installed November 2000(13)	

Note: This table does not include every installed U.S. coal-fired cyclone boiler OFA retrofit project.
Source: (12) US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005 (except as noted below)
* Vendor experience list (GE Energy for Allen Station Units 1-3; RJM for BL England Unit 2)
(13) Burns & McDonnell internal database.

Coal burning cyclone-fired utility boilers in the United States that have been retrofitted with SCR technology are listed in Table A.2-2. This list includes at least eighteen cyclone-fired boilers burning western subbituminous coal (or PRB blended with midwestern bituminous coal). The highest emission reductions listed in Table A.2-2 for SCR systems are for clean reactor catalyst and ideal operating conditions.

TABLE A.2-2 – Cyclone-Fired Boiler High-Dust SCR Installations

[1] – original design fuel for all listed cyclone boilers was bituminous coal
[2] – Generator nameplate rating, March 2002 Energy Information Administration report DOE/EIA-0095(2000). Actual unit MW output rating may be higher or lower than nameplate.
[3] – Burns & McDonnell internal database.
[4] – as reported to US EPA, available from their website at http://cfpub.epa.gov/gdm/index.cfm
[5] – includes application of separated overfire air for combustion NO_X control
[6] – current fuel believed to be a blend of subbituminous and bituminous coals
[7] – NAD = no published data from SCR emission testing found on these units.
[8] – original air preheaters were tubular-type; changed to rotary-type during SCR retrofit
[9] – Design NO_X removal efficiency is higher, approx. 90%.
[10] – current fuel believed to be subbituminous coal

For Merrimack Unit 1's SCR, inlet (i.e. uncontrolled) NO_X was 1.34 lb/mmBtu, for a blend of high sulfur bituminous and medium or low sulfur bituminous coals, and requires year-round SCR operation for compliance. The catalyst was designed for 88.9% NO_X removal efficiency and 5 ppm ammonia slip. SCR commercial service date July 20, 1999. [(14) Babcock Borsig Power 2000 technical paper on SCRs].

For Merrimack Unit 2's SCR, inlet (i.e. uncontrolled) NO_X was 2.66 lb/mmBtu, for a blend of high sulfur bituminous and medium or low sulfur bituminous coals, and requires year-round SCR operation for compliance. Initial testing demonstrated 70% removal(15), which exceeded the 65% requirement to achieve a 0.92 lb/mmBtu permit limit. The catalyst was designed for 85-95% NO_X removal efficiency and 5 ppm ammonia slip(16).

Northern Indiana Public Service Company (NIPSCO)
Bailly Unit 8 Crushed Coal, cyclone-fired, opposed-wall-fired 1968 vintage
360 MW B&W boiler Urea/ammonia conversion for high-dust SCR, 2004 startup
Boiler fires a blend of 85% western subbituminous (PRB) coal, with Illinois bituminous coal.
Commercial Fuel Tech urea-based system installed in 2004 to convert urea to ammonia for injecting reagent ahead of boiler economizer outlet and high-dust SCR. An OFA system was retrofitted in 2000(13).
Source: Fuel Tech experience list dated 1/28/2005; (13)Burns & McDonnell internal database.

Northern Indiana Public Service Company (NIPSCO)
Michigan City Unit 12 Crushed Coal, cyclone-fired, opposed-wall-fired 1974 vintage
520 MW B&W boiler Urea/ammonia conversion for high-dust SCR, 2003 startup
Boiler fires western subbituminous (PRB) coal.
Commercial Fuel Tech urea-based system installed in 2003 to convert urea to ammonia for injecting reagent ahead of boiler economizer outlet and high-dust SCR. An OFA system was retrofitted in 1998(13).
Source: Fuel Tech experience list dated 1/28/2005; (13)Burns & McDonnell internal database.

Northern Indiana Public Service Company (NIPSCO)
Schahfer Unit 14 Crushed Coal, cyclone-fired, opposed-wall-fired 1975 vintage
520 MW B&W boiler Urea/ammonia conversion for high-dust SCR, 2004 startup
Boiler fires western subbituminous (PRB) coal.
Commercial Fuel Tech urea-based system installed in 2004 to convert urea to ammonia for injecting reagent ahead of boiler economizer outlet and high-dust SCR. An OFA system was retrofitted in 2000(13).
Source: Fuel Tech experience list dated 1/28/2005; (13)Burns & McDonnell internal database.

TABLE A-3 – Low-Dust Pulverized Coal-Fired Boiler SCR Installations

Operator/Facility[1,2]	SCR Startup Date[3]	Average NO_X Emission Rates[4] (lb/mmBtu)	Unit Size[5], MW
AEP/Cardinal Unit 3[6]	5/01/03	0.74 / 0.34 / 0.135	650
Carolina P&L/Mayo Unit 1[7]		- / (0.36) / N/A	368 x 2
Carolina P&L/Roxboro Unit 4[7,8]	5/07/01	0.57 / 0.26 / 0.081	372 x 2
Cinergy/East Bend Unit 1	4/01/02	- / (0.28) / 0.067	648

Dayton P&L/Killen Station Unit 2	11/01/03	- / (0.48) / 0.06[9]	666
Dynegy Midwest Gen/Havana Unit 6[10]	(2000)	0.46 /0.20 / 0.102[9]	488
PSEG Power LLC / Mercer Unit 1[11]	(2005)	- / (0.63) / N/A	320
PSEG Power LLC / Mercer Unit 2[11]	(2004)	- / (0.76) / N/A	320

[1] – Burns & McDonnell internal database.

[2] – Current fuel is eastern or midwestern bituminous coal, except Havana

[3] – US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005, except where noted. Dates in () are believed to be accurate but have not been confirmed.

[4] – The three values are "Pre-control average", "2004 annual average", and "2003 ozone season average" NO_X emission rates, as reported to US EPA. Pre-control and year 2004 annual average data as shown in US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005, posted on their website: http://docket.epa.gov/edkpub/do/EDKStaffItemDetailView?objectId=090007d48084562b. Values shown in parentheses are year 2003 annual average where 2004 data is not available. Year 2003 and 2003 ozone season data is available from the EPA's website at http://cfpub.epa.gov/gdm/index.cfm, includes application of separated overfire air for combustion NO_X control where applicable.

[5] – Generator nameplate rating, March 2002 Energy Information Administration report DOE/EIA-0095(2000). Actual unit MW output rating may be higher or lower than nameplate.

[6] – This boiler has low-NOx burners for combustion controls.

[7] – Carolina Power & Light plants listed here have two boilers per unit, total nameplate for Mayo is 736 MW, Roxboro is 745 MW; emission numbers are the average of both boilers.

[8] – This boiler has low-NOx burners and overfire air for combustion controls.

[9] – This is preliminary data reported to the US EPA for 2004 ozone season average emission rate.

[10] – This boiler's current fuel is believed to be subbituminous coal.

[11] – Mercer boilers listed have low-dust SCR with flue gas reheat. Unit size is approximate, not nameplate.

N/A = complete 2004 ozone season data is not available, and 2003 ozone season data is not representative of the post-SCR installation emission rate.

SELECTIVE NON-CATALYTIC REDUCTION

Pulverized coal-fired boilers

American Electric Power (AEP)   Pulverized Coal, cell-burner, opposed wall-fired B&W boiler
Cardinal Unit 1   1967 vintage; Low NO_x burners installed in October 1998
600 MW (nominal)   Brilliant, Ohio
Fuel Tech urea-based SNCR installed in October 1998.
Fuel Tech, DOE, EPRI-member utilities SNCR demonstration project. Tested in March-April 1999, claimed 65% reduction with LNBs + SNCR w/ 5 ppm NH_3 slip, (from pre-LNB retrofit baseline of 1.20 lb/mmBtu*) down to 0.52 lb/mmBtu at 620 MW (100% MCR). SNCR reduced NO_X 31% below LNBs alone (0.75 lb/mmBtu baseline), at 620 MWg (100% MCR), 34% reduction at 75% MCR (450 MWg), and 42% reduction at minimum load (340 MWg, 55% MCR) ≤ 5% ammonia slip(17), burning eastern bituminous coal. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005; (1)ICAC White Paper, (17) 2000 Fuel Tech technical paper, *Riley Power (Babcock Power Inc.) experience list 8/16/04.

Carolina Power & Light (Progress Energy)
Asheville Unit 1   Pulverized Coal, front wall fired
200 MWe DB Riley boiler   1964 vintage, eastern bituminous coal, June 2000 SNCR startup
Fuel Tech commercial SNCR installation claimed 25% NOx reduction from low-NO_X burner w/o OFA baseline of 0.58 lb/mmBtu (down to 0.44 lb/mmBtu on SNCR alone). Urea-to-NOx NSR not stated. (Also see FLGR + SNCR installation summaries for pulverized coal boilers).
Source: Fuel Tech experience list dated 1/28/2005.

Carolina Power & Light (Progress Energy)   Pulverized Coal, Tangentially-fired
Cape Fear Unit 5   1956 vintage; eastern bituminous coal
154 MW CE boiler   SNCR startup in 2002
Mobotec USA “Rotamix” ammonia-based SNCR system injects aqueous ammonia liquid into a high velocity boosted separated overfire air (ROFA) system at the boiler.
CP&L technical paper claimed to lower NO_X from 0.28 lb/mmBtu baseline by 43% to 0.16 lb/mmBtu in 2002 with 5 ppm NH_3 slip following the installation of ROFA in 2000.
Overall reduction 73% from full-load pre-ROFA baseline 0.60 lb/mmBtu to 0.16 lb/mmBtu(18).
Mobotec claimed further NO_X reduction was possible by injecting urea in place of ammonia, achieving 0.13 lb/mmBtu instead of 0.18 lb/mmBtu, which would be 54% decrease from 0.28 lb/mmBtu with ROFA alone, or 78% overall decrease(19). Ammonia-to-NOx NSR not stated.
Source: (18) CP&L 2002 Technical paper; (19) Mobotec 2003 technical paper.

Carolina Power & Light (Progress Energy)   Pulverized Coal, Tangentially-fired
Cape Fear Unit 6   twin-furnace (eight corner), 1958 vintage; eastern bituminous coal
175 MW CE boiler   SNCR startup in 2001
Mobotec USA “Rotamix” ammonia-based SNCR system, injects aqueous ammonia liquid into a high velocity boosted separated overfire air (“ROFA”) system at the boiler.
CP&L technical paper claimed to lower NO_X from 0.23 lb/mmBtu baseline by 22% to 0.18 lb/mmBtu with 5 ppm NH_3 slip following the installation of ROFA+SNCR in 2001(18). Presentation slide graph shows no reduction for Rotamix beyond ROFA alone at full load NO_X emission rate of 0.23 lb/mmBtu. Ammonia-to-NOx NSR not stated.
Overall reduction 67% from full-load pre-ROFA baseline 0.54 lb/mmBtu to 0.18 lb/mmBtu.
Mobotec claimed further NO_X reduction was possible by injecting urea in place of ammonia, achieving 0.10 lb/mmBtu instead of 0.18 lb/mmBtu, which would be 56% decrease from 0.23 lb/mmBtu with ROFA alone, or 81% overall decrease(19). Urea-to-NOx NSR not stated.
Source: (18) CP&L 2002 Technical paper; (19) Mobotec 2003 technical paper.

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Cinergy (formerly Cincinnati G&E) Pulverized Coal, Tangentially-fired,
Miami Fort Unit 6 (Ohio) 1960 vintage; startup prior to 2000
163 MW CE boiler
Fuel Tech urea-based SNCR system, claimed to lower NOx by 35% from 0.55 lb/mmBtu baseline(1).(assume eastern bituminous coal). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, (1) ICAC White Paper.

Conectiv (formerly Delmarva Power & Light)
Edgemoor Unit 3 Pulverized Coal, Tangentially-fired, 1954 vintage
84 MW CE boiler mid-March 1996 startup; (assume eastern bituminous coal)
Hamon Research-Cottrell supplied a urea-based SNCR system. HRC claimed 35% NOx reduction with less than 10 ppm ammonia slip. Urea-to-NOx NSR not stated.
Another source shows a 30% reduction from 0.54 lb/mmBtu baseline(1).
Source: Hamon experience list (not listed by Fuel Tech); (1) ICAC White Paper.

Conectiv (formerly Delmarva Power & Light) Pulverized Coal
Indian River Units 3 & 4 (Millsboro, DE) Unit 3 is front wall-fired, 1974 vintage
178MW and 440 MW Unit 4 is turbo-fired opposed-wall, 1980 vintage
B&W, DB Riley boilers Spring 2000 startup (eastern bituminous coal)
Hamon Research-Cottrell supplied a urea-based SNCR system (not listed by Fuel Tech) on both units. HRC claimed 35% NO_X reduction with less than 5 ppm ammonia slip. Urea-to-NOx NSR not stated.
An REI 1999 technical paper shows a pre-SNCR baseline of 0.37 and 0.44 lb/mmBtu, respectively. (20)
Another source listed these units as having a pre-control NO_X baseline of 0.97 and 0.57 lb/mmBtu, and 2004 post-SNCR startup average of 0.32 and 0.33 lb/mmBtu, respectively. (12)

Dominion Generation (Virginia E&P Co.) Pulverized Coal, Tangentially-fired
Clover Station, Units 1 & 2 (VA) ABB/CE boilers, 1995, 1996 vintage
2 x 465 MW (eastern bituminous coal)
Urea-based SNCR (Fuel Tech system) 1995, 1996 startup (initial commercial)
Fuel Tech claimed NOx reduced by 25% from 0.32 lb/mmBtu baseline (to 0.24 lb/mmBtu).
Source: Fuel Tech experience list dated 1/28/2005. Urea-to-NOx NSR not stated.

Dynegy Midwest Generation (formerly Illinois Power) Pulverized Coal, Tangentially-fired
Vermillion Station, Unit 1 1955 vintage
82 MW CE boiler, bituminous Illinois coal
Mobotec USA "Rotamix" urea-based SNCR system with rotating opposed fired air (ROFA).
Mobotec 2004 technical paper claimed to lower NO_X by 55% from 0.22 lb/mmBtu baseline to 0.10 lb/mmBtu in April 2004 with urea-based Rotamix SNCR and < 5 ppm CO. NH_3 slip not mentioned. Overall reduction 83% from full-load pre-ROFA baseline 0.58 lb/mmBtu to 0.10 lb/mmBtu (21). Urea-to-NOx NSR not stated.
Source: (21) Mobotec 2004 technical paper.

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Eastern Utilities Associates,
Montaup Electric Company
Somerset Unit 8 (Massachusetts)
112 MW CE boiler

Pulverized Coal, Tangentially-fired
1959 vintage
Summer 1995 startup
(eastern bituminous coal)

Hamon Research-Cottrell supplied a urea-based SNCR (Fuel Tech system), claimed to lower NOx below 0.38 lb/mmBtu (Mass. RACT). Urea-to-NOx NSR not stated.
Another source listed 28-60% NOx reduction from a 0.49-0.89 lb/mmBtu baseline(1).
Source: Hamon experience list, Fuel Tech experience list dated 1/28/2005, (1)ICAC White Paper.

First Energy
Eastlake Unit 3 (Ohio)
130 MW CE boiler (w/ division wall)
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, Tangentially-fired,
1954 vintage
(eastern bituminous coal)
SNCR startup prior to 2000

Fuel Tech claimed to lower NOx from 20-32.5% from 0.34-0.40 lb/mmBtu baseline(1). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, (1) ICAC White Paper.

First Energy
Sammis Unit 2 (Ohio)
180 MW Foster Wheeler boiler SNCR startup Fall 1999
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, wall-fired,
1960 vintage
(eastern bituminous coal)

Fuel Tech claimed to lower NOx from 25-30% from 0.45 lb/mmBtu baseline (1). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, (1) ICAC White Paper.

First Energy
Sammis Units 6 & 7 (Ohio)
680 MW B&W Universal Pressure boilers
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, wall-fired,
1969 & 1971 vintage
(eastern bituminous coal)
SNCR startup after 1999

Fuel Tech claimed to lower NOx from 25% from 0.38 lb/mmBtu baseline. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005.

New England Power Company (NEPCO)
Salem Harbor Station
Units 1, 2 & 3
84 MWe x 2, & 156 MWe B&W boilers
Urea-based SNCR (Fuel Tech system)

Pulverized Coal, front wall-fired,
1952, 1952, 1958 vintage (eastern bit. coal)
SNCR startup prior to 2000

Fuel Tech claimed 66% (50-75%) NOx reduction from baseline of 1.0 ± 0.1 (range 0.85-1.12) lb/mmBtu, (which would lower NOx to around 0.34±0.07 lb/mmBtu). Urea-to-NOx NSR not stated. {These NOx reduction percentages may include impact of low-NOx burners}.
Source: Fuel Tech experience list dated 1/28/2005, (1)ICAC White Paper.

1 x 50 MW, 2 x 65 MW, 1 x 85 MW CE boilers eastern bituminous coal
Urea-based SNCR (Fuel Tech system) SNCR startup prior to 2000
Vendor claimed to lower NOx by 15-27.5% from 0.28 – 0.42 lb/mmBtu baselines. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005.

HYDROCARBON-ENHANCED AMMONIA SNCR (NOxStar™)

Pulverized coal-fired boilers

Tennessee Valley Authority (TVA) Pulverized Coal twin-furnace, tangentially-fired,
Kingston Power Station (TN) 1955 vintage eastern bituminous coal
Unit 9, 200 MWe CE boiler NOxStar™ startup January 2002
Demonstration of NOxStar™ hydrocarbon-enhanced ammonia-based SNCR installation.
Mitsui Babcock claimed 68% NOx reduction from baseline of 0.55 lb/mmBtu down to 0.17 lb/mmBtu with boosted OFA and NOxStar™ with < 5 ppm ammonia slip; NOxStar™ alone reduced NOx by 53%(22); boosted OFA only reduced NOx from 0.55 to 0.45 lb/mmBtu (18% reduction). Ammonia-to-NOx NSR not stated.
TVA's website reported that "an earlier version of NOxStar was installed at Kingston Fossil Plant Unit 9 in 2002 with mixed results. NOx reductions were achieved, but the boiler was damaged" (http://www.tva.gov/environment/repotrs/envreports/aer/2003/env_compliance.htm)
Source: (22) Mitsui Babcock Technical paper, October 2003.

Tennessee Valley Authority (TVA) Pulverized Coal, wall-fired
Colbert Station (AL) 1955 vintage
Unit 4, 192 MWe twin-furnace B&W boiler w/ FGR eastern bituminous coal
First commercial installation of NOxStar™ hydrocarbon-enhanced ammonia-based SNCR technology.
Mitsui Babcock showed 80% NOx reduction from baseline of 0.50 to 0.10 lb/mmBtu; using < 0.1% of total boiler heat input for propane input and 1% of total steam flow generated in the boiler for lance cooling(23); 2004 SNCR system startup. Ammonia-to-NOx NSR not stated.

Pulverized coal-fired boilers)

Conectiv (formerly Delmarva Power & Light)
Edgemoor Unit 4
160 MW CE boiler

Pulverized Coal, Tangentially-fired
1966 vintage, eastern bituminous coal
1999 startup

GE-EER Gas Reburn project added gas supply piping, metering, hangers, supports, reburn injectors and cooling air piping; OFA ductwork, injection nozzles and wall ports, field instrumentation. No FGR or OFA booster fans.
Vendor claimed to lower NOx up to 48% from baseline of 0.32 lb/mmBtu to 0.16 lb/mmBtu) at full load with reburn operation. No claims of percent reburn fuel included.
GE-EER technical paper shows approx. 32% NOx reduction for gas reburn with 4-mill operation at 160 MW load from 0.31 lb/mmBtu LNB + OFA baseline w/o reburn fuel (down to 0.21 lb/mmBtu), and 48% NOx reduction for gas reburn with 3-mill operation, to 0.16 lb/mmBtu (24).
Source: Sept. 2005 GE-EER experience list; (24) GE-EER 2004 Technical paper. Listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference)

Dynegy (formerly Illinois Power)
Hennepin Unit 1
71 MW CE boiler

Pulverized Coal, Tangentially-fired
1966 vintage
eastern bituminous coal

GE-EER Gas Reburn, 1990 startup (not currently operating); GE-EER Orimulsion Reburn, 1997.
DOE Clean Coal demonstration project (included sorbent injection).
Vendor claimed gas reburn w/ OFA lowered NOx up to 67% from baseline of 0.75 lb/mmBtu to 0.25 lb/mmBtu) at full load; 65% reduction from baseline of 0.75 lb/mmBtu down to 0.26 lb/mmBtu with subsequent Orimulsion reburn operation.
GE-EER 2004 technical paper shows 18% gas reburn fuel yielded minimum NOx emissions(6).
Another technical paper showed this 80 MW US DOE Clean Coal demonstration project in January 1991-January 1993 lowered NOx by 67% from 0.75 lb/mmBtu baseline (to 0.25 lb/mmBtu) with 18 percent reburn fuel(5).
Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL 2004 Reburn Conference technical paper, and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference). (Also see Conventional Oil reburn installation summaries for pulverized coal boilers).

REBURN – GAS, CONVENTIONAL continued

Pulverized coal-fired boilers)

AES (formerly New York State Gas & Electric (NYSEG)

Greenidge #6 (NY)	Pulverized Coal, Tangentially-fired,	1953 vintage
100 MW CE boiler	GE-EER Conventional Gas Reburn, 1996 startup	

Vendor claimed to lower NOx 55% from 0.63 lb/mmBtu baseline to 0.28 lb/mmBtu at full load with reburn operation burning eastern bituminous coal. Gas Research Institute predicted would achieve 76% (down to 0.15 lb/mmBtu) w/ advanced gas reburn.

GE-EER 2004 technical paper shows 23% reburn fuel yielded minimum NOx emissions around 0.23 lb/mmBtu(6).

EPA's "Scorecard on Reburning 6/1/2004" shows a 109 MW t-fired boiler (listed as Greenidge Unit 4) lowered NOx by 50% from 0.50 lb/mmBtu baseline (to 0.25 lb/mmBtu) with 10 percent reburn fuel (no longer operating) (5).

Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Potomac Electric Power (formerly West Pennsylvania Power)

Chalk Point Station	Pulverized Coal	opposed wall-fired B&W boilers
Units 1 & 2	1964, 1965 vintage	eastern bituminous coal
360 MW (nominal)	GE-EER Gas Reburn, 2000 startup	

Vendor claimed to lower NOx up to 43% and 45% from 0.60 lb/mmBtu baseline to 0.34 and 0.33 lb/mmBtu) at full load with reburn operation, respectively. No claims of percent reburn fuel included.

Source: 2002 GE-EER experience list. Listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Xcel Energy (formerly Public Service Company of Colorado)

Cherokee Unit 3	Pulverized coal, wall-fired, 1962 vintage
175 MW B&W boiler	western bituminous coal
DOE Clean Coal demonstration project	November 1992-January 1995

Gas reburn demonstration performed with Dept. of Energy and Gas Research Institute 1992-1995. Existing boiler with 16 burners was retrofitted with low NO_X burners and GE-EER gas reburn OFA, FGR, and reburn injectors. Added OFA booster fan, 800 hp flue gas recirculation fan for injection mass momentum, for increased gas injection mass momentum (which was subsequently removed). The CGR installation portion has since been decommissioned.

Vendor claimed to lower NOx up to 64% from baseline of 0.73 lb/mmBtu to 0.26 lb/mmBtu) at full load with reburn operation.

GE-EER 2004 technical paper shows 15-20% reburn fuel yielded minimum NOx emissions(6).

A 2004 DOE-NETL technical paper showed this project achieved 0.46 lb/mmBtu NO_X emissions with low NO_X burners alone (37% reduction), further reduced NO_X by 44% with 12.5 percent reburn fuel(5).

A 2001 DOE-NETL technical paper claimed a NOx reduction of 65% at an average reburn gas heat input of 18% of total boiler fuel input, with and without FGR. Demonstrated 70% NOx reduction at higher reburn input rates. Referred to technology as GR-LNB. FGR was added for gas injection momentum but was subsequently removed to reduce fuel input. (25)

Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL 2004 Reburn Conference technical paper and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference); (25) DOE-NETL 2001 Technical paper; also in (9) DOE 1999 Topical Report Number 14.

REBURN – OIL, CONVENTIONAL

Pulverized coal-fired boilers

Dynegy (formerly Illinois Power)	Pulverized Coal, Tangentially-fired	
Hennepin Unit 1	1966 vintage, eastern bituminous coal	
71 MW	CE boiler	1997 startup

GE-EER Orimulsion Reburn system w/ OFA, claimed orimulsion reburn lowered NOx up to 65% from baseline of 0.75 lb/mmBtu to 0.26 lb/mmBtu at full load with Orimulsion reburn operation (installed after gas reburn was demonstrated in early 1990's). No claims for percent reburn fuel included.
GE-EER 2004 technical paper shows 60% reduction with subsequent Orimulsion reburn (6).
Source: GE-EER experience list; (6) GE-EER 2004 Technical paper. Orimulsion not mentioned in (5) DOE-NETL 2004 Reburn Conference technical paper or DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference). (Also see Conventional Gas Reburn installation summaries for pulverized coal boilers).

New Brunswick Power	
Coleson Cove,	Bunker C/Orimulsion–fired, opposed-wall
St. John, New Brunswick, Canada	
3x 350 MW B&W Boilers	

Sixteen new low-NO$_X$ oil/Orimulsion burners, eight reburn burners, nine SOFA ports, two combustion air booster fans, reburn and OFA wall penetration openings, OFA windboxes, ductwork, dampers, and accessories were added(7).
Another technical paper showed this reburn system lowered NOx by 78% from 1.0 lb/mmBtu baseline to 0.22 lb/mmBtu at 25 percent reburn fuel input(5).
Source: (7) B&W 2004 Technical Paper;(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Georgia Power	Pulverized Coal, Tangentially-fired
Scherer Unit 1	1982 vintage
887 MW CE boiler	2000 oil reburn startup

GE-EER Oil Reburn system, claimed to lower NOx from baseline of 0.36 lb/mmBtu.
GE-EER 2004 Technical paper shows reduction up to 48% (to 0.19 lb/mmBtu) at 800 MW load with oil reburn operation. No claims of percent reburn fuel included(24).
Source: Sept. 2005 GE-EER experience list shows this as a coal reburn project with eastern bituminous coal, reducing NO$_X$ emissions 33% from 0.36 to 0.24 lb/mmBtu;
(24) GE-EER 2004 Technical paper. Not listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – COAL, MICRONIZED, CONVENTIONAL

Pulverized coal-fired boilers

AES (formerly New York State Electric and Gas Milliken Station Unit 1)

Cayuga	tangentially-fired, pulverized coal, 1956 vintage	
148 MWe, CE boiler	eastern bituminous coal	
GE-EER micronized coal reburn system		1996 startup (still operating)

US DOE Clean Coal demonstration project from March 1997-April 1999 lowered NOx with this reburn system by 29% from 0.35 lb/mmBtu baseline to 0.25 lb/mmBtu at 14 percent reburn fuel input(5). Not listed in GE-EER's experience list nor in their 2004 technical paper.
Source: (5) DOE-NETL 2004 Reburn Conference technical paper and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – COAL, MICRONIZED, CONVENTIONAL continued

Pulverized coal-fired boilers

E. ON US Holdings (formerly Louisville Gas and Electric)
R.D. Green Station Units 1 & 2 (KY) wall-fired, pulverized coal, vintage unknown
293 MWe, 2 boilers eastern bituminous coal
GE-EER coal reburn system Startup dates: 2003 & 2002, respectively
Vendor claimed to lower NOx up to 57% from baseline of 0.45 lb/mmBtu to 0.20 lb/mmBtu at full load with reburn operation.
Reburn system listed on EPA's "Scorecard on Reburning 6/1/2004" shows NOx lowered by 44% from baseline of 0.45 lb/mmBtu down to 0.25 lb/mmBtu (with unknown reburn fuel input(5)).
Another technical paper showed baseline NOx with existing low-NOx burners was 0.45 lb/mmBtu, and reduced NOx emission 40% to 0.27 lb/mmBtu with OFA, and further reduced NOx emissions 22% down to 0.21 lb/mmBtu with the coal reburn system in operation[26].
Source: (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference);

Cheng Loong (not in United States)
Unit #1, 250 MWe wall-fired, bituminous pulverized coal, vintage & mfr unknown
GE-EER coal reburn system 2000 Startup (still operating)
Source: GE-EER experience list
Vendor claimed to lower NOx 44% from baseline 0.45 lb/mmBtu to 0.25 lb/mmBtu) at full load with OFA alone; further reduced NOx 28% to 0.18 lb/mmBtu, for 60% overall reduction. Recent (2004) data shows NOx down to 0.14 lb/mmBtu (69% overall) with up to 30 percent reburn fuel(24).
Source: (24) GE Energy 2004 Technical paper; GE-EER experience list. Listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – GAS, CONVENTIONAL w SNCR

Pulverized coal-fired boilers)

NRG Somerset Pulverized Coal, Tangentially-fired, vintage
Unit 6 Boiler 8 (NY) GE-EER Conventional Gas Reburn,
120 MW CE boiler Fuel Tech SNCR, 2003 startup
Reburn vendor claimed to lower NOx 55% from 0.45 lb/mmBtu baseline to 0.20 lb/mmBtu at full load with reburn operation burning Venezuelan coal. The SNCR system further reduced NOx emissions 45% down to 0.11 lb/mmBtu, for an overall reduction of 77%.(26).
Source: Sept. 2005 GE Energy experience list; (26) March 2004 Modern Power Systems issue.

REBURN – FUEL LEAN GAS REBURN (FLGR)

Pulverized coal-fired boilers

Duke Power Company tangentially-fired, pulverized coal
Riverbend Unit 7 eastern bituminous coal 1954 vintage
140 MWe, CE boiler 1998 FLGR startup, gas reburn decommissioned since then
Previously installed ABB/CE's Low NOx Concentric Firing System (LNCFS-1) with Close-Coupled Overfire Air (CCOFA); (pre-mod NOx + combustion mods date not known).
Commercial FLGR installation claimed 34% NOx reduction from full-load baseline of 0.42 lb/mmBtu down to 0.29 lb/mmBtu w/ the combustion modifications and FLGR gas reburn fuel at 7% of total boiler heat input. CO emissions were above 1000 ppm corrected to 3% O_2.(27)
Vendor claimed to lower NOx 57% from 0.47 lb/mmBtu baseline to 0.20 lb/mmBtu) at full load with separated OFA alone; further reduced NOx 45% to 0.11 lb/mmBtu with low-NOx burners, OFA, gas reburn, and SNCR, for 77% overall reduction; no claims for amount of reburn fuel(24).

EPA's "Scorecard on Reburning 6/1/2004" showed this reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input(5).
Source: (27) ESA, GRI, NGB 1998 Technical paper; (24) GE Energy 2004 Technical paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – FUEL LEAN GAS REBURN (FLGR) continued
Pulverized coal-fired boilers
Wisconsin Electric Power Company (WEPCO)
Pleasant Prairie Unit 1 DB Riley, turbo-fired PC, Powder River Basin coal
620 MWg 1980 vintage 1999 startup
Fuel Tech listed FLGR installation and claimed 20% NOx reduction from baseline of 0.45 lb/mmBtu (to 0.36 lb/mmBtu). No claims of percent reburn fuel input included.
Source: Fuel Tech experience list dated 1/28/2005. (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference). (Also see FLGR + SNCR installation summaries for pulverized coal boilers).

REBURN – FUEL LEAN GAS REBURN w/ SNCR (Amine-Enhanced FLGR)
Pulverized coal-fired boilers
Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 startup
Commercial urea-based Fuel Tech SNCR +FLGR installation claimed 50% NOx reduction from baseline of 0.58 lb/mmBtu (426 ppm) down to 0.29 lb./mmBtu w/ 5 ppm ammonia slip(1). Low NO_X burners were previously retrofitted in 1997 without separated overfire air(28). This is 33 % lower than 0.44 lb/mmBtu baseline for SNCR alone. (Also see SNCR installation summaries for pulverized coal boilers). Urea-to-NOx NSR not stated.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(5).
Another technical paper showed 52% NOx reduction down to 0.28 lb/mmBtu at all loads, from 99 MWg to 207 MWg (48% to 100% MCR) with an average NH_3 slip of 3 ppm. FLGR alone achieved 23% NOx reduction with 6% reburn fuel and < 400 ppm CO at full load. (28)
Source: Fuel Tech experience list, (1)ICAC White Paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference); (28) CP&L and Fuel Tech 2001 Technical paper.
(Also see SNCR installation summaries for pulverized coal boilers).

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Hudson Station, Unit 2 Pulverized Coal, opposed-wall-fired, 1968 vintage
660 MWe Foster Wheeler boiler eastern bituminous coal March 1999 startup
Commercial SNCR + FLGR urea-based Fuel Tech installation claimed 40% NOx reduction from baseline of 0.65 lb/mmBtu (down to 0.39 lb/mmBtu) w/ 10 ppm ammonia slip(1). This is 20 % lower than 0.49 lb/mmBtu baseline for SNCR alone. Urea-to-NOx NSR not stated.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(5).
Source: Fuel Tech experience list, (1)ICAC White Paper;(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).
(Also see SNCR installation summaries for pulverized coal boilers).

REBURN – FUEL LEAN GAS REBURN w/ SNCR (Amine-Enhanced FLGR) continued

Pulverized coal-fired boilers

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Mercer Station (2) twin-furnace boilers, 320 MWe each, DB Riley turbo-fired
Unit 1 and Unit 2 front wall PC, wet-bottom (slagging ash) eastern bituminous coal
Furnace #11 & #12 1960 vintage May 1999 startup
Furnace #21 & 22 1961 vintage May 1999 startup
Commercial urea-based Fuel Tech SNCR + FLGR installation claimed 60% NOx reduction from baseline of 1.4 lb/mmBtu (down to 0.56 lb/mmBtu) w/ 5 ppm ammonia slip (1). This is 72 % lower than 2.0 lb/mmBtu baseline without control. Initial demonstration of AEFLGR coinjected amine-enhanced natural gas into Furnace 22 in 1998. Subsequently installed AEFLGR on both units to reduce NOx starting in May 1999 using (2) levels of AEFLGR retractable gas injectors and (2) levels of SNCR injectors(29). Urea-to-NOx NSR not stated, goal was NSR < 1.25.
{Note both units have since been retrofitted with low-dust tail-end SCRs in 2004; SNCR systems are still capable and operated as needed, mostly for flyash conditioning to aid ESP performance}
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 1999, but not currently operating(5).
Source: Fuel Tech experience list, (1)ICAC White Paper; (29) PSE&G, FT and ESA 2000 Technical paper;(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Wisconsin Electric Power Company (WEPCO)
Pleasant Prairie Unit 1 DB Riley, turbo-fired PC, Powder River Basin coal
620 MWg 1980 vintage 1999 startup
Fuel Tech urea-based SNCR +FLGR demonstration installation claimed 56% NOx reduction from baseline of 0.45 lb/mmBtu to 0.20 lb/mmBtu w/ 5 ppm ammonia slip(1). This is 44 % lower than 0.36 lb/mmBtu baseline for FLGR alone.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(5).
Source: Fuel Tech experience list, (1)ICAC White Paper and F.T. experience list 0207;
(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

LOW NO_x BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR

Pulverized coal-fired boilers

AEP Cardinal Unit 1 Pulverized Coal cell-burner, opposed wall-fired B&W boiler
600 MW (nominal) 1967 vintage; Low NO_x burners installed in October 1998
Produced 0.75 lb/mmBtu NOx post-LNB install baseline at full load.
LNBs reduced NO_X 57% from 1.20 down to 0.52*, produce NO_X at approx. 0.57 lb/mmBtu at min. load w/o SNCR (range 0.51 to 0.65) and produce 0.75 lb/mmBtu NO_X at approx. 585 MW (top of load range tested, NO_X range 0.73 to 0.86 lb/mmBtu) (17).
(50) original B&W circular burners were recently replaced on Cardinal Units 2 & 3 by Buckeye Power with DB Riley (now Babcock Power) CCV type low NOx burners.
Source: *Riley Power (Babcock Power Inc.) 8/16/04 experience list; (17) 2000 Fuel Tech technical paper. (Also see SNCR installation summaries for pulverized coal boilers).

Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 startup
Low NO_X burners were previously retrofitted in 1997 without separated overfire air(22). NOx reduction was 46% from pre-LNB installation baseline of 1.08 lb/mmBtu (12) down to 0.58 lb./mmBtu (28).

(Also see SNCR, and FLGR with SNCR installation summaries for pulverized coal boilers).
Source: (12) 2005 US EPA Docket OAR-2002-0076-0446 Technical Support Document spreadsheet; (28) CP&L and Fuel Tech 2001 Technical paper.

LOW NO_x BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued

Pulverized coal-fired boilers

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 5 1956 vintage; eastern bituminous coal
154 MW CE boiler ROFA startup in 2000
Mobotec USA's Rotating Opposed Fire Air (ROFA) is a high velocity boosted separated overfire air system claimed to lower NO_X without retrofitting low-NOx burners. This was the first U.S. installation of Mobotec USA's "Rotating Opposed Fire Air" (ROFA) on a utility boiler, which utilizes a booster fan.
CP&L technical paper claimed to lower NO_X 53% from full-load pre-ROFA baseline 0.60 lb/mmBtu to 0.28 lb/mmBtu with ROFA alone following the installation of ROFA in 2000(18).
Source: (18) CP&L 2002 Technical paper. (Also see SNCR installation summaries for pulverized coal boilers).

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 6 twin-furnace (eight corner), 1958 vintage; eastern bituminous coal
175 MW CE boiler ROFA startup in 2001
This unit's "ROFA" system was installed as part of a "Rotamix" SNCR + ROFA system.
CP&L technical paper shows ROFA alone reduced NOx 57% from full-load pre-ROFA baseline 0.54 lb/mmBtu to a NO_X emission rate of 0.23 lb/mmBtu. (18)
Source: (18) CP&L 2002 Technical paper. (Also see SNCR installation summaries for pulverized coal boilers).

Conectiv (formerly Delmarva Power & Light)
Indian River Units 3 & 4 (Millsboro, DE) Unit 3 is front wall-fired, 1974 vintage
178MW and 440 MW Unit 4 is turbo-fired opposed-wall, 1980 vintage
B&W, DB Riley boilers eastern bituminous coal
REI performed CFD modeling on both units for potential SNCR application.
Unit 3 has Riley Low NOx burners (16), (8) front wall and (8) rear wall OFA ports, (8) wall boundary air ports, (66) side wall OFA slots, claimed baseline NOx around 0.37 lb/mmBtu w/o SNCR (20).
Unit 4 has (24) front and rear wall down-fired burners, (28) front and rear wall SOFA ports, claimed NOx around 0.44 lb/mmBtu w/o SNCR (20) {furnace has "Mae West" belt}.
Riley provided 16 CCV low-NOx burners for Unit 3 in 1994, and claimed to reduce NOx emissions by 67% from pre-LNB baseline of 1.05 lb/mmBtu down to 0.34 lb/mmBtu.
Source: (20)REI 1999 Technical Paper; Riley Power (Babcock Power Inc.) 8/16/04 experience list. (Also see SNCR installation summaries for pulverized coal boilers).

Dayton Power & Light Pulverized Coal, Tangentially-fired
Killen Station, Unit 2 1955 vintage
632 MW CE boiler, bituminous Illinois coal
GE-EER provided low-NOx burners in 1999. Vendor claimed full load NO_X was reduced by 23% from a 0.57 lb/mmBtu baseline down to 0.44 lb/mmBtu.
Source: GE-EER Experience list 2/1/02. (Also see low-dust SCR installation list for pulverized coal boilers)

LOW NO$_x$ BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued

Pulverized coal-fired boilers

Dynegy Midwest Generation (formerly Illinois Power) Pulverized Coal, wall-fired
Havana Station, Unit 6 1978 vintage
460 MW B&W boiler, bituminous Illinois coal
GE-EER provided modifications to the original B&W dual-register burners, and an OFA system in 2000. Vendor claimed full load NO$_X$ was unchanged from 0.38 lb/mmBtu baseline.
Source: GE-EER Experience list 2/1/02. (Also see low-dust SCR installation list for pulverized coal boilers)

Dynegy Midwest Generation (formerly Illinois Power) Pulverized Coal, Tangentially-fired
Vermillion Station, Unit 1 1955 vintage
82 MW CE boiler, bituminous Illinois coal
This rotating opposed fire air (Mobotec USA ROFA) system was installed in July 2002, as part of a "Rotamix" SNCR + ROFA system, without low-NOx burners.
Mobotec 2004 technical paper claimed to lower full load NO$_X$ by 62% from 0.58 lb/mmBtu baseline to 0.22 lb/mmBtu in July 2002 (without LNB or SNCR). (21)
Source: (21) Mobotec 2004 technical paper. (Also see SNCR installation summaries for pulverized coal boilers).

Georgia Power Pulverized coal, opposed wall-fired,
Harlee Branch Unit 1 250 MW B&W boiler, 1965 vintage 2003 startup
Harlee Branch Unit 2 359 MW Riley boiler, 1967 vintage 1998 startup
B&W provided 24 DRB-4Z low NOx burners for Unit 1 B&W boiler, 24 DRB-XCL low NOx burners for Unit 2 Riley boiler (believe southeast coast lignite is primary fuel).
Source: B&W's experience list. No NOx reduction claims.

Kansas City Power & Light Pulverized coal, opposed wall-fired, 600 MW B&W boiler
Hawthorn Unit 5 30 burners, 2001 vintage, (Powder River Basin coal)
B&W provided 30 DRB-4Z low NOx burners and 11 OFA ports with the new boiler.
Source: B&W's experience list. No NOx reduction claims.

New England Power Company (NEPCO)
Salem Harbor Station Pulverized Coal, front wall-fired,
Units 1, 2 & 3 1952, 1952, 1958 vintage (eastern bit. coal)
84 MWe x 2, & 156 MWe B&W boilers LNBs startup in 1995, 1995, and 1993
Riley claimed Unit 1 LNBs reduced NOx emissions by 57% from baseline of 1.10 lb/mmBtu down to 0.42 lb/mmBtu; Unit 2's LNBs achieved 42% NOx reduction from a baseline of 0.95 lb/mmBtu down to 0.55 lb/mmBtu; Unit 3's LNBs achieved 60% NOx reduction from a baseline of 1.05 lb/mmBtu down to 0.42 lb/mmBtu.
Source: Riley Power (Babcock Power Inc.) 8/16/04 experience list.
(Also see SNCR installation summaries for pulverized coal boilers).

Northeast Utilities (formerly Public Service of New Hampshire)
Shiller Station Pulverized Coal/#6 Fuel oil, front-wall-fired
Units 4, 5, & 6 1952, 1955, 1957 vintage
50 MWe x 3 Foster Wheeler boilers
RJM provided (6) Low NO$_x$ burner modifications per boiler in 1994, 1992, & 1994 respectively;
LNBs reduced NOx 43% from 0.85 to 0.48, 50% from 1.0 to 0.50, and 51% from 0.82 to 0.40 lb/mmBtu.
Source: RJM experience list

LOW NO$_x$ BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued
Pulverized coal-fired boilers

Potomac Electric Power (formerly West Pennsylvania Power)

Chalk Point Station	Pulverized Coal	opposed wall-fired
Units 1 & 2	1964, 1965 vintage	eastern bituminous coal
360 MW (nominal)	B&W boilers	

DB Riley (now Babcock Power) CCV type low NOx burners retrofitted in 1993 and 1994, respectively. Vendor claimed to lower NOx up to 52% and 50% from 1.35 and 1.40 lb/mmBtu baselines (to 0.65 and 0.70 lb/mmBtu, assumed at full load).
Source: Riley Power (Babcock Power Inc.) 8/16/04 experience list. (Also see Conventional Gas Reburn installation summaries for pulverized coal boilers).

Xcel Energy (formerly Public Service Company of Colorado)

Cherokee Unit 3	Pulverized coal, wall-fired, B&W boiler, 16 burners, 1962 vintage
175 MW	October 1992 baseline testing started (western bituminous coal)

Installed (16) Foster Wheeler Controlled Flow/Split Flame low NO$_x$ replacement burners as part of a DOE Clean Coal Technology gas reburn demonstration performed with Gas Research Institute 1992-1995.
Uncontrolled NOx w/ original B&W flare-type burners was 0.73 lb/mmBtu. Replacement LNBs (assuming OFA included) reduced NO$_X$ 37% to 0.46 lb/mmBtu(25).
Source: (25) DOE NETL 2001 Technical paper.

ASH IMPACTS ON SCR CATALYST PERFORMANCE

EXECUTIVE SUMMARY

The ash deposition behavior of the lignites from North Dakota is the most complex and severe of any coals in the world, and installation of catalysts for NO_x reduction is going to be plagued with problems. The Center lignite fired at the Milton R. Young (MRY) Power Station is highly variable in abundance of various types of ash/slag-forming components. Ash-forming components consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with oxygen functional in the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. The alkali and alkaline-earth elements combine with minerals during combustion, resulting in low-melting-point phases that cause a wide range of fireside deposition problems. In addition, the alkali and alkaline-earth elements also form very small particles that are carried into the backpasses of the combustion system and react with flue gas to form sulfates that can cause deposition, blinding, and plugging problems in selective catalytic reduction (SCR) systems. This report analyzes these problems, and concludes that SCR is not a feasible option to control NOx emissions at MRY Power Station because of the high sodium levels present in the coal.

Following is a list of the key problems that are associated with Center lignite which have not been overcome and, in our opinion, make the installation of SCR at the MRY plant technically infeasible for NO_x control.

➢ Blinding of Catalyst Pores by High Sodium Compounds

  X High levels of alkali and alkaline-earth elements present in the coal fired at the MRY plant produce small particles that react to form sulfates that blind the catalyst pores. The high levels of sodium in the coals combined with calcium will produce low-melting-point eutectic sulfate compounds that will form and melt inside the pores of the catalyst.
  - Alkali and alkaline earth sulfates are enhanced by cyclone fired system. The cyclone firing results in partitioning of the ash between bottom slag and the body of the boiler. The sulfate forming materials are more concentrated in the ash as a a result of cyclone firing.

  - Sulfate formation is enhanced by the presence of an SCR catalyst; this accelerates the sulfation reactions, causing blinding of the catalyst.

  - The sulfate reactions are more severe at MRY because of the high temperature where an SCR would be installed. The higher temperature increases the rate of formation of sulfates and rate of pore plugging.

  - The testing conducted by the Germans found catalyst deactivation and blinding occurs when firing coals with lignite or brown coals that have ashes that are rich in alkali and alkaline-earth elements. .

- The findings by the Germans were confirmed by recent SCR catalyst slipstream testing that showed significant evidence of sodium and calcium-rich sulfate formation that fill and plug the catalyst at both lignite- and subbituminous-coal-fired power plants. The results of this recent testing showed that the presence of sodium significantly enhanced the formation of bonding of particles and more rapid sulfation, filling of pores, and rapid increase in pressure drop across the catalyst.

- Deposit carryover, or "popcorn ash," plugging the top of the SCR catalyst is a significant problem because of the extremely high deposition rates of the Center coal. When firing Center coal, deposits form on various parts of the boiler requiring continuous sootblowing. The sootblowing of upstream heat-exchange equipment will cause deposit fragments to be carried back to the SCR catalyst, resulting in plugging. In addition, during sootblowing of the SCR catalyst, the entrainment of deposit fragments along with the sootblowing media will result in significant erosion of the catalyst surfaces.

- Recent testing with subbituminous and lignitic coals indicated a significantly higher level of pore filling and plugging in the catalyst exposed to lignite ash as compare to subbituminous coal ash. The catalyst pores as well as the catalyst surface in the lignite tests were completely coated with a sodium calcium sulfate material, while only pore filling was found in the subbituminous coal testing. The pressure drop across the catalyst exhibited for lignite was 4 to 5 times greater than that found for a catalyst exposed to subbituminous coal ash. The plugging occurred over a 1000 hour test period.

- Cold Side SCR Installation

  - High-sodium lignite coal from the Center Mine Hagel A and B seam coal produces significant levels of homogeneously condensed sodium sulfate that pass through the ESP and wet scrubber.

  - These small particles have been shown to pass through a wet scrubber and will accumulate on surfaces of tail-end SCR systems. The accumulated materials require sootblowing to remove the particulate and will result in increased opacity.

  - Liquid pyrosulfate materials at temperatures as low as 535°F from sodium sulfate materials occurs in coal-fired power systems and is well documented. Pyrosulfates will form and cause blinding of tail-end SCR devices. In addition, SCR systems are known to catalyze the formation of SO_3 from SO_2. The presence of SO_3 significantly enhances the formation of the pyrosulfates.

ASH IMPACTS ON SCR CATALYST PERFORMANCE

INTRODUCTION

Ash produced during combustion of coal in conventional power systems is a major problem that results in decreased efficiency, unscheduled outages, equipment failures, and increased cleaning. The many ways in which the detrimental effects of ash manifest themselves in a boiler system include fireside ash deposition on heat-transfer surfaces, corrosion and erosion of boiler parts, poor slag flow, and production of fine particulates that are difficult to collect. Decades of research have been conducted to develop a better understanding of the chemical and physical processes of ash formation and deposition in combustion systems. Overviews of ash-related issues and compilations of work by many investigators can be found by referring to the work of Mehta and Benson (1), Schobert (2), Baxter and DeSollar (3), Couch (4), Williamson and Wigley (5), Benson and others (6), Benson (7), Bryers and Vorres (8), Raask (9, 10), and Benson (11). This work has led to a detailed understanding of ash formation and behavior in combustion systems as well as the development of predictive methods (12, 13).

The chemical composition and physical characteristics of ash-forming or inorganic components (mineral and organically associated elements) of the fuel(s) fired have an influence on the following processes in the combustion systems:

- Firing conditions such as cyclone, pulverized coal, and low-NO_x burners
- Transformations of coal inorganic components to ash particulate and vapor-phase species
- Boiler design characteristics, including number of burners, radiant section area, tube bank spacing, access for cleaning, and number of sootblowers
- Ash transport to heat-transfer surfaces in utility boilers
- Erosion wear and sticking
- Ash deposit growth and impact on heat transfer
- Ash blinding and plugging of selective catalytic reduction (SCR) catalysts
- Ash deposit removability

The ash deposition in North Dakota lignite-fired power plants is a major problem that impacts all fireside surfaces of the power plant. The ash problems are due to the variable and complex nature of inorganic components associated with lignite coals (2). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. During the gas-cooling processes in the boiler, the gas-phase species condense and the liquid-phase materials solidify. The abundance of these gas-phase and liquid materials entrained in the bulk gas flow is highly dependent upon coal composition and system operating conditions. The inorganic materials are transported to heat-transfer and catalyst surfaces by diffusion, electrophoresis, thermophoresis,

and inertial impaction. The particle sticking and accumulation rates are dependent upon the quantity of ash and the abundance and viscosity of the liquid-phase components. In high-temperature regions of the boiler, high-temperature sodium–calcium–aluminosilicate liquid phases act as the sticky material, causing deposit initiation, growth, and development of deposit strength. As the temperature of the flue gases decreases, the condensation and reaction of flame-volatilized species play a more significant role in the formation of deposits from lignite coals. The formation of sodium and/or calcium magnesium sulfates dominates the deposit accumulation mechanisms at lower temperatures. The aluminosilicate phases are dominant above about 1800°F. Below about 1800°F, the sulfate phases become stable, with an optimum temperature of formation of about 1400°F, and can form at temperatures as low as 300°F.

The most significant problems that prohibit the successful operation of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates and phosphates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency (14–16).

INORGANIC COMPOSITION OF LOW-RANK COALS

Inorganic elements in coal occur as discrete minerals, organically associated cations, and cations dissolved in pore water. The fraction of inorganic components that are organically associated varies with coal rank. Lower-ranked subbituminous and lignitic coals have high levels of oxygen, which act as bonding sites for cations such as sodium, magnesium, calcium, potassium, strontium, and barium (other minor and trace elements may also be present in this form). In higher-ranked coals, bituminous and anthracite, inorganic components consist mainly of minerals. Mineral grains are usually the most abundant inorganic component in coal. The major mineral groups found in coals include silicates, aluminosilicates, carbonates, sulfides, sulfates, phosphates, and some oxides.

The behavior of ash produced during coal combustion is related to the abundance, size, and association of mineral grains in the coal. In addition, the association of the mineral grain with the coal matrix influences the temperature and gaseous environment the mineral is exposed to during combustion. A mineral associated with the organic part of a coal particle is said to be included. A mineral that is not associated with organic material is referred to as excluded. The behavior of the organically associated elements, those elements that are atomically dispersed in the coal matrix, must also be measured as to their abundance in the coal. The organically associated elements will react and interact with the other ash-forming constituents during combustion.

The Center lignite is highly variable in abundance of various types of ash/slag-forming constituents. Ash-forming components in the Center lignite are of two types. The first form may constitute up to 50% of the ash and is derived from inorganic elements (sodium, magnesium, calcium, and potassium) associated with oxygen functional in the organic matrix of the coal. The second type consists of mineral grains (sand, clay, limestone, and pyrite). The minerals are discrete particles of ash-forming species and the sources of silicon, aluminum, iron, titanium, and minor amounts of the calcium and potassium. The Center lignite fired at the Milton R. Young (MRY) plant has been examined extensively because of its problem with ash behavior. Analyses

of as-fired and drill core samples have been conducted. The mean and the range of selected components are shown in Figure 1. The results indicate that both the abundance of ash and the abundance of major oxides in the ash vary significantly. In addition, the abundance of alkali and alkaline-earth elements (Na and Ca) varied dramatically. Variations in Si were found to be the most significant. High levels of Ca and/or Na were found for lower-ash coals as compared to high levels of Al and Si associated with higher-ash coals (17, 18).

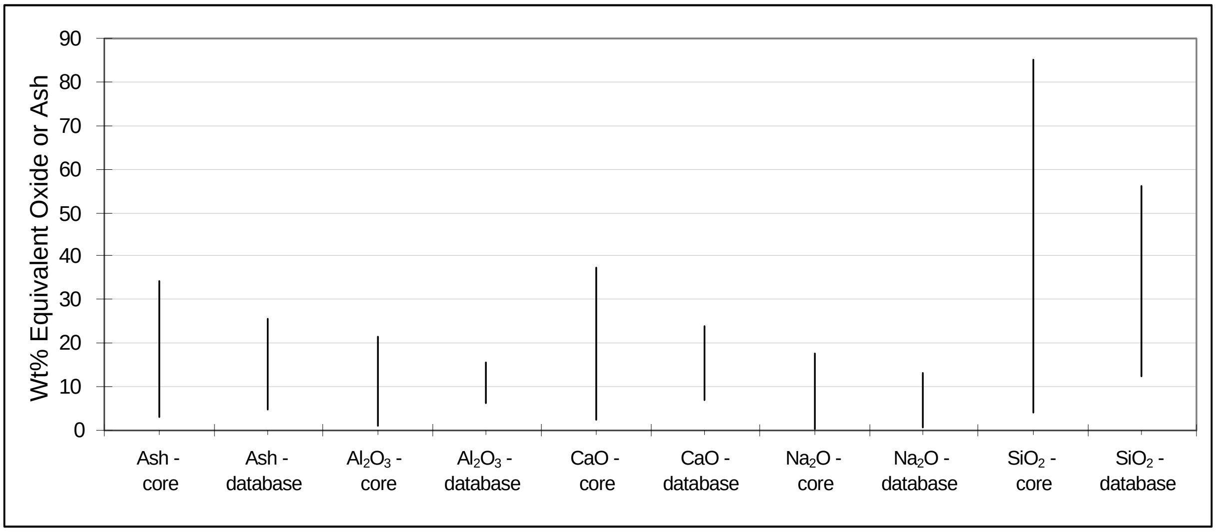

Figure 1. Variability of ash and selected constituents in core analysis database provided by BNI Coal, Ltd. and Minnkota as fired coal analysis database.

The variability of the ash-forming components has been examined for the approximately 5000 samples characterized to date. Wide variations in ash contents and the major ash-forming constituents are observed. During the mining processes, the inorganic components are mixed, and some of the extreme characteristics are diluted (17).

INORGANIC TRANSFORMATIONS AND ASH FORMATION

The inorganic coal components undergo complex chemical and physical transformations during combustion to produce intermediate ash species. The inorganic species consist of vapors, liquids, and solids. The partitioning of the inorganic components during combustion to form ash intermediates depends upon the association and chemical characteristics of the inorganic components, the physical characteristics of the coal particles, the physical characteristics of the coal minerals, and the combustion conditions.

The physical transformation of inorganic constituents depends on the inorganic composition of the coal and combustion conditions. The inorganic components can consist of organically associated cations, mineral grains that are included in coal particles, and excluded mineral grains. There is a wide range of combinations of mineral–mineral, mineral–coal,

mineral–cation–coal, and mineral–mineral–cation–coal associations in coal. These associations are unique to each coal sample.

The physical transformations involved in fly ash formation include 1) coalescence of individual mineral grains within a char particle, 2) shedding of the ash particles from the surface of the chars, 3) incomplete coalescence due to disintegration of the char, 4) convective transport of ash from the char surface during devolatilization, 5) fragmentation of the inorganic mineral particles, 6) formation of cenospheres, and 7) vaporization and subsequent condensation of the inorganic components upon gas cooling. As a result of these interactions, the ash has a bimodal size distribution. The submicron component is largely a result of the condensation of flame-volatilized inorganic components. The mass mean diameter of the larger particles is approximately 12 to 15 μm, depending upon the coal and combustion conditions. The larger-size particles have been called the residual ash by some investigators (19) because these ash particles resemble, to a limited degree, the original minerals in the coal. Processes such as ash mineral coalescence, partial coalescence, ash shedding, and char fragmentation during char combustion and mineral fragmentation, all play an important role in the size and composition of the final fly ash. Loehden and others (20) and Zygarlicke and others (21) indicate that three potential modes for fly ash generation can be used to describe fly ash particle-size and composition evolution. The first, “fine limit,” assumes that each mineral grain forms a fly ash particle and that the organically associated elements form fly ash particles of less than 2 μm. The second, “total coalescence,” assumes one fly ash particle forms per coal particle. The third, “partial coalescence,” suggests that the fly ash composition and particle size evolve because of partial coalescence.

The transformations of excluded minerals are dependent upon the physical characteristics of the mineral. Excluded minerals such as quartz (SiO_2) can be carried through the combustion system with its angular structure still intact. Excluded clay minerals can fragment during dehydration, melt, and form cenospheres. The behavior of excluded pyrite depends upon its morphology. Some of the pyrite may be present as framboids. Framboidal pyrite may fragment more easily than massive pyrite particles. In addition, the decomposition of pyrite is very exothermic, and it transforms to pyrrhotite and oxidizes to FeO, Fe_3O_4, and Fe_2O_3 during combustion.

ASH DEPOSITION ON HEAT-TRANSFER AND OTHER SURFACES EXPOSED TO ASH AND FLUE GAS

The characteristics of a deposit depend upon the chemical and physical characteristics of the intermediate ash species, geometry of the system (gas flow patterns), gas temperature, gas composition, and gas velocity. Figure 2 illustrates the ash deposition phenomena in utility boilers. Ash particle accumulations occur via transport of particles to the fireside surfaces (heat transfer, ceramic materials, support materials, SCR catalysts, baghouse materials, and ESP wires and plates) and sticking of the particles. The transport mechanisms important for ash deposition include small-particle mechanisms for particles less than 10 μm that involve thermophoresis, electrophoresis, and vapor-phase and small-particle diffusion; and large-particle mechanisms for particles greater than 10 μm that involve inertial impaction. The ability of larger particles to stick depends upon the quantity and viscosity of the liquid phase on the particle surface.

Thermophoresis is a phenomenon that involves the transport of very small particles as a result of a thermal gradient from hot gases to cooler surfaces. Electrophoresis is the transport of particles because of a difference in charge. Vapor-phase and small-particle diffusion occurs in the boundary layer next to the surface and results in transport of ash to the surface. Inertial impaction is a larger-particle phenomenon where the particles are of a sufficient size and density to leave airflow patterns around the tube and impinge upon the surface of a tube or deposit. Deposits that form in high-temperature regions of the boiler, such as the radiant section, are called slag deposits. Deposits that form in lower-temperature regions of the boiler, such as in the convective pass on steam tubes and lower-temperature surfaces such as SCR catalysts, are called fouling deposits. Slag deposits are usually associated with a high level of liquid-phase components and are exposed to radiation from the flame. This is a description that many researchers use to aid in classification of deposits since some engineers call any type of deposit "slag". Slag deposits are typically dominated by silicate liquid phases, but may also contain moderate to high levels of reduced iron phases such as FeO and FeS. The liquid characteristics of the silicates are highly dependent upon the quantities of Na, Mg, Ca, K, and Fe ash on the silicates. In addition, the initiating layers of slag deposits may consist of very fine particulate and can produce a reflective ash layer. This phenomenon is especially evident when high organically associated calcium subbituminous coal is fired. These coals produce small CaO particles that usually form the initiating layers.

Fouling deposits form in the lower-temperature regions of the boilers and, in most cases, do not contain the high levels of liquid phases that are usually associated with slagging-type deposits. Fouling deposits contain lower levels of liquid phases as compared to slag deposits. The fouling deposit liquid phases usually consist mainly of sulfates that bind the particles together. Fouling deposits typically form as a result of the reaction of gas-phase sulfur oxide species with particles rich in alkali and alkaline-earth elements.

ASH-RELATED EXPERIENCES AT MRY FACILITY

The MRY is a minemouth electrical generating plant located near Center, North Dakota. The station consists of two units: Unit 1, rated at 276 MWg, began production in 1970; Unit 2, rated at 506 MWg, began production in 1977. Both Units 1 and 2 are equipped with B&W cyclone-fired boilers; the Unit 1 boiler has seven cyclones, and the Unit 2 boiler has twelve cyclones. Annual station gross generation is approximately 5.5 million MWh.

BNI Coal Ltd. is the sole coal supplier for the MRY Station. Coal is mined from the nearby Center mine, which consists of three distinct seams varying from 2½–9 feet thick. Coal is strip-mined using two draglines and is loaded with front-end loaders and delivered to the plant with bottom-dump haul trucks. Annual coal production is 4.3 million tons per year.

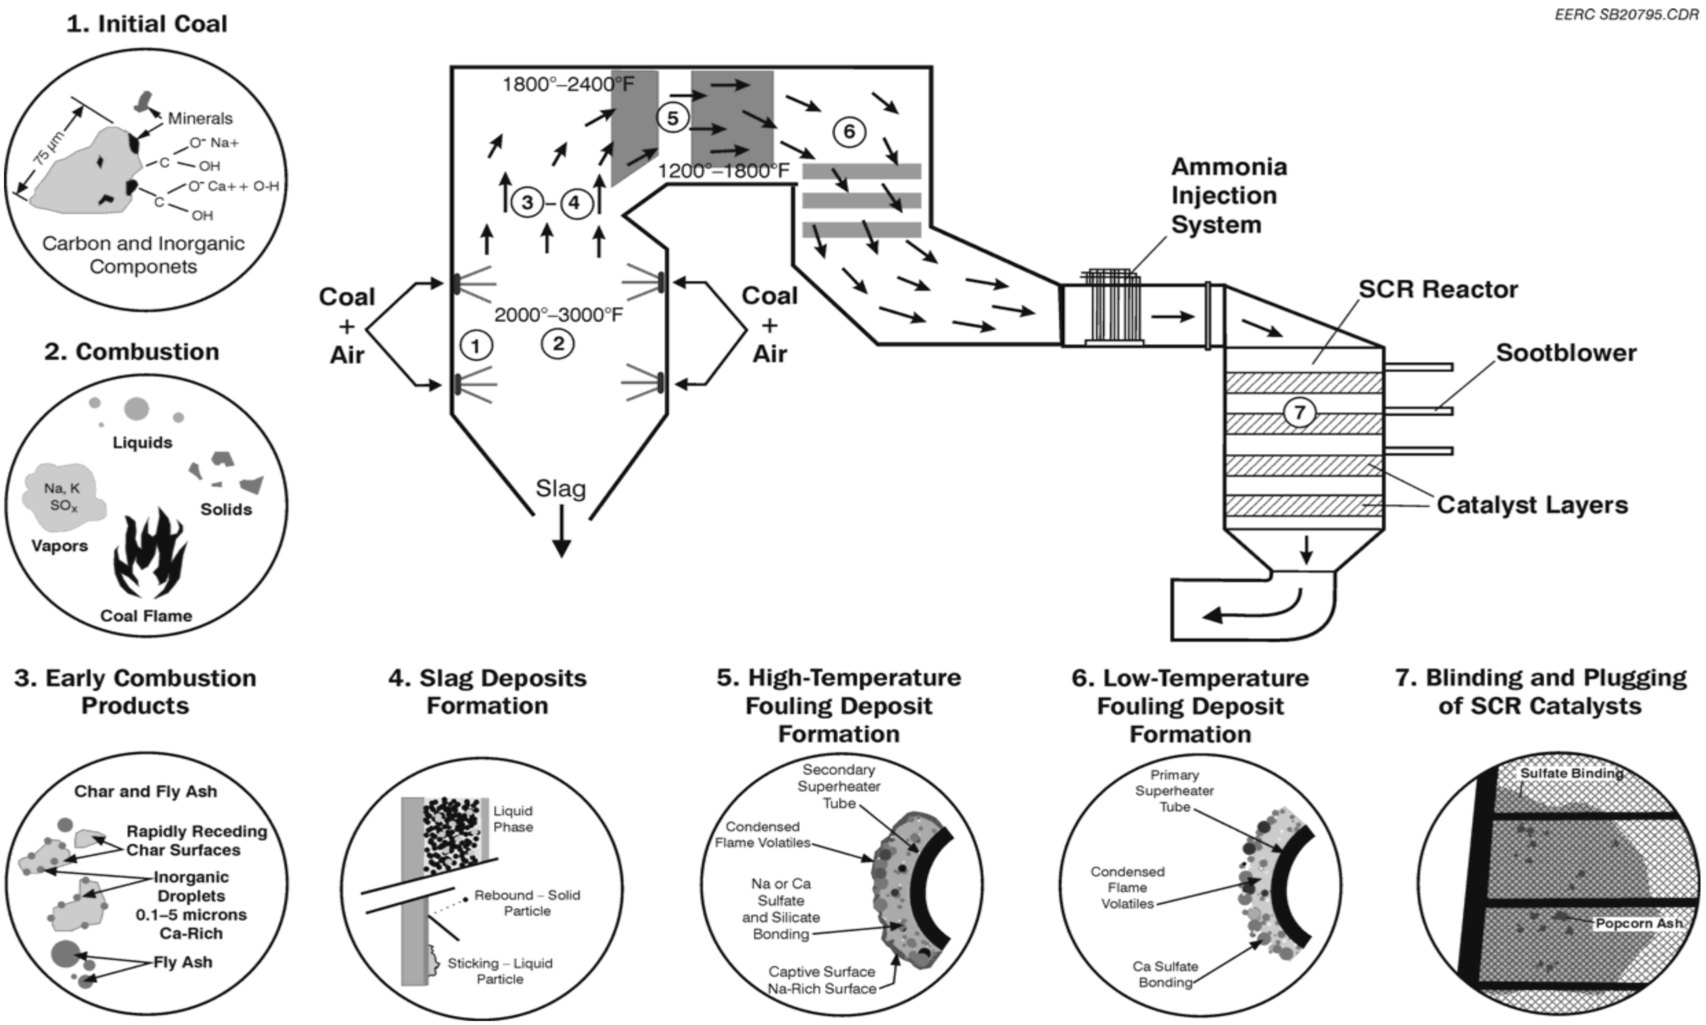

Figure 2. Overall processes of ash deposition typical of a lignite- or subbituminous-fired boiler.

History of Furnace Slagging/Fouling

Prior to 1991, besides annual maintenance outages, load reductions and forced outages due to furnace slagging/fouling were the largest cause of production loss. In 1985, operating guidelines were established that reduced furnace slagging/fouling, including deslagging outages scheduled every six months.

In 1991, a 3-month boiler cleaning cycle was proposed and initiated. The goal of this program was to increase annual generation by running the units at higher sustained loads and scheduling boiler-cleaning outages at 3-month intervals. However, furnace slagging/fouling continued to have a significant impact on plant operations. Success was measured in the number of production days between boiler-cleaning outages.

During the mid-1990s, a major outage every third year was scheduled for each unit. In addition, Unit 1 cleaning outages were scheduled for 80–90-day runs (four cleaning outages per year), and Unit 2 cleaning outages were scheduled for 65–75-day runs (five cleaning outages per year). The problem was that furnace and convection-pass surfaces gradually become coated with ash deposits, which, over time, sootblowers cannot remove. Some of the contributors to the ash deposits were as follows:

- Organically associated sodium is a primary contributor to deposition problems. Sodium is vaporized in the cyclones and condenses on other ash particles, causing them to become sticky and deposit at the furnace exit. The problem is associated with sulfate formation and occurs in the convective pass, including the economizer. Samples show that sodium in the ash varies from 0.6%–13.0%.

- Organically associated calcium is another component that causes deposition problems. Unlike sodium, calcium does not produce a vapor-phase component. Calcium does react with silicate (derived from clays) to cause low-melting-point phases that produce wall deposits and deposits in the high-temperature regions of the convective pass. Calcium also produces very small particles that will be transported to heat-transfer surfaces, resulting in the formation of thin, light-colored layers called reflective ash. These small particles of ash are carried through to the back passes where they are sulfated and can combine with sodium to cause the formation of strongly bonded sulfate-based deposits. Samples show that calcium in the ash varies from 6.8%–24.0%.

- Clay minerals and quartz – Center lignite can contain high levels of illite, which has a 1:3 Al:Si ratio and high levels of potassium, both of which cause wall slagging and high-temperature fouling. Quartz and other clays can significantly contribute to the mass of the deposits. Samples show that ash content varies from 5.0%–25.5%.

Advanced Boiler Performance Indices

Advanced indices are used to relate the coal characteristics as determined by computer-controlled scanning electron microscopy (CCSEM) and chemical fractionation to ash behavior in a coal-fired utility boiler (12). Fuel performance is estimated in terms of slag flow behavior,

abrasion and erosion wear, wall slagging, high-temperature silicate-based convective pass fouling, and low-temperature sulfate-based convective pass fouling. The following indices are used to assess the effects of ash behavior on utility boiler performance:

- Convective-Pass Fouling Indices

  Sulfation Index: Indicates the propensity of deposit to form in the convective pass of the utility boiler in the temperature range from 1000°–1750°F. This index is based on the availability of alkali (Na and K) and alkaline-earth (Ca and Mg) elements to react with SO_2 and SO_3 to form sulfates. The sulfates are the primary materials that cause particle-to-particle bonding in high-calcium coals. The sulfates are thermodynamically stable at temperatures below about 1650°F. Index values range from 1 (low) to 10 (severe).

  Silicate Index: Indicates the propensity of deposits to form from 1600°–2400°F. This index is related to the formation of deposits in which the silicate material is the primary component that bonds the deposits together. The information used to derive the index includes the size of the minerals such as quartz and clay minerals, availability of alkali and alkaline-earth elements, and viscosity of the silicate liquid phase. Index values range from 1 (low) to 200 (severe).

- Waterwall Slagging

  Slagging Index: Indicates the propensity of a deposit to form on the radiant walls from 2000°–3000°F. The basis of the slagging index is the size of the minerals (especially the illite, quartz, and pyrite), association of the calcium (calcite can contribute to slagging), and viscosity of the silicate-based liquid phase. Index values range from 1 (low) to 20 (severe).

- Wear Indices

  Abrasion Index: This index indicates the potential for wear of fuel preparation and handling equipment. The wear is related to the hardness of minerals in the coal. The primary minerals of concern include quartz and pyrite. The index values range from 0.1 (low) to 10 (severe).

  Erosion Index: This index indicates the potential for wear of boiler parts due to the impaction of fly ash particles. The erosion index is dependent upon the size of the ash/mineral particle, size of the particle, and velocity of the particle. The index values range from 0.1 (low) to 1.0 (severe).

- Cyclone Slagging Index: This index provides information on the slag flow behavior in cyclones. The factors that are included in this index include the partitioning of the ash in the cyclone based on size and association of the ash-forming components in the coal. The partitioning of the ash between the slag and entrained ash can significantly influence the flow behavior of the slag. Standard partitioning criteria have been developed to provide the composition of the slag. The composition is used to estimate the viscosity of the slag as a function of temperature. The index values have several ranges as follows: 1 (low viscosity), 1.5–2.5 (optimum viscosity), >3.0 (slag freezing).

- Strength Development Index: The strength index is based on the ability of the deposited material to develop strength. Strength development is primarily dependent upon the abundance and viscosity of the liquid-phase components in the deposits. Index values less than 0.25 indicate that the material will produce weak deposits; index values of 0.25–0.34 indicate weak-to-moderate-strength deposits; index values of 0.34–0.41 indicate high-strength deposits; and index values >0.41 indicate flowing slag.

Indices were calculated for a range of coals from the Center mine, and the propensity for ash deposition in various portions of the boiler indicates wide variations, as shown in Table 1. The BNI numbers indicate the location in the seams where the coal originated: Kinneman Creek seam (KC), Hagel A (HA), and Hagel (HB). Each seam has a different distribution of minerals and organically associated elements that can have a significant impact on the formation of deposits in the system. Comparison of Center lignite to subbituminous and bituminous coals from other regions of the United States, shown in Table 2, indicates significant differences in the potential to form deposits in the boilers. In all cases, the lignite (not the worst coal from Center mine) from the Center mine has a high propensity to produce deposits as compared to the other coals.

Another indication of the variability of lignites can be illustrated based on the calculation of the temperature where the slag flow would occur. This is defined as the T250 temperature, where the slag viscosity is 250 poise. Frequency distributions of the T250 values for all the data for coals analyzed are illustrated in Figure 3. Calculations of T250 values for 1212 samples obtained from the Center mine database (17) were made using empirical relations derived from CCSEM and chemical fractionation data and knowledge of how ash partitions in the cyclone. Figure 3 shows a bimodal distribution in the T250 based on the Urbain equation calculations. The primary mode was at a value of 2000°F. The secondary mode was at about 2700°F. The results indicate that many of the coals have a sufficiently low T250 for good slag flow. However, coals with T250 at 2700°F are not suitable for maintaining good slag flow.

Figures 4 through 6 illustrate the variations in T250 for the various seams of coals characterized. The HA and HB seam coals appear to have large numbers of samples, with T250 values at or near 2000°F. The KC seam coal, as illustrated in Figure 6, has extremely high T250 values. Based on these data, the KC coals are not favored relative to the slag flow behavior of the ash.

Frequency distributions of cyclone slagging index values indicated significant variations in slagging potentials of coals mined from the three seams, KC, HA, and HB. This information proved particularly useful in planning the mining and firing of coal from the KC seam.

During a July 1999 test burn, the composition of the cores was used to examine and illustrate the variability of the delivered coal quality based on base-to-acid ratio calculated from the ash composition. Figure 7 shows the variation in the base-to-acid-ratio and the seam where the coal was loaded. The base-to-acid ratios were calculated from core data that corresponded to the location in the seam where the coal was mined. There is a significant variation in the base-to-acid ratio for the coals. The coals that have the highest base-to-acid ratio are typically from the HA seam. HB seam coals generally have an intermediate base-to-acid ratio. KC or top-seam coal has the lowest base-to-acid ratio. Lower base-to-acid-ratio coals typically produce slag with high viscosities.

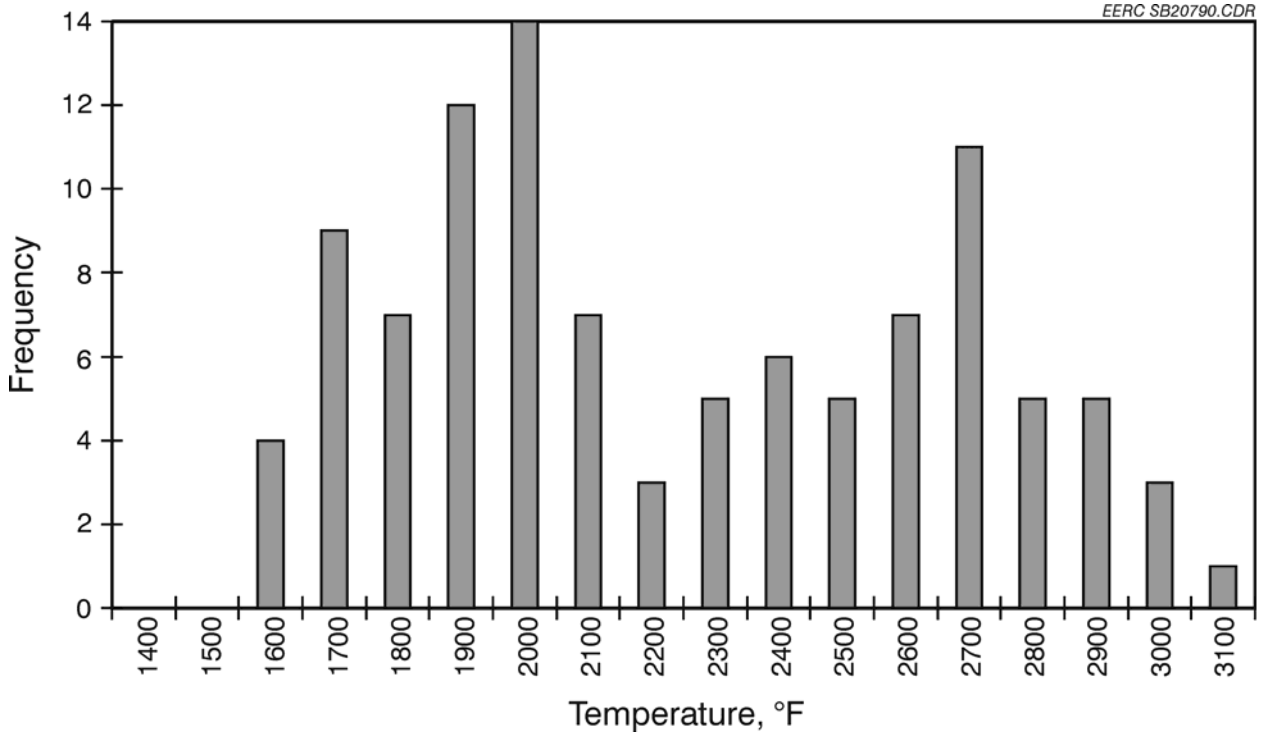

Figure 3. T_{250} frequency distribution for all Coal Quality Management System (CQMS) data, °F.

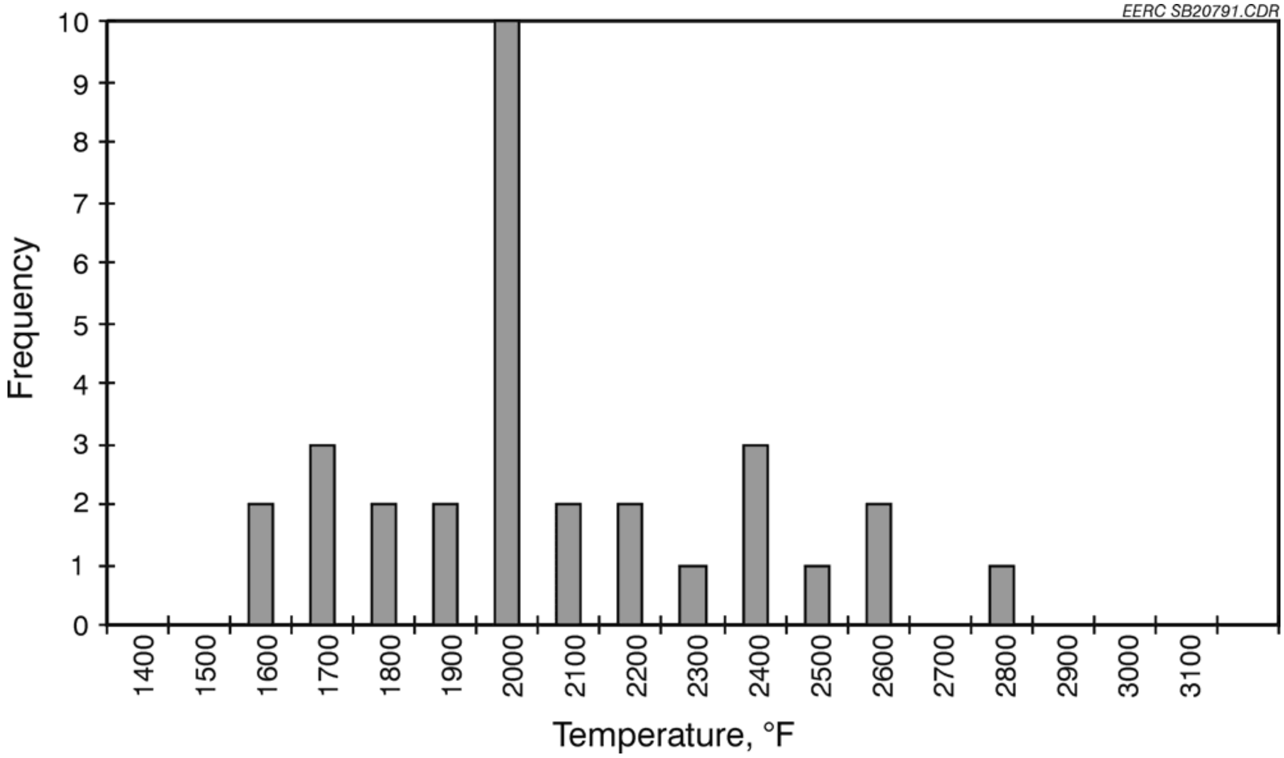

Figure 4. T_{250} distribution for HA seam coal.

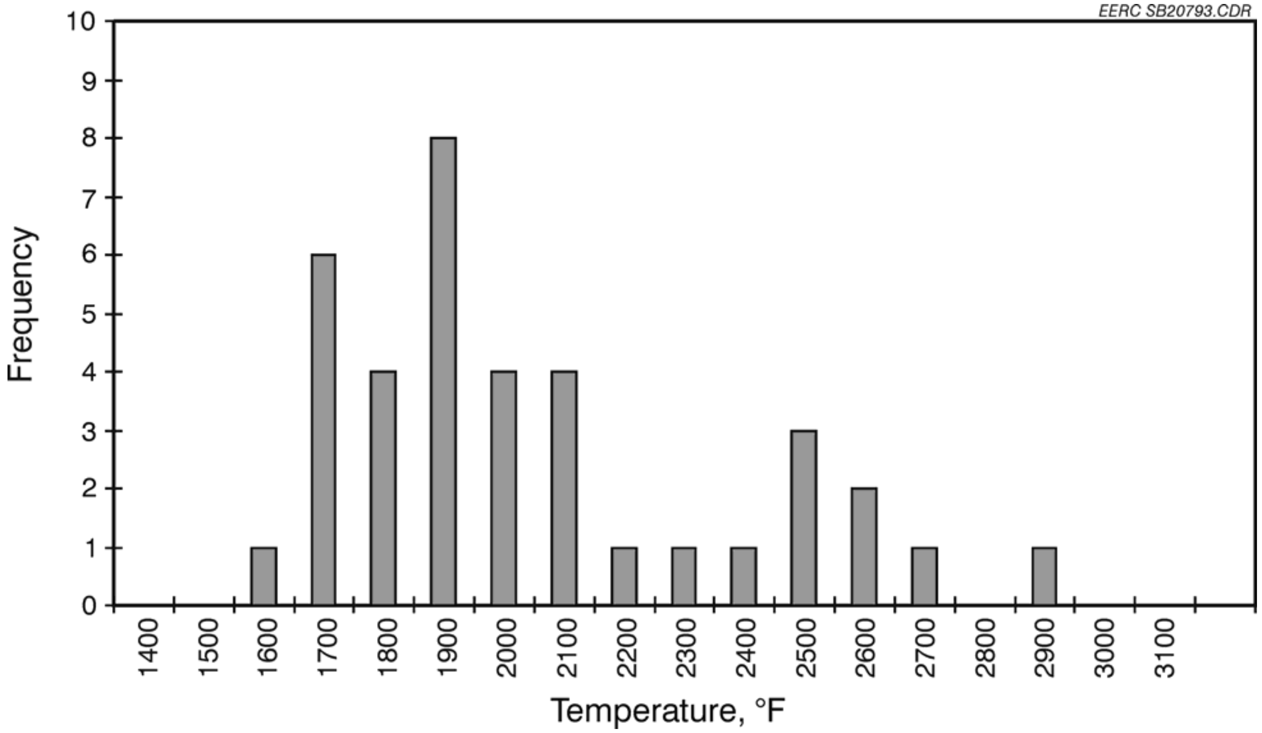

Figure 5. T_{250} distribution for HB seam coal.

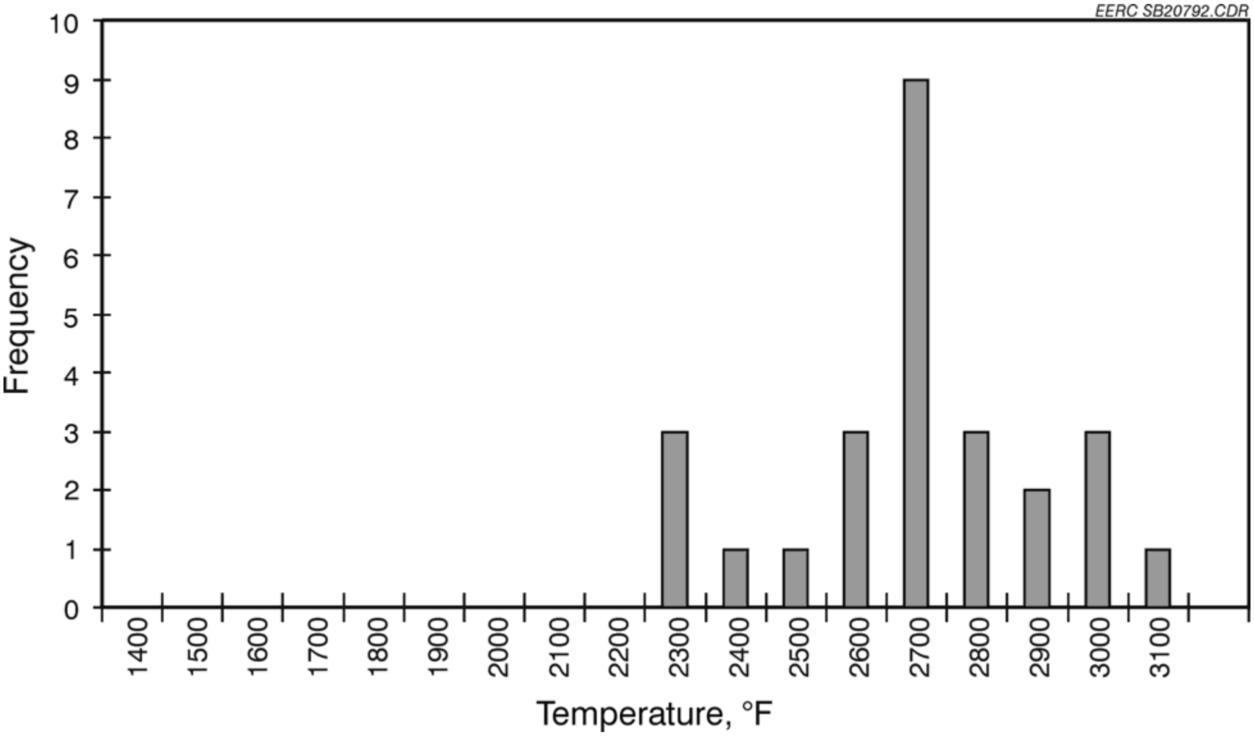

Figure 6. T_{250} distribution for KC seam coal.

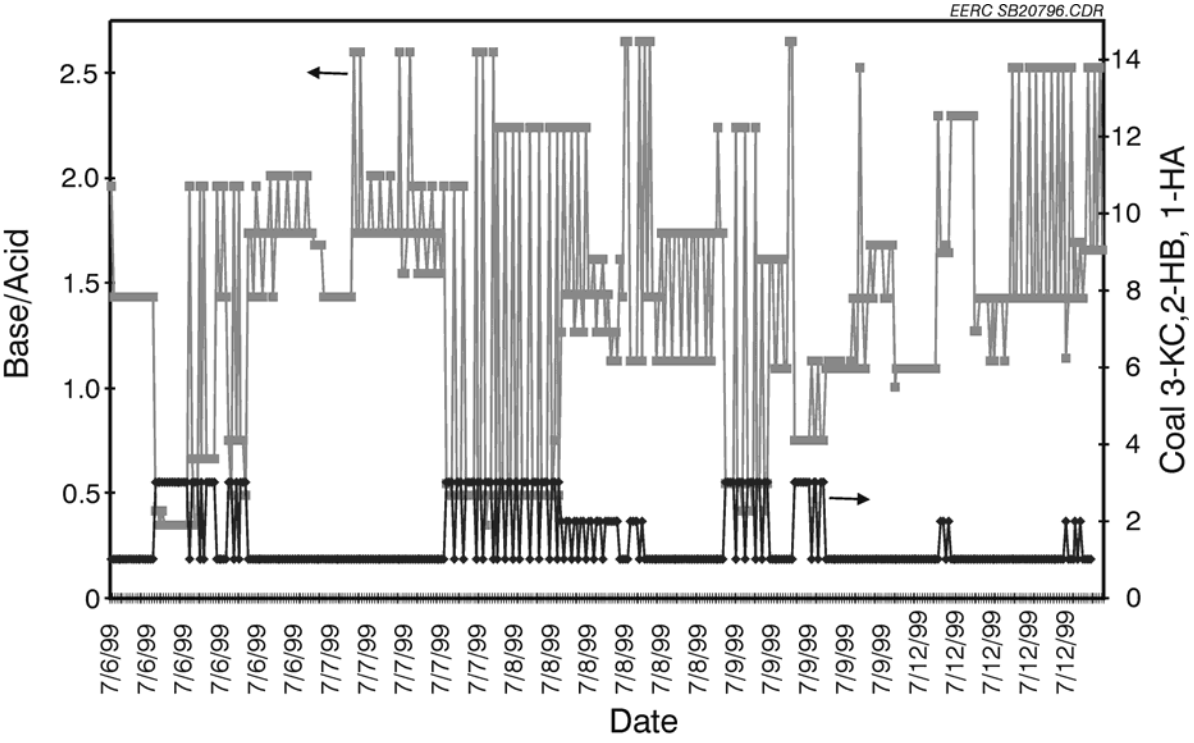

Figure 7. Variations in the delivered coal quality during a test burn period.

Figure 7 shows the sequence of deliveries beginning on July 6 and ending on July 12, 2004. During this period, the majority of the coal delivered was from the HA seam, followed by KC, and HB. Most of the deliveries alternated between KC and HA. Figure 6 shows several instances where significant quantities of KC coal were delivered, on July 6 through July 9. The quantity of KC coal delivered will have the potential to increase the viscosity of the slag and result in poor slag flow from the cyclones.

ASH-RELATED IMPACTS ON SCR CATALYST PERFORMANCE

Ash-related impacts on SCR catalyst performance will depend upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design (14–16, 22). The problems currently being experienced on SCR catalysts include the following:

- Formation of sulfate- and phosphate-based blinding materials on the surface of catalysts.
- Carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing on top of the SCR catalysts.

Licata and others (14) conducted tests on a South African and German Ruhr coal and found that the German Ruhr coal significantly increased the pressure drop across the catalyst because of the accumulation of ash. They found that the German coal produced a highly adhesive ash consisting of alkali (K and Na) sulfates. In addition, they reported that the alkali elements are in a water-soluble form and highly mobile and will migrate throughout the catalyst material, reducing active sites. The water-soluble form is typical of organically associated alkali elements in coals. The German Ruhr Valley coal has about 9.5% ash and 0.9 % S on an as-received basis, and the ash consists mainly of Si (38.9%), Al (23.2%), Fe (11.6%), and Ca (9.7%), with lower levels of K (1.85%) and Na (0.85%) (15). Cichanosicz and Muzio (16) summarized the experience in Japan and Germany and indicated that the alkali elements (K and Na) reduced the acidity of the catalyst sites for total alkali content (K+Na+Ca+Mg) of 8%–15% of the ash in European power plants. They also found that alkaline-earth elements such as calcium react with SO_3 on the catalyst, resulting in plugging of pores and a decrease in the ability of NH_3 to bond to catalyst sites. The levels of calcium in the coals that caused blinding ranged from 3%–5% of the ash.

The mechanisms for this type of low-temperature deposition have been examined and modeled in detail at the Energy & Environmental Research Center (EERC) in work termed Project Sodium and Project Calcium in the early 1990s; however, the focus of those projects was specific to primary superheater and economizer regions of boilers and not SCR systems (22, 23). Deposit buildup of this type can effectively blind or mask the catalyst, diminishing its reactivity for converting NO_2 to N_2 and water and potentially creating increased ammonia slip (14). Arsenic and phosphates, which are not uncommon in low-rank coals, may also play a role in catalyst degeneration. Arsenic is a known catalyst poison (14) in applications such as catalytic oxidation for pollution control. Phosphates can occur in low-temperature ash deposits to create blinding effects, and they also occur with arsenic and can cause catalyst poisoning (23).

Lignite and subbituminous coals produce ash that plugs and blinds catalysts (25–28). The problems currently experienced with SCR catalysts include the formation of sulfate- and phosphate-based blinding materials on the surface of catalysts and the carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing them on top of the SCR catalysts (14). The most significant problem that limits the successful application of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates, phosphates, and possibly carbonates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency (14–16, 27–28). The degree of the ash-related impacts on SCR catalyst performance depends upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design (15–16, 24, 27–28).

In studies (7) the impacts of temperature and the presence of catalyst on the ability of ash to sulfate were examined. The tests were conducted using a thermogravimetric analyzer (TGA). TGA testing was conducted using a <5-µm-size fraction of ash produced from Powder River Basin (PRB) coals and lignites and exposing them to vapor-phase sulfur dioxide with and without catalyst at several temperatures. The aim of the testing was to determine the potential of the formation of sulfates to cause particle-to-particle bonding that leads to the formation of deposits in the temperature range where SCR catalysts are used. The TGA testing is focused on determining the reactivity of the <5-µm ash produced from selected PRB and blends to sulfur dioxide and gas-phase phosphorus species as a function of temperature. Testing was conducted to determine the weight gain with flue gas containing ammonia. The impact temperature on the weight gain due to the formation of sulfates for a PRB blend is shown in Figure 8. The rates of sulfation were found to increase with increased temperature. The results show an increase in the weight gains when ammonia and phosphorus were added. Ground catalyst was mixed with PRB and placed in the TGA. Increases in weight gain were observed when catalyst was added as compared to baseline cases for 100% PRB, as shown in Figures 8 and 9, respectively. The presence of catalyst enhances the formation of sulfates.

Full-Scale Slipstream Testing

More recently (8), the behavior of ash and mercury in flue gas produced from the combustion of lignite and subbituminous coals from the United States of America in selective catalytic reduction (SCR) systems for nitrogen oxide removal has been examined. Typically, these coals contain ash-forming components that consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, these coals produce ash that has an abundance of alkali and alkaline-earth-rich oxide particles (<5 µm) that are carried into the backpasses of the combustion system and react with flue gas to form sulfates and possibly carbonates. The forms of mercury in the flue gas produced from the lignite and subbituminous coals are dominated by the elemental form. Slipstream testing was conducted at two subbituminous-fired power plants and one lignite-fired power plant to determine the impacts of ash on SCR plugging, blinding, and mercury oxidation.

The SCR slipstream system consists of two primary components: the control room and the SCR reactor. The reactor section consists of a catalyst section, an ammonia injection system, and sampling ports for NO_x at the inlet and exit of the catalyst section. The control room houses a computer system that logs data and controls the gas flow rates, temperatures, pressure drop across the catalyst, and sootblowing cycles. The computer is programmed to maintain constant temperature of the catalyst, gas flow rates, sootblowing cycles, and ammonia injection. The computer is equipped with a modem that allows for downloading of data and modification of the operation of the reactor from a remote computer located at the EERC.

Flue gas is isokinetically extracted from the convective pass of the boiler upstream of the air heater. The temperature is typically about 790°F. The flue gases pass through a 4-inch pipe equipped with sampling, thermocouple, and pressure ports. Ammonia is injected into the piping upstream of the reactor section. The reactor consists of a steel housing that is approximately 8.5 inches square and 8 feet long. The reactor section has three components, including a flow straightener, a pulse section or sootblower, and a catalyst test section. A metal honeycomb is used as a flow straightener upstream of the catalyst section and is about 6 inches long. A purge section was installed ahead of the catalyst test section to remove accumulated dust and deposits. The catalyst test section is located downstream of the purge section. The entire catalyst section is insulated and equipped with strip heaters for temperature control. The catalyst test section is 3.28 ft (1 m) in length and houses three catalyst sections. Thermocouple and pressure taps are located in the purge sections for measurements before and after each section.

The induced-draft fan is used to extract approximately 400 acfm (200 scfm) of flue gas from the convective pass of the utility boiler to achieve an approach velocity of 5.2 m/s (17.0 ft/s). The gas velocity is similar to that found in full-scale applications. The total gas flow through the reactor represents a thermal load of approximately 300 kW.

The range of operating conditions for the reactor is listed below:

X Gas temperature: ~700°–800°F
X Gas flow rate: 400–500 acfm
X Approach velocity range: 5.0–5.5 m/sec
X Ammonia injection rate: 0.5:1 with NO_x level
X Tempering air for fan: ~ 50–200 scfm
X Catalyst dP: 0.5–1.0 inches water column
X Fan sized for up to 30 inches water column

The catalyst installed at the Baldwin and Coyote Stations was the Haldor Topsoe catalyst. Topsoe's DNX-series of catalysts comprises SCR DENOX catalysts tailored to suit a comprehensive range of process requirements. DNX-series catalysts are based on a corrugated, fiber-reinforced titanium dioxide (TiO_2) carrier impregnated with the active components vanadium pentoxide (V_2O_5) and tungsten trioxide (WO_3). The catalyst is shaped to a monolithic structure with a large number of parallel channels. The unique catalyst design provides a highly porous structure with a large surface area and an ensuing large number of active sites. The pitch of the catalyst was approximately 6 mm.

The catalyst installed at the Columbia Station was a Babcock Hitachi plate-type catalyst. This catalyst is a TiO_2-based plate catalyst, developed and manufactured by Hitachi. The pitch of the catalyst was approximately 10 mm.

The coals produced ash that had significant accumulations of ash on the catalyst on both macroscopic and microscopic levels. On a macroscopic level, there were significant observable accumulations that plugged the entrance as well as the exit of the catalyst sections. On a microscopic level, the ash materials filled pores in the catalyst and, in many cases, completely masked the pores within 4 months of operation.

The deposits on the surfaces and within the pores of the catalyst consisted of mainly alkali and alkaline-earth element-rich phases that have been sulfated. The results of this testing found that the <5-µm ash rich in alkali and alkaline-earth elements is captured on the surface and within the catalyst pores. These materials react with SO_2/SO_3 in the flue gas, resulting in the formation of a continuous phase that blinds the catalyst. The ability of elemental mercury to be oxidized across the SCR catalyst was investigated at a North Dakota lignite-fired plant. These results showed no oxidation of mercury across the SCR catalyst.

The reactor was installed at the Baldwin Station and operated for a 6-month time period on the Haldor Topsoe catalyst. The information obtained from testing included pressure drop, sootblowing cycles, and reactor temperatures. Figure 10 show the pressure drop across the catalyst test periods from 0 to 2 months. During the first two months of operation, the pressure was about 0.5 inches of water; at the end of two months, the pressure drop was about 0.8 inches of water, indicating plugging had occurred. The air was pulsed a minimum of every 8 hours in an attempt to maintain cleanliness. The reactor was monitored on a daily basis, and adjustments in pulsing cycles were made in order to minimize deposit accumulation. However, for the first two months, the pressure drop steadily increased. There are several periods where the unit was taken off-line; during those times, the temperature of the catalyst was maintained. At 2-month intervals, a section of catalyst was removed and replaced with a new one.

For Months 2 through 4, the pressure drop was highly variable initially but was about 0.8 inches of water. From Months 4 through 6, the pressure drop was maintained between 0.6 and 0.8 inches of water. This is due to the installation of a fresh catalyst section and leaving two thirds of the catalysts in place that were partially plugged. The gas velocity in the single section of new, clean catalyst was high because of channeling, and the result of the high gas flow was less deposition and accumulation. Gas velocity has a significant impact on the potential for deposits to form. However, at high gas velocity, low NO_x conversion is likely.

The reactor was installed at the Columbia Station and operated for a 6-month period of time with the Babcock Hitachi catalyst. The information obtained from the testing included pressure drop information, sootblowing cycles, and reactor temperature. Figure 11 shows the test periods from 0 to 2 months. The pressure drop across the SCR upon installation was about 0.4 inches of water and increased to an average of about 0.5 inches of water, but ranged from less than 0.4 to greater than 0.8 inches of water. The pressure drop for Months 2 to 4 increased from about 0.5 to 0.7 inches of water because of accumulation of ash. After cleaning the reactor and replacing one catalyst section, the pressure drop was about 0.3 but increased to over

0.6 inches of water up to about 4100 hours. There was an outage at the plant, and aggressive pulsing of the reactor was conducted; the pressure drop was brought back down to 0.3 but rapidly increased to over 0.5 inches of water within 500 hours.

The same reactor that was installed at the Baldwin Station was moved and installed at the Coyote Station. In addition, the same Haldor Topsoe catalyst type was used in the reactor. The reactor was operated for a 6-month period of time. Figure 12 shows the test periods from 0 to 2 months. As this paper is being prepared, the reactor is still operating on-site. The pressure drop across the catalyst upon installation was about 0.4 inches of water. After only 750 hours, the pressure drop was 1.5 inches of water, indicating significant plugging and blinding. Very aggressive air pulsing was conducted, with little success in removing the deposits. The pressure drop for the catalyst was over two times greater than the pressure drop observed for the Baldwin Station utilizing the same reactor and same catalyst. At about 1700 hours, the reactor was cleaned, and a section of catalyst was removed for characterization. The pressure drop after cleaning was about 0.8 to 1.0 inches of water. The pressure drop did not increase as rapidly because of the higher velocities through the clean section of the catalyst.

The tops of the catalysts were photographed during inspection and sampling of the catalyst sections. Figure 13 shows the ash materials that accumulated on the catalyst inlet after 2 months of operation. The most significant accumulation was noted for the Coyote Station, followed by Columbia and Baldwin. The Coyote Station had some larger pieces of ash deposit material on the surface as well as plugging of the catalyst passages. The Baldwin Station showed some obvious deposition along the walls of the reactor and some accumulation on the inlet sections. The Columbia Station showed more significant accumulation and plugging than the Baldwin Station.

After 4 months, the tops of the catalysts were photographed during inspection and sampling of the catalyst sections, as shown in Figure 14. The most significant accumulation was noted for the Coyote Station and some accumulation for the Baldwin Station.

SCR Ash Deposit Characterization

The characteristics of the ash materials that collected on the catalyst surfaces and pores were characterized by SEM and x-ray microanalysis and, in selected cases, XRD was used to determine the crystalline phases present. The catalysts were sampled after 2, 4, and 6 months. The sections were sampled, and approximately 2.5-cm squares were mounted for SEM analysis on double-stick tape and in epoxy resin. The double-stick tape samples allowed for characterization of the external morphology of the particles and catalyst surface. The samples mounted in resin were cross-sectioned and polished, which allowed for more detailed and quantitative analysis of the bonding materials and materials that accumulated in the pores of the catalyst. Detailed information on all the samples can be found elsewhere (add FPT reference). Examples of two deposit and catalyst analysis are presented here.

The 6-month sample from the Baldwin Station showed extensive sulfation of the alkaline-earth elements present in the deposits. Figures 15a and 15b show regions of the catalyst where all the pores were blocked and a minimal amount of deposit on the surface of the catalyst. Figure

15c shows a higher-magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The chemical compositions of selected points that indicate the presence of high levels of calcium and sulfur are listed in Table 3. There is much more extensive bonding of the materials with the sulfate matrix as compared to the 2-month sample. In addition, there are some regions of high levels of calcium, aluminum, and sulfur present. The calcium aluminum materials are likely derived from the calcium aluminum phosphate minerals found in the coal fired at this plant.

The 4-month sample from the Coyote Station showed particles adhering to the surface and filling pores in the catalyst. Figure 16 shows the 4-month sample from the Coyote Station. The catalyst showed particles adhering to the surface and completely filling and masking the pores in the catalyst. The external morphology of the catalyst surface shows the masking of the catalyst surface. Chemical compositions of selected points are shown in Table 4. The 4-month sample shows more sulfation than the two months of exposure samples. Figures 16b and 16c shows a higher-magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of sodium-, calcium-, and sulfur-rich material, likely in the form of calcium sulfate. Significant sodium was found in the deposits, as shown in Table 4. The sample shows significant evidence of sulfation after 4 months of exposure and was much more pronounced than the samples for the Baldwin and Columbia Stations that are fired on PRB coals. The presence of sodium enhances the bonding and sulfation of the particles to form a strongly bonded matrix (22).

SCR Deposit Formation Mechanisms

The mechanism for the formation of deposits that blind SCR catalysts involves the transport of very small particles rich in alkali and alkaline-earth elements, the surface of the catalyst, and reactions with SO_2/SO_3 to form sulfates. The formation of SO_3 from SO_2 is catalyzed by the SCR; this, in turn, increases the reaction rate of SO_3 to form sulfates. In some cases, the alkali and alkaline-earth elements will also react with CO_2 to form carbonates. XRD analysis identified $CaSO_4$ as a major phase and $Ca_3Mg(SiO_4)_2$ and $CaCO_3$ as minor phases.

Lignite and subbituminous coals contain high levels of organically associated alkali and alkaline-earth elements including sodium, magnesium, calcium, and potassium, in addition to mineral phases. The primary minerals present in these coals include quartz, clay minerals, carbonates, sulfates, sulfides, and phosphorus-containing minerals (6).

During combustion, the inorganic components in the coal are partitioned into various size fractions based on the type of inorganic component, their association in the coal, and combustion system design and operating conditions. Significant research has been conducted on ash formation mechanisms and relationships to impacts on power plant performance (1–6, 9–13, 19–21, 29). During combustion, the inorganic components associated with western subbituminous and lignite coal typically are distributed into various size fractions of ash. The smaller size fractions of ash are dominated by partially sulfated alkali and alkaline-earth elements. These ash particles are largely derived from the organically associated cations in the coal. The larger size fraction has higher levels of aluminum and silicon derived from the mineral fraction of the ash-forming component of the coal. Entrained ash was extracted from the Columbia Station at the point of the inlet to the SCR reactor and was aerodynamically classified and analyzed. The composition of the size fractions was compared to the chemical composition of the ash deposited on and in the catalyst, as shown in Figure 17. The comparison shows that the composition of the particle captured in the SCR catalyst is very similar to the <5-µm size fraction. The deposited material shows significantly more sulfation than the entrained-ash size fraction, indicating that the sulfation process occurs after the particles are deposited in the catalyst.

The mechanism of SCR catalyst blinding when firing lignite or subbituminous coals is shown in Figure 18 (30). The requirements for the formation of deposits that blind SCR catalyst include firing a coal that produces significant levels of <5-µm-sized particles. The particles are transported into the pores of the catalyst and subsequently react with SO_3 to form sulfates. The sulfate forms a matrix that bonds other ash particles. The SCR catalyzes the formation of SO_3 and thereby increases the rate of sulfation (24, 25). The sulfation of CaO increases the molar volume, resulting in the filling of the pore. For coals that have high sodium contents, formation of low-melting-point phases such as pyrosulfates is possible (31). Pyrosulfate materials can melt at temperatures as low as 535°F in coal-fired power systems.

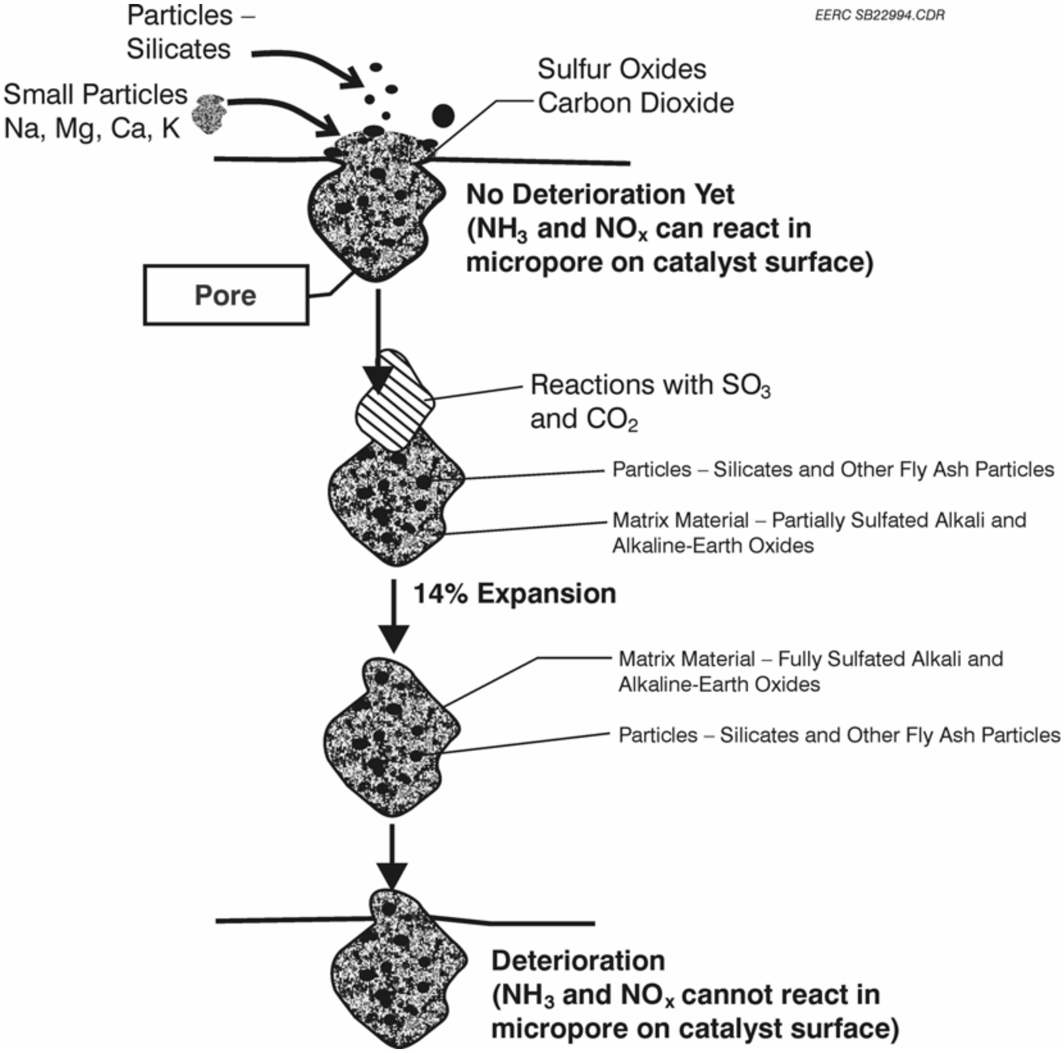

Figure 18. Mechanism of SCR catalyst blinding via the formation of sulfates and carbonates (modified after Pritchard and others [30]).

Low-Temperature Pyrosulfates

The presence of sodium sulfate in the flue gas exiting a scrubber will cause problems to low-dust and tail-end devices such as selective catalytic reduction (SCR) systems for NO_x reduction. There are two problems associated with the fine particulate rich in sodium sulfate on downstream devices. These include accumulation of fine particles on the SCR that, when sootblown, will cause opacity problems, and that the fine particles on the SCR will form pyrosulfates such as $(K_{1.5}Na_{0.5})S_2O_7$ that have melting points as low as 535°F (31) that will blind the catalyst. The presence of these compounds in low-temperature corrosion deposits is well known (32). In addition, the presence of SO_3 enhances the formation of the low-melting-point pyrosulfates (31). The sodium sulfate materials will cause opacity and SCR catalyst blinding problems that limit the feasibility of the low-dust or tail-end SCR technology for use with high-sodium lignite coals.

The sodium sulfate materials will be transported to the catalyst surfaces by diffusion, electrophoresis, and, possibly, inertial impaction. The particles are held in place by weak electrostatic and van der Waals forces. Once accumulation takes place, the sodium sulfate particles will react with flue gas components, resulting in the formation of pyrosulfates. The formation of pyrosulfates involves the following processes (31):

1. Formation of sulfates such as Na_2SO_4 and K_2SO_4
2. Conversion of SO_2 to SO_3 in the bulk gas phase – catalytically active surface such as an SCR catalyst – $SO_2 + \frac{1}{2} O_2 \rightarrow SO_3$
3. Pyrosulfate formation – $Na_2SO_4 + SO_3 \rightarrow Na_2S_2O_7$

The melting points of selected pyrosulfate phases are shown in Table 5.

Table 5. Melting Points of Selected Pyrosulfate Compounds

Compound	Temperature, °C	Temperature, °F
$K_3Fe(SO_4)_3$	618	1144
$K_3Al(SO_4)_3$	654	1209
$KFe(SO_4)_2$	694	1281
$Na_3Fe(SO_4)_3$	624	1155
$Na_3Al(SO_4)_3$	646	1195
$NaFe(SO_4)_2$	690	1274
$Na_2S_2O_7$	401	754
$K_2S_2O_7$	300	572
$(K_{1.5}Na_{0.5})S_2O_7$	279	535

Melting points for pyrosulfates between 535° and 770°F have been reported in the literature. Much of the past work has focused on the formation of these phases on tube surfaces. These species contribute to the corrosion of heat-transfer surfaces in coal-fired power plants. The exact melting point depends on the relative amounts of sodium and/or potassium.

There is significant evidence for the formation of sodium-rich fine particulate in full-scale power plants when firing high-sodium-containing coals. For example, Minnesota Power's Boswell Energy Station found that when it fired high-sodium, lower-ash subbituminous coal, it experienced increases in opacity. Hurley and Katrinak (33) conducted a field-testing project on Unit No. 4, a pulverized coal-fired boiler equipped with an electrostatic precipitator and a wet scrubber, to better understand the reasons for the opacity problems. During the field testing, sampling of the coals, flue gases, and scrubber materials was conducted. The particulate in flue gases downstream of the scrubber was aerodynamically classified using an impactor and multicyclone. The sized fractions were analyzed to determine the composition of the submicron-sized fraction.

The results of the study indicated that the particulate collected downstream of the scrubber was coal-related and caused by the high sodium content of one of the coals. Vapor-phase sodium condenses in the convective pass to form fine sodium sulfate particles or other Na species that later react with ash particles. Pure Na_2SO_4 particles are too small to be removed by scrubbing.

CONCLUSION: SCR IS NOT FEASIBLE FOR NO_X REDUCTION AT MILTON R. YOUNG

The ash deposition behavior of the lignites from North Dakota is the most complex and severe of any coals in the world, and installation of catalysts for NO_x reduction is going to be impossible because of the formation of sodium calcium sulfates in the pores of the catalyst. Following is a list of the key roadblocks associated with lignites which have not been overcome and, in our opinion, make the installation of SCR catalyst at the MRY plant technically infeasible for NO_x control.

- High alkali and alkaline-earth elements present in the coal fired at the MRY plant form sulfates that blind the catalyst.
    - Cyclone-firing partitions the ash during combustion. As a result the level of sodium and calcium in the fly ash is enhanced and will increase the SCR catalyst blinding.
    - Sulfate reactions increase with increasing temperature, and the suggested temperature of installation at the MRY facility is higher than typical installations; therefore, sulfation problems are enhanced.
    - Sulfate formation is also enhanced by the presence of an SCR catalyst; this accelerates the sulfation reactions, causing blinding of the catalyst.
    - The high levels of sodium in the coals combined with calcium produces low-melting-point eutectic compounds that will melt on the surface.
    - Sulfates form on the surfaces of catalysts firing PRB coals. Lignites will be several orders of magnitude worse because of the higher levels of sodium.

- The ash components to impact SCR performance in Japan and Europe (14–16) include alkali and alkaline-earth elements that result in sulfate formation. The total calcium content and the sum of the calcium, magnesium, potassium, and sodium provide an indication of the problems that occur. For the coals fired at the MRY power plant, the CaO content ranges from 6.8%–19.99%, and the sum of the alkali and alkaline-earth elements range from 9.33%–29.87% of the ash. The levels of calcium in Center lignite are 2 to 4 times higher than the problematic coals in Japan and Europe.

- The finding or work conducted in Germany and Japan were confirmed by recent SCR catalyst slipstream testing that showed significant evidence of sodium and calcium-rich sulfate formation that fill and plug the catalyst at both lignite (North Dakota)- and subbituminous-coal-fired power plants. The results of this recent testing showed that the presence of sodium significantly enhanced the formation of bonding of particles and more rapid sulfation, filling of pores, and rapid increase in pressure drop across the catalyst.

- Deposit carryover, or popcorn ash, plugging the top of the SCR catalyst with deposit fragments, is a significant problem because of the extremely high deposition potential of the coal. The formation of deposits in various parts of the boiler requires continuous sootblowing. The deposit fragments are likely going to be carried with the bulk gas flow to the SCR catalyst, resulting in plugging.
- The variability of the lignite is a problem of unique concern at MRY. The deposition potential of the coal is always changing rapidly, resulting in rapid growth and formation of deposits in various sections of the boiler. Aggressive sootblowing of all fireside surfaces is already required to maintain full-load operation. The sootblowing of upstream heat exchange equipment will cause deposit fragments to be carried back to the SCR catalyst, and during sootblowing of the SCR catalyst, the entrainment of deposit fragments along with the sootblowing media will result in significant erosion of the catalyst surfaces.

The ash-related impacts of the lignites from North Dakota are the most complex and severe of any coals in the world, and installation of tail-end SCR systems for NO_x reduction will not be possible. The key problems associated with lignites that have not been overcome and, in our opinion, make the installation of tail-end SCR systems at the MRY plant technically infeasible for NO_x control at MRY's Units 1 and 2 are listed below:

X High-sodium lignite coal from the Center Mine Hagel A and B seam coal produces extreme levels of homogeneously condensed sodium sulfate that pass through the wet scrubber. In addition, the cyclone-firing system captures much of the ash as slag, resulting in a decrease in ash that is available for providing condensation sites for vapor-phase sodium compounds upon gas cooling. This results in an increased homogeneous condensation of sodium sulfate.

X These small particles pass through a wet scrubber and will accumulate on surfaces of tail-end SCR systems. The accumulated materials cannot feasibly be resolved through conventional sootblowing and cleaning technologies to remove the particulate.

X Recent testing with subbituminous and lignitic coals indicated a significantly higher level of pore filling and plugging in the catalyst exposed to lignite ash as compare to subbituminous coal ash. The catalyst pores as well as the catalyst surface in the lignite tests were completely coated with a sodium calcium sulfate material, while only pore filling was found in the subbituminous coal testing. The pressure drop across the catalyst exhibited for lignite was 4 to 5 times greater than that found for a catalyst exposed to subbituminous coal ash. The plugging occurred over a 1000 hour test period.

The formation of liquid pyrosulfate materials at temperatures as low as 535°F from sodium sulfate materials occurs in coal-fired power systems and is well documented. Pyrosulfates will form and cause blinding of tail-end SCR devices. In addition, SCR systems catalyze the formation of SO_3 from SO_2. The presence of SO_3 significantly enhances the formation of the pyrosulfates at MRY to an extreme level that cannot be dealt with effectively using cleaning technologies that exist today.

APPENDIX C

COST METHODOLOGY

CAPITAL COST ESTIMATE DETAILS FOR NO_X CONTROLS

O&M COST ESTIMATE DETAILS FOR NO_X CONTROLS

C.1 METHODOLOGY FOR ESTIMATED COSTS

The summary economic evaluations of each alternative are presented in the cost impact sections of the main report. Capital and O&M cost estimates for each alternative are presented individually. The Levelized Total Annual Cost (LTAC) for all the alternatives for control of a single pollutant (i.e. NO_X) from a single unit is then presented together with Unit Control Costs. The Levelized Total Annual Cost (LTAC) represents the levelized annual cost of procurement, construction and operation over a 20 year design life, again in current (2006) dollars. As a minimum, the design life for any alternative was taken to be that recommended by “The EPA Air Pollution Control Cost Manual”, Sixth Edition, January 2002, EPA/452/B-02-001[i].

The LTAC is also used to calculate the average annual and incremental cost effectiveness of each alternative. The LTAC represents an annual payment in current day dollars sufficient to finance the project over its entire life.

In determining the LTAC a Capital Recovery Factor and an O&M Levelization Factor were calculated from the project economic conditions and then applied separately to the estimated capital and O&M costs. The equation used is shown below.

$$LACC / NPV = \left(\frac{i(1+i)^n}{(1+i)^n - 1} \right) = CRF$$

Where,
LACC = Levelized Annual Capital Cost
NPV = Net Present Value of the capital investments required.
i = discount rate
n = design life in years
CRF = Capital Recovery Factor

Therefore:

$$LACC = CRF \times NPV$$

For the economic conditions described in Table C.1-1 the Capital Recovery Factor was calculated to be 0.08718.

In determining the levelized annual O&M cost the estimated annual O&M cost, the inflation rate, the discount rate, and the equipment life are taken into account. The O&M Levelization Factor (OMLF) was calculated as follows.

$$LAOMC / A_1 = \left(\frac{1+i_d}{1+i_i} - 1 \right) \left(\frac{i_d (1+i_d)^n}{(1+i_d)^n - 1} \right) = OMLF$$

Where,
A = Levelized Annual O&M Cost (LAOMC)
A_1 = Total annual O&M cost in current dollars
i_d = discount rate
i_i = inflation rate
n = design life in years

Therefore:

$$LAOMC = OMLF \times A_1$$

For the economic conditions described in Table C.1-1 the Operating and Maintenance Levelization Factor was calculated to be 1.24873.

The Levelized Total Annual Cost, or LTAC is the sum of the levelized capital cost and the levelized O&M cost. Therefore:

$$LTAC = LACC + LAOMC = (CRF \times P) + (OMLF \times A_1) = 0.08718 \times P + 1.24873 \times A_1$$

The differences between alternatives are also presented graphically in the form of a plot of the annual emissions reduction (tpy) versus the LTAC for each alternative. This form of plot graphically depicts the cost effectiveness or Unit Control Cost (in $/ton of pollutant reduction) of each alternative relative to all of the others. The cost effectiveness is also referred to as the Unit Control Cost and defined as the LTAC divided by the annual emissions reduction (ton/yr). The area on the plot indicated by the various data points represents the cost effectiveness envelope for the alternatives under consideration. A smooth line is drawn on this plot connecting the rightmost points (those with the lowest cost for a given level of emissions reduction). This line is referred to as the Dominant Control Curve (DCC). The DCC defines the right hand boundary of the envelope encompassing all of the alternatives considered. The DCC is used as a screening tool between considered alternatives. Those alternatives whose plotted position is above and/or to the left of the DCC are not as cost effective as those forming the line and thus can be eliminated from further analysis if desired.

In order to compare various pollutant control alternatives, the Unit Control Cost and the incremental Unit Control Cost of each alternative were also calculated and tabulated for comparison purposes. The Unit

Control Cost compares control technologies on a basis of dollars expended per ton of pollutant reduced ($/ton). This relationship is graphically depicted in the DCC chart.

To more accurately compare between alternatives with different costs and control efficiencies, the incremental cost effectiveness is also determined for those alternatives on the DCC. The incremental cost effectiveness is defined as the LTAC of a given control option minus the LTAC of an alternative, divided by the difference between the annual emissions reduction (tpy) of the given control option and the alternative being evaluated. The combination of these two economic analyses can be used as an argument for the elimination of control technologies with significantly greater marginal control costs than the given case. The equation used for the incremental cost effectiveness is shown below.

$$ICF = \frac{(LTAC_1 - LTAC_2)}{(AE_1 - AE_2)}$$

Where,

ICF = Incremental cost effectiveness ($/incremental ton removed)
$LTAC_1$ = Levelized Total Annual Cost of control alternative No. 1 ($/yr)
$LTAC_2$ = Levelized Total Annual Cost of control alternative No. 2 ($/yr)
AE_1 = Control option No. 1 Annual Emissions Reduction (ton/yr)
AE_2 = Control option No. 2 Annual Emissions Reduction (ton/yr)
(The higher cost, more effective control option is subscript 1 in this equation.)

The economic analyses presented in this report not only include the estimated capital and O&M costs for each alternative, but also the LTAC for economic comparison of the various alternatives. In addition, the Unit Control Cost or cost effectiveness is presented for each alternative. Finally, a comparison between alternatives, in the form of the marginal cost effectiveness, is presented in both numerical and graphical form. Thus a comprehensive comparison of the economic impacts of each alternative, as well as the differences in economic impact between alternatives is clearly presented.

Table C.1-1 – Economic Factors(1),(2)

Total Possible Operating Hours per Year	8,760
Amortization Life, Years	20
Cost of Money	6%
Property Taxes, Insurance, %	NA
Conversion Tax (in lieu of property tax)	NA
Amortization Rate for APC Capital Costs	6%
Interest During Construction (IDC)	6%
Discount Rate (used to calculate NPV)	6%
Construction Cost Escalation	3%
Non-Fuel O&M Escalation	2.5%
Fuel (coal and natural gas) Escalation	2.5%
Auxiliary Electric Power Cost, $/MW-hr	$35.00
Urea Cost, ($/ton delivered, 50% aqueous solution)	$380.00
Natural Gas ($/mmBtu)	$7.98

(1) - All financial percentages and unit auxiliary electric power cost were provided by MPC.
(2) - All costs are in 2006 dollars unless noted otherwise.

C.2 NOx CONTROLS - CAPITAL COST ESTIMATES

The capital costs to implement the various NO_X control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. In the cases of SNCR and FLGR, preliminary vendor budgetary cost information was obtained and used in place of, or to adjust, the published unit output cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy, or better.

The limitations of these capital cost estimates developed from unit capital cost factors multiplied by unit output are:

- Scope basis uncertainty – inability to precisely determine what scope of supply, including such things as balance-of-plant (BOP) systems and equipment improvements were required, assumed, or accounted for when developing the unit cost factors. Some alternatives may have higher indirect or BOP capital costs than others. Similarly, the inclusion of general facilities, preproduction and inventory costs, and other indirect costs is not known. It is likely that the utility owner's final total expenditure for the implementation of the alternatives, especially options that are most capital cost-intensive, will be greater than the calculated cost estimates.
- Location-specific influences – most NO_X control techniques have been applied primarily to eastern bituminous coal-fired plants located near large metropolitan areas, not in largely rural, upper midwestern United States locales. The amount of space available is dependent on the existing powerplant equipment and building layout and property plot area, versus what is expected to be required for implementing various control technologies. Transportation and local/regional labor costs are also variables.
- Size influences – some technologies' capital costs are more sensitive to "economies of scale" than others.
- Capacity margins – some technologies' may require higher capacity margins to allow sustained operation at high throughput rates over extended periods of time.
- Reliability concerns – some technologies' have been refined to a higher degree, and others may require more component redundancy than others in order to avoid performance reductions and potential outages for failures and repairs or replacements.
- Inflationary influences – the significant increases in 2004-2005 for raw material costs, especially steel and alloys for fabrication of structural and mechanical components, has occurred after many of these technologies were installed in projects upon which the referenced unit capital cost factors were based.

- Market conditions – as demand increases for emission controls, some alternatives become more cost-competitive, while others do not. This can be influenced by the relative supply and demand for the technology and number of suppliers who can furnish it. The demand for some alternatives can also be strongly influenced by the stringency of the local, state, and national regulatory requirements. Schedule for implementation and availability of local/regional labor for installation contractors are also market-driven factors.

The estimated NO_X control costs are in addition to capital costs to provide normal replacements of the existing Milton R. Young Station's major power generating equipment.

C.2.1 Separated Overfire Air Capital Cost Estimates

Installation of separated overfire air systems typically includes windbox and/or secondary combustion air supply duct modifications, boiler waterwall tube openings, airflow distribution devices (dampers/registers), airflow controls and measurement instrumentation, and related structural and electrical tie-ins to the existing plant facilities. A basic separated overfire air retrofit system installed on a lignite-fired cyclone boiler includes ports across the front and rear walls of the upper furnace. The unit capital cost factor is expected to be above the high end of the typical published cost range of \$5-10/kW[ii] (\$12.0/kW or \$3,080,000[iii] for MRYS Unit 1), due to the large ducts, relatively tall furnace (compared to typical bituminous coal-fired cyclone boilers), and the need to avoid existing obstructions within the boiler house.

An advanced form of SOFA unique to North Dakota lignite-fired boilers will include relocation of the existing lignite drying system vent port openings from the lower primary furnace to the upper furnace, to be placed at the same elevation as the new SOFA ports. This requires extension of the existing cyclones' lignite drying systems' vent piping to supply the new boiler furnace ports. This is expected to cost in the area of +\$4.7/kW or approximately \$1,200,000 for Unit 1's additional capital cost over and above the basic SOFA system. Overall, the advanced version of separated overfire air technology is estimated to have an installed capital cost of approximately \$16.6/kW (\$4.3Million) for MRYS Unit 1.

C.2.2 Reburn Capital Cost Estimates

C.2.2.1 Coal Reburn Capital Cost Estimates

There is one alternative that includes a new coal reburn system. Capital cost estimates for coal reburn systems are highly dependent on the requirements for reburn fuel preparation and feeding to the boiler. For the purposes of this analysis, the application of a pulverized coal reburn system assumed the need to make extensive additions to the existing fuel preparation equipment in the existing plant facilities and feeding to new furnace injectors. At least two new fine-grind pulverizers, or MPS-89 standard pulverizers followed by dynamic classifiers are expected to supply the amount of finely ground reburn coal for this method.

Addition of new electrical loads for the pulverized coal preparation equipment to the existing plant facilities will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power will be available for powering the new pulverizers/micro-mills and related new coal reburn equipment, but this has not been confirmed.

The existing crusher bays do not have floor space available to allow the new milling equipment for reburn fuel preparation to be located adjacent to the existing coal crushers. This will require a separate building or addition to the existing powerhouse to be built to provide sufficient space to enclose the new milling and coal silo/handling equipment. Separate modified pulverized coal-style burners or coal injectors will be installed through new openings in the upper furnace front and rear waterwalls at or above the elevation of the existing lignite drying system vent ports, along with new overfire air ports located at a higher elevation, above the reburn fuel injectors. This would have the capacity to supply approximately up to thirty percent of the total full load fuel heat input to the boiler through the coal reburn injectors. This coal reburn system design was not expected to change the existing cyclone silo/feeder arrangement, such that all cyclones would remain operational. To achieve maximum NO_X emission control, only the advanced form of SOFA for pulverized coal reburn was included. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BACT analysis.

The installed capital cost of pulverized coal reburn for the cyclone boilers at Milton R. Young Station used in this cost effectiveness analysis was estimated based upon a Clean Air Markets Division [CAMD] of the US EPA dollar per kilowatt unit capital cost factor for cyclones. The installed capital cost estimate of $21,900,000 for MRY Station Unit 1’s pulverized coal reburn alternative used in this cost effectiveness analysis was estimated based upon applying a 3.5% assumed inflation cost adjustment to the CAMD unit capital cost factor for cyclones of \$82.33/kW (x 1.035 = \$85.2/kW) included in a WRAP (Western Regional Air Partnership) draft report[iv] published on their website, dated April 26, 2005. The cost to relocate the lignite drying system vent ports (+\$4.7/kW) was added to the inflation-adjusted CAMD number (\$85.2 + \$4.7/kW = \$89.9/kW), since coal reburn is expected to include separated overfire air but not the extra costs for the special improvements identified for air-staged lignite-firing in cyclone boilers. This increased the installed capital cost by \$1,200,000 for MRY Station Unit 1's coal reburn system to a total of \$23,561,000. This does not include the additional particulate matter collection capacity considered necessary to limit the expected negative impact on opacity from this option.

To control particulate matter (PM) emissions that would be expected to increase from installation and operation of pulverized or micronized coal reburn, additional PM collection capacity will be required. A hybrid form of PM collection that supplements the existing electrostatic precipitator's performance, referred to as COHPAC (COmpact Hybrid PArticulate Collector). This was estimated in 2002 dollars at \$20,191,000 for MRY Station Unit 1's COHPAC[3]. Adjusted by an escalation factor of 1.2623, the installed capital cost of the COHPAC addition was estimated to be \$23,561,000 for MRY Station Unit 1 in 2006 dollars. When the COHPAC addition was combined with the Lignite Reburn and ASOFA alternatives, the resulting total estimated capital costs were \$46,656,000 for MRYS Unit 1 (\$89.9 + \$91.7 = \$181.5 /kW).

C.2.2.1 Gas Reburn Capital Cost Estimates

Conventional gas reburn options assume that seventeen percent of the total fuel heat input to the boiler is through the new gas reburn injectors to be located in the lower secondary furnace above the top rows of cyclones. Eight to twelve gas reburn injectors would be expected to be required in this case. Seven percent of the total fuel heat input to the boiler through the gas reburn injectors is assumed to be supplied for the fuel lean gas reburn alternatives. Four to eight gas reburn injectors could be assumed in FLGR™ cases. Gas reburn options assume that a new high-pressure gas pipeline would be brought from near Bismarck, ND approximately twenty six miles. The pipeline diameter is proportional to the amount of fuel required for the specific alternative, ranging from 24 inches for conventional gas reburn to 12 inches for fuel lean gas reburn cases. A station gas main, with new gas trains, consisting of valves, metering, and safety shutoff valves for the front and rear boiler for the gas injectors' supply, would be furnished and installed.

The capital costs for conventional gas reburn alternatives were estimated considering unit capital costs published in published technical literature. One vendor that has supplied numerous domestic utility boiler gas reburn systems (GE Energy, formerly GE-EER) published \$10/kW for gas reburn in a 2001 technical paper[v]. Another source published a 2005 technical paper[vi] that provided a unit capital cost range for gas reburn of \$15/kW to \$30/kW. Neither source included a detailed scope description nor cost breakdown for engineering, equipment, materials, and labor to install a gas reburn system.

Site-specific needs and challenges identified for applying conventional gas reburn to Milton R. Young Station, and lack of detailed gas reburn project scope and equipment descriptions available in published technical literature leads to a much greater degree of uncertainty with regards to an accurate capital cost estimate for this alternative. For the purposes of this study, the estimated installed capital cost for a conventional gas reburn system with advanced SOFA on MRYS Unit 1 is expected to be approximately \$9.9M (\$38.6/kW), which is above the top end of the previously stated range, before adding the new underground gas pipeline capital costs. This study assumed an average unit capacity capital cost factor of \$22/kW for conventional gas reburn, plus the additional costs for the advanced from of SOFA over basic SOFA (+\$1.2M or +\$4.6/kW) and the new high-pressure gas pipeline. This results in a an estimated installed capital cost for conventional gas reburn system with advanced SOFA on MRYS Unit 1 of \$11.1M (\$25.7/kW) plus the new high-pressure gas pipeline costs. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BACT analysis.

Fuel lean gas reburn (without SOFA) capital cost estimates were based upon a late 2004 budgetary proposal[vii] by a vendor (Fuel Tech) with experience in supplying FLGR™ equipment, typically combined with an SNCR system. Estimated capital costs of \$3M include budgetary numbers for the equipment installation, including installation management, material and labor, with a –43% price adjustment assumed for 257 vs 450 MW for a fuel lean gas reburn system without SOFA on MRY Unit 1, not including the capital cost for the gas supply pipeline. Costs for work outside the vendor's scope, such as balance-of-plant additions plus other indirect costs were estimated to add approximately \$0.5M (25% plus 10% contingency) to the adjusted vendor's estimated installed cost of \$1.7M for their scope of supply. These adjustments result in a total installed capital cost for FLGR (without SOFA) estimated to be \$2.2M plus the capital cost for the gas supply pipeline. Adding the incremental costs for the advanced from of SOFA over no SOFA (+\$4.3M (+\$16.6/kW) results in an estimated installed capital cost for a fuel gas reburn system with advanced SOFA on MRYS Unit 1 of \$6.6M (\$25.7/kW) plus the new high-pressure gas pipeline costs.

The capital cost estimates for the new high-pressure underground gas supply pipeline assumed $7 per inch of diameter per foot of length. This was calculated to be approximately $23M for conventional gas reburning and $11.5M for FLGR™. The cost analysis for each NO_X control alternative involving a particular form of gas reburn assumed that both boilers at Milton R. Young Station select the same alternative that burns natural gas. Therefore, the estimated capital costs for gas reburn alternatives reflect a capacity-based proportional share of the gas pipeline capital costs, avoiding double-counting. This results in an estimated installed capital cost for MRYS Unit 1's share of the gas pipeline to be $8.1M / for the conventional gas reburn alternative and $4M for fuel-lean gas reburn alternatives.

The total installed capital costs for conventional gas reburn (with ASOFA) with MRYS Unit 1's share of the total capital cost for the gas supply pipeline estimated to be $18M ($70.6/kW). The total installed capital costs for FLGR™ (with ASOFA) with MRYS Unit 1's share of the total capital cost for the gas supply pipeline were estimated to be $10.6M ($41.4/kW). Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BACT analysis.

C.2.3 SNCR Capital Cost Estimate

The alternatives that include selective non-catalytic reduction systems assume the use of urea unless noted otherwise. The SNCR systems' preliminary design and estimated capital costs were based upon a 450 MW lignite-fired cyclone boiler in a late 2004 budgetary proposal[7] by a vendor (Fuel Tech) with experience in supplying SNCR equipment. Circulation, metering, dilution, control, and injection equipment is included. A 180,000 gallon field-erected stainless steel storage tank will hold the 50% urea solution (as delivered by truck). Individual and multiple nozzle lances with multiple levels of urea reagent injection will be designed and located to optimize distribution and accommodate various boiler load conditions. Estimated capital costs of $4.9 Million include budgetary numbers for equipment installation, including installation management, material and labor assumed for a SNCR system applied to a 450 MW boiler. Costs for work outside the vendor's scope, such as outdoor reagent storage tank and building enclosure/equipment foundations and containment, and balance-of-plant additions plus other indirect costs were estimated to add approximately $1.9 Million (25% plus 10% contingency) to the vendor's estimated installed cost for their scope of supply. This results in an estimated total capital cost for SNCR (without SOFA) of $6.8M for a 450 MW lignite-fired cyclone boiler.

Applying these adjustments to a 257 MW boiler, estimated direct capital costs of $2.800,000, plus $1,000,000 for indirect costs yields a total installed capital cost for applying SNCR to MRY Station Unit 1 of approximately $3,836,000 ($14.9/kW).

C2.5 Layered Technology Capital Cost Estimates

Capital costs were generally estimated based upon simple arithmetic addition of individual unit output capital cost factors for combinations of available NO_X reduction technologies, such as SNCR with ASOFA. An advanced form of separated overfire air system included the lignite-fired cyclone boiler equipment changes within the estimated unit capital cost factors.

Adding the advanced SOFA capital cost of $4.3 Million to the previous estimated installed capital cost of $3.8 Million yields a total estimated installed capital cost of $8.113 Million ($31.6/kW) for the SNCR with ASOFA alternative for MRYS Unit 1.

As previously discussed, Lignite (coal) reburn (CR) was assumed to be combined with advanced SOFA and a COHPAC addition considered necessary to limit the expected negative impact on opacity from this option. The installed capital cost of the COHPAC addition was estimated to be $23,561,000 for MRY Station Unit 1. When the COHPAC addition was combined with the Lignite Reburn and ASOFA alternatives, the resulting total estimated capital costs were $46,656,000 for MRYS Unit 1 ($89.9 + $91.7 = $181.5 /kW).

C.3 Operating and Maintenance Cost Estimates for MRY Station NO_X Control

An evaluation was performed to determine the estimated operating and maintenance cost impacts of installing and continuously operating various feasible NO_X control technologies on Milton R. Young Station Unit 1. These were estimated to be in addition to existing O&M costs to operate and maintain the MRY Station equipment.

The expected loss of electrical power sales from the operation of the specific NO_X control alternative was included as an annualized cost, assuming $35 per megawatt-hour. This was determined to include estimates for:

- Reduction in annual unit output due to an expected negative reliability (i.e. uptime availability) impact for each alternative. This generation reduction was calculated by multiplying the estimated additional numbers of outage hours per year by the average running plant capacity factor for that specific alternative, multiplied by the historic 12-month average unit gross electrical power output (MW_g) determined during the same period as the highest 12-month rolling summation NO_X pounds.
- Net additional auxiliary electric power demand for the added control equipment for each specific alternative based on assumptions for gross horsepower, plus additional power demand for existing fans caused by flue gas pressure drop (COHPAC for additional PM collection capacity), with adjustment for expected reductions in power demand (such as a decrease in existing coal crusher and feeder electric demand for the pulverized coal reburn case).
- The average running plant capacity factor for each alternative, which may also include an expected negative impact on the unit capacity from operation of the technology. This assumes that the control technique limits the gross electrical power output of the Unit (such as causing an increase in flue gas flow) such that the firing rate of the boiler cannot be maintained or raised to compensate for the load impact. Examples are lower boiler thermal efficiency (higher unit heat rate) when firing natural gas (due to higher moisture content of the flue gas).

For the SNCR alternative that involves a chemical reagent injected for NOx control, such as urea, the annual reagent consumption based on an assumed actual stoichiometric ratio (ASR) of moles of equivalent NH_3 injected per mole of uncontrolled NO_X emission estimated at the point of injection, converted to a mass rate (lbs/hr) by multiplying by the estimated annual number of hours of operation and the estimated NOx reduction fraction, and then multiplied by unit reagent cost (for a specific inlet NO_X concentration, emission reduction percentage and ammonia slip level).

General annual maintenance costs were assumed to be 1.5 percent of the estimated installed capital cost for each alternative, except for the coal conveying and grinding equipment portion of the coal reburn alternative, which was assumed to be 3 percent. The periodic bag replacement costs and other COHPAC system maintenance costs were estimated to be approximately 5.3% of the installed capital cost of the additional particulate matter collection equipment.

Additional operating labor costs directly attributable to each alternative were assumed to be zero for all alternatives.

Other operating costs include:

- Reagent dilution water for those alternatives that involve a chemical reagent injected for NOx control, typically four times the amount of urea consumption (assumes urea is a 50% solution as delivered and is injected as a 10% solution); this follows EPA OAQPS convention[1].
- Heat required for urea reagent storage, for those alternatives that involve a chemical reagent injected for NOx control; the source of heat is assumed to be auxiliary electrical power, but could be auxiliary steam (depending on heat source availability and plant preference).
- Additional coal consumption for those alternatives that involve a chemical reagent injected for NOx control to compensate for the heat of vaporization of the reagent dilution water;
  This follows EPA OAQPS convention[1], but is not accepted practice by an experienced SNCR vendor (Fuel Tech) who claims that the heat produced from the exothermic reaction of urea and NO_X is approximately equal to the heat required to evaporate the dilution water. For the purposes of this study, this additional coal consumption has been included in the annual O&M costs.

The sum of the estimated annual O&M costs was multiplied by the O&M levelization factor (1.24873) for each alternative to yield levelized total annual O&M costs.

C.3.1 Separated Overfire Air O&M Cost Estimate

Operation of SOFA is expected to add a small amount of O&M cost, primarily electricity consumed by the conventional SOFA damper electric drive actuator and airflow measuring system transmitter on each port. Using the existing forced draft, induced draft, and flue gas recirculation fans is not expected to change the overall amount of fan horsepower demand to be supplied by those fans' electric motors. Maintenance of the new overfire air ports and relocated lignite drying system vent ports is included, assumed to be 1.5 percent of the installed capital cost. This is included in every control alternative's estimated O&M cost.

SOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, assuming consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for MRYS boilers can be routinely established. A Unit availability reduction of 2.2% (188 hours per year), for M.R. Young Station Unit 1 was assumed, which allows for forced or extended scheduled boiler outages that may result from problematic cyclone slag tapping operational conditions encountered during substoichiometric cyclone operation with SOFA. The expected loss of electrical power sales from the reduction in annual electrical power output due to a decrease in expected Unit availability from ASOFA operation is included in every control alternative's estimated O&M cost.

Boiler furnace waterwall tube maintenance may increase slightly as a result of more fireside corrosion due to substoichiometric cyclone operation with SOFA. There may be some changes in the degradation rate of the boiler's furnace waterwall tubes resulting from exposure of more area of the furnace walls to slightly air-starved conditions during SOFA operation. Such conditions can promote corrosion from sulfur compounds in the furnace gases being created above the cyclones and below the SOFA injection ports. Due to the relatively moderate amounts of sulfur content in the lignite, modest amount of air-staging of the existing cyclones during SOFA operation, and the potential use of recirculated flue gas along the lower furnace walls, the expected change in corrosion rate of the boiler tubes should be minor. This degradation is expected to occur over many years of operation, and normally requires periodic replacement of the deteriorated sections of boiler furnace waterwall tubes to avoid forced outages to repair tube leaks or failed sections. The additional costs associated with potential change in the frequency of furnace wall tube failures and changeouts are difficult to estimate, and have not been quantified.

C.3.2 Reburn O&M Cost Estimates

The alternatives that include a new coal reburn system assume the use of new equipment for preparing the reburn fuel to replace 25% of the MRY Station Unit 1 boiler's total fuel heat input. Two additional lignite silos, with coal feeders and fine-grind pulverizers followed by dynamic classifier(s), are assumed to be located in a new separate building or powerhouse enclosure. Booster fan(s) addition was included because the existing forced draft fans were assumed to be incapable supplying the additional amount of primary air to the fine-grind pulverizers and dynamic classifier(s) for processing and conveying the reburn fuel. Using the existing forced draft, induced draft, and flue gas recirculation fans is not expected to significantly change the overall amount of fan horsepower demand to be supplied by those fans' electric motors. The expected loss of electrical power sales from the additional auxiliary electric power demand for the reburn milling equipment from an estimated 0.6% (1.5 MW) reduction in net output was included as a cost, assuming $35 per megawatt-hour for MRY Station Unit 1. Electrical power consumed by the increased load on boiler fans to overcome the higher flue gas system pressure drop, plus the COHPAC particulate collection system support equipment was estimated to be a 1.2% (3.2 MW) reduction in net output for Unit 1.

Maintenance of the separate reburn coal injectors, fuel and primary air piping, and reburn fuel milling equipment is expected to be similar to the expenses associated with typical pulverized coal burners. The estimated additional annual maintenance costs for a new micronized coal reburn system was assumed to be 3.0 percent of the installed capital cost, or roughly $693,000 per year, for MRY Station Unit 1. The estimated additional annual maintenance costs (inflation adjusted from 2002 to 2006 $) for the COHPAC system was approximately $1,223,000 for MRYS Unit 1. Boiler furnace waterwall tube and superheater/reheater tube maintenance may increase slightly as a result of more erosion due to increased particulate emissions or fouling by flyash deposits resulting from coal reburn operation with ASOFA. The additional costs associated with potential change in the frequency of boiler tube failures and changeouts are difficult to estimate, and have not been quantified.

The estimated impacts on operation and maintenance costs for the coal reburn alternative that include a new pulverized or micronized coal reburn system are approximate. The seven (Unit 1) existing coal crushers for preparing the main (cyclone) fuel fraction will have slightly lower electrical demand. This was estimated as -0.26 MW (-0.1%) for MRYS Unit 1. Addition of new electrical loads for the micronized coal preparation equipment to the existing plant facilities will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power will be available for powering the new pulverizers/classifiers and related new coal reburn equipment, but this has not been confirmed.

Coal Reburn with ASOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, assuming consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for MRYS boilers can be routinely established. A Unit availability reduction of 3.7% (316 hrs/yr), for M.R. Young Station Unit 1 was assumed, which allows for forced or extended scheduled boiler outages that may result from problematic operational conditions encountered during coal reburn operation with ASOFA. This reduction in annual electrical power output due to a decrease in expected Unit availability is included in the coal reburn control alternative's estimated O&M cost.

A Running Plant Capacity Factor reduction of 0.5% of annual gross electrical output was assumed for the coal reburn alternative. This would result in an estimated 1.2 MW average load decrease for M.R. Young Station Unit 1. This expected loss of electrical power sales from the reduction in net output due to this plant capacity impact was included in the estimated annual O&M costs.

Conventional and fuel-lean gas reburn options will involve higher operating costs compared with the existing operation of M.R. Young Station. Natural gas supply was assumed to be available near Bismarck, ND, but this has not been confirmed. The estimated unit cost of this natural gas was assumed to average $7.98/million Btu on a levelized annual cost basis, with a "credit" of $0.71 per mmBtu for avoided cost of consumption of lignite coal reduced by the natural gas heat input. The estimated annual cost of natural gas for the conventional gas reburning alternative applied to MRYS Unit 1 is approximately $29.7M per year. The estimated annual cost of natural gas for the FLGR™ alternative applied to MRYS Unit 1 is approximately $12.3M per year.

The new gas reburn injectors, station gas main and injector gas trains would add a minor amount of expense to current maintenance requirements, assumed to be 1.5 percent of the installed capital cost. Maintenance of separated overfire air nozzles is expected to be similar to the expenses associated with Unit 2's existing flue gas recirculation ports.

C.3.3 SNCR O&M Cost Estimate

The alternatives that include selective non-catalytic reduction systems will involve higher operating costs compared with the existing operation of MRY Station Unit 1. Urea reagent supply was confirmed to be available regionally. The estimated unit cost of this 50% aqueous urea solution was assumed to average approximately $379/ton delivered (2006$). Consumption of urea reagent for SNCR with ASOFA was based upon preliminary numbers allowing for a boiler flue gas exit ammonia slip of 5 ppmvd. These were estimated as approximately 200 gph for SNCR when applied to MRY Station Unit 1 with ASOFA.

New electrical loads are required for high flow urea circulation, in-line and storage tank heating, water dilution, and reagent metering equipment. These auxiliary electrical demands and reagent dilution water usage were calculated based upon equations published in EPA Office of Air Quality Planning and

Standards (OAQPS) publication EPA/452/B-02-001, Section 4.2, NOx Controls – NOx Post-Combustion, Chapter 1 - Selective Non-Catalytic Oxidation[1]. Compressed air for reagent atomization and lance purging and cooling, as well as multiple nozzle lance water cooling are additional demands on the existing plant facilities. These powerhouse building service supplies were assumed to be available, but this has not been confirmed. The new urea reagent injection nozzle lances, reagent pumps, dilution water pumps, and distribution piping/valve trains would add a minor amount of expense to current maintenance requirements, assumed to be 1.5 percent of the installed capital cost.

SNCR with ASOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, assuming urea injection does not impact the ability to maintain consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for MRYS boilers. A Unit availability reduction of 3.2% (273 hrs/yr), for M.R. Young Station Unit 1 was assumed, which allows for forced or extended scheduled boiler outages that may result from problematic operational conditions encountered during SNCR-related operation with ASOFA. This reduction in annual electrical power output due to a decrease in expected Unit availability is included in the these control alternatives' estimated O&M costs.

A Running Plant Capacity Factor reduction of 0.15% of annual gross electrical output was assumed for the SNCR with ASOFA alternative. This would result in an estimated 0.37 MW average load decrease for M.R. Young Station Unit 1. This expected loss of electrical power sales from the reduction in net output due to this plant capacity impact was included in the estimated annual O&M costs.

C.3.4 Layered Technology O&M Cost Estimates

Operating and maintenance costs for combinations of available NO_X reduction technologies were estimated based upon simple arithmetic addition of individual cost estimates. SNCR was combined with advanced SOFA, as previously shown. Pulverized coal reburn was assumed to be combined with advanced SOFA (and a COHPAC addition for PM control). The auxiliary electrical demands and reagent dilution water usage for SNCR with ASOFA were calculated based upon equations published in EPA Office of Air Quality Planning and Standards (OAQPS) publication EPA/452/B-02-001, Section 4.2, NOx Controls – NOx Post-Combustion, Chapter 1 - Selective Non-Catalytic Oxidation[1].

C.3.5 Summary of O&M Costs Estimates for MRY Station NOx Control

The results of this evaluation for estimated variable operating and maintenance costs for the individual NOx control alternatives are summarized in this section. The expected reductions in Unit availability (uptime) and capacity are included in Tables C.3-1 through C.3-4 for MRYS Unit 1. Tables C.3-5 and C.3-6 for MRYS Unit 1 include the estimated urea reagent and dilution water usage rates and costs for the alternatives that involve SNCR with ASOFA NO_X control technologies.

TABLE C.3-1 – Expected Availability Reductions for MRY Unit 1 NO_X Controls

		Estimated Annual Average Unit Operating Time			
Alt.[1]	**NOx Control Technique**	**Unit Availability[2]**	**Unit Operating Time[3], hrs/yr**	**Unit Outage Time[4], hrs/yr**	**Unit Operating Time Reduction[5], hrs/yr**
E	SNCR w/ ASOFA	0.942	8255	505	273
D	Gas Reburn w/ ASOFA	0.952	8340	420	188
C	Coal Reburn w/ ASOFA	0.937	8212	548	316
B	FLGR w/ ASOFA	0.952	8340	420	188
A	Advanced SOFA (ASOFA)	0.952	8340	420	188
	Baseline	0.973	8528	232	0

1 – Alternative number has been previously assigned from least removal to highest removal percentage.
2 – 12-month baseline availability is assumed at 97.3 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.
3 – Annual operating time is annual average availability multiplied by 8760 hrs/yr of possible uptime.
4 – Annual outage time is 8760 hrs/yr possible operating time minus estimated annual operating time.
5 – Annual operating time reduction resulting from the implementation of the individual NOx control technique is the difference between the baseline and expected annual outage times.

TABLE C.3-2 – Expected Capacity Reductions for MRY Unit 1 NO_X Controls

Alt. Label(1)	NOx Control Technique	Estimated Annual Average Unit Electrical Power Generation Reduction from Operating Time Reduction		
		Unit Running Plant Capacity Factor(2)	Unit Generation Reduction(3) kW-hrs/yr	Unit Generation Reduction Cost(4), 1000$/yr
E	SNCR w/ ASOFA	0.965	67,660,606	2,368
D	Gas Reburn w/ ASOFA	0.957	46,120,681	1,614
C	Coal Reburn w/ ASOFA	0.961	77,958,350	2,729
B	FLGR w/ ASOFA	0.962	46,400,200	1,624
A	Advanced SOFA (ASOFA)	0.966	46,586,546	1,631
	Baseline	0.966	0	0

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.

(2) – 12-month baseline running plant capacity factor is assumed at 96.6 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

(3) – Annual electricity generation reduction is annual operating time reduction multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the 12-month average gross output of 244.4 MW.

(4) – Annual electricity generation reduction cost is the annual electricity generation reduction (kW-hrs/yr) resulting from the implementation of the individual NOx control technique multiplied by the incremental value of electricity generation, assumed to be $35.00/MW-hr. All cost figures in 2006 dollars.

TABLE C.3-3 – Expected Auxiliary Electrical Power Demand Changes for MRY Unit 1 NO_X Controls

Alt. Label(1)	NOx Control Technique	Estimated Annual Average APC NOx Equipment Auxiliary Electrical Power Demand and Usage				
		Gross Demand (2) kW	**Credit(3) kW**	**Total Net Demand(4) kW**	**Power Usage(5) kW-hrs/yr**	**Power Usage Cost(6), 1000$/yr**
E	SNCR w/ ASOFA	73.1	0	73.1	582,411	20
D	Gas Reburn w/ ASOFA	1	133	(132)	(1,054,343)	(37)
C	Coal Reburn w/ ASOFA	4,666	261	4,405	11,905,082	1,217
B	FLGR w/ ASOFA	1	73	(72)	(578,744)	(20)
A	Advanced SOFA (ASOFA)	1	0	1	8,058	0.3

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.

(2) – The APC NOx equipment gross auxiliary electrical power demand of alternatives is the sum of individual technologies combined by simple addition. Actual power demands may differ from this due to positive or negative synergistic effects. Coal reburn includes 1,507 kW for feed preparation and conveying equipment demand plus 3,158 kW for the COHPAC system addition for PM control.

(3) – The APC NOx equipment auxiliary electrical power demand credit of coal reburn alternatives is the estimated result of lower cyclone coal preparation and feeder power demand due to lower boiler cyclone coal equipment loading. Actual power demands may differ from this due to accuracy of estimates for assumed amount of operating horsepower reduction.

(4) – The total net auxiliary electrical power demand is the sum of the gross demand and credit.

(5) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique.

(6) – The annual change in APC NOx equipment auxiliary electrical power demand electricity cost is the annual change in kW-hrs/yr for these alternatives resulting from the implementation of the individual NOx control technique multiplied by the incremental value of auxiliary electricity generation, assumed to be $35.00/MW-hr. All cost figures in 2006 dollars.

TABLE C.3-4 – Expected Auxiliary Electrical Power Demand and Generation Reduction Cost Changes for MRY Unit 1 NO_X Controls

Alt. Label[1]	NOx Control Technique	Estimated Annual Change in Unit Generation Due to APC NOx Equipment Auxiliary Power Electricity Demand and Generation Reduction			
		APC Electrical Power Usage[2] kW-hrs/yr	Unit Generation Reduction[3] kW-hrs/yr	Total Unit Electrical Power Generation Change[4] kW-hrs/yr	Total Unit Electrical Power Generation Change Cost[5] 1000$/yr
E	SNCR w/ ASOFA	582,411	67,660,606	68,243,017	2,389
D	Gas Reburn w/ ASOFA	(1,054,343)	46,120,681	45,066,338	1,577
C	Coal Reburn w/ ASOFA	11,905,082	77,958,350	89,863,432	3,946
B	FLGR w/ ASOFA	(578,744)	46,400,200	45,821,456	1,604
A	Advanced SOFA (ASOFA)	8,058	46,586,546	46,594,605	1,631

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.

(2) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique.

(3) – Annual electricity generation reduction is annual operating time reduction multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the 12-month average gross output of 244.4 MW.

(4) – The total unit electrical power generation change is the sum of the annual change in APC NOx equipment auxiliary electrical power demand electricity usage plus the annual electricity generation reduction resulting from the implementation of the individual NOx control technique.

(5) – The total unit electrical power generation change cost is the total generation change (kw-hrs/yr) multiplied by the incremental value of electricity generation, assumed to be $35.00/MW-hr. All cost figures in 2006 dollars.

TABLE C.3-5 – Expected NOx Reagent Usage and Cost Estimates for MRY Unit 1 NO_X Controls

Alt. Label(1)	NOx Control Technique	NOx Reduction Reagent Urea Usage(2)			NOx Reduction Reagent Dilution Water Usage(3)	
		lbs/hr	tons/yr	1000$/yr	1000 gal/yr	1000$/yr
E	SNCR w/ ASOFA	1,894	7,544	2,861	7,232	7

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.
(2) – All cost figures in 2006 dollars.
(3) – Reagent dilution water usage assumes potable water is added to create a 10% urea concentration (4 parts water to 1 part urea solution at 50% concentration) prior to injection. Dilution water unit cost assumed to be $1.00 per thousand gallons.

TABLE C.3-6 – Expected Heat Input and Equivalent Coal Cost to Evaporate Aqueous Urea for MRY Unit 1 NO_X Controls

Alt. Label(1)	NOx Control Technique	Estimated Annual Average Unit Equivalent Coal Consumption Cost for Aqueous Urea Evaporation		
		Heat Required to Evaporate Aqueous Urea(2), mmBtu/yr	Equivalent Coal Consumption for Heat Input(2), Tons/yr	Coal Consumption Cost(2), 1000$/yr
E	SNCR w/ ASOFA	54,315	4,077	38

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.
(2) – Heat required to evaporate urea reagent dilution water assumes 900 Btu/lb required based on a 10% urea concentration (4 parts water to 1 part urea solution at 50% concentration) injected for the estimated amount of urea usage. Coal heat content of 6,662 Btu/lb, unit cost of $0.71/mmBtu.

EXECUTIVE SUMMARY

The Milton R. Young Station of Minnkota Power Cooperative, Inc. (Minnkota) and Square Butte Electric Cooperative (Square Butte) includes two cyclone-furnace, lignite-fired steam-electric generating units (SEGUs). The units both fire North Dakota lignite supplied from the adjacent mine, near Center, North Dakota. Unit 1 has a nominal 235 MW net design output capacity rating, is typically capable of sustained output of approximately 250 MW_g (gross), and has a gross design output capacity rating of 257 MW_g. Unit 1 is owned and operated entirely by Minnkota. Unit 2 has a nominal 439 MW net design output capacity rating, is capable of sustained output of approximately 460 MW_g (gross), and has a gross design output capacity rating of 477 MW_g. Unit 2 is owned by Square Butte Electric Cooperative (Square Butte), and operated by Minnkota.

A Notice of Violation (NOV) from the United States Environmental Protection Agency (US EPA or EPA) was issued to Minnkota Power Cooperative on June 21, 2002. The NOV alleged that modifications had been made at the Milton R. Young Station that would have required a construction permit under New Source Review (Code of Federal Regulations 40 CFR 52.21, and North Dakota Administrative Code NDAC 33-15). As a result of this allegation, a civil complaint was filed by the United States of America and the State of North Dakota against Minnkota Power Cooperative Inc. ("Minnkota") and Square Butte Electric Cooperative ("Square Butte") in the United States District Court for the District of North Dakota. A Consent Decree (CD) has been approved that represents a final negotiated settlement of the United States' and North Dakota's claims against Minnkota and Square Butte. The Consent Decree requires Minnkota and Square Butte to perform a "NO_X Top-Down Best Available Control Technology (BACT) Analysis" to describe the emission limits for NO_X that will be required at Units 1 and 2, expressed as a 30-Day Rolling Average NO_X Emission Rate [Consent Decree paragraph 24, page 7, and paragraph 5, page 4].

Burns & McDonnell was retained to conduct a Top-Down BACT Analysis for nitrogen oxides (NO_X) at the Milton R. Young Station. The results of the BACT analysis are presented in this study report.

The procedures mandated by the Consent Decree for performing a Top-Down BACT Analysis are outlined in Chapter B of the U.S. EPA's New Source Review Workshop Manual: Prevention of Significant Deterioration and Nonattainment Area Permitting, Draft, October 1990 ("EPA's NSR Manual"). The MRY Station BACT analysis was performed in accordance with this procedure. The

EPA's NSR Manual outlines five basic steps that are to be followed in this BACT analysis. These basic steps for such a BACT analysis are summarized as follows:

Step 1 – Identify All Control Technologies
Step 2 – Eliminate Technically Infeasible Options
Step 3 – Rank Remaining Control Technologies by Control Effectiveness
Step 4 – Evaluate Most Effective Controls and Document Results
Step 5 – Select BACT

A Best Available Control Technology (BACT) analysis was performed for Milton R. Young Unit 2 for NO_X using the EPA's "top-down" approach. Best Available Control Technology is defined as "an emissions limitation (including a visible emission standard) based on the maximum degree of reduction for each pollutant subject to regulation under Act which would be emitted from any proposed major stationary source or major modification which the Administrator, on a case-by-case basis, taking into account energy, environmental, and economic impacts and other costs, determines is achievable for such source or modification through application of production processes or available methods, systems, and techniques, including fuel cleaning or treatment or innovative fuel combustion techniques for control of such pollutant" (40 CFR 52.21, NSR Manual B.1).

Unit 2 at Milton R. Young Station is a cyclone-fired boiler that burns North Dakota lignite. The method of firing is very significant in analyzing control options for NO_X emissions. A cyclone boiler produces inherently higher uncontrolled NO_X levels than pulverized-coal and circulating fluidized bed boilers. There have been no new coal-burning cyclone-fired boilers built and installed in the United States since the early 1980's. Consequently, there are no examples of BACT control options listed in the RACT/BACT/LAER Clearinghouse database for consideration and direct application of published NO_X emission permit limits on the Milton R. Young cyclone-fired boilers.

Step 1 – Identify All Control Technologies

The Consent Decree requires that the NO_X Top-Down BACT Analysis for the Milton R. Young Station "include an evaluation of Selective Catalytic Reduction (SCR), Selective Non-Catalytic Reduction (SNCR), Overfire Air (OFA), Rich Reagent Injection (RRI), as well as other NO_X control technologies" potentially applicable for lignite-fired cyclone boilers [Consent Decree paragraph 65, page 19]. Other identified control techniques, such as fuel switching and fuel cleaning, and combustion-related emission control technologies, such as fuel reburn and oxygen-enhanced combustion, were also considered.

Step 2 – Eliminate Technically Infeasible Options

The BACT evaluation determined that not all the technologies identified were considered available and applicable. The technically infeasible alternatives were eliminated from further evaluation, along with feasible technologies with economic impacts that were unreasonable compared to other cost-efficient alternatives to control NO_X emissions for MRY Station Unit 2.

The technical feasibility of applying NO_X emission reduction techniques and technologies at Milton R. Young Station is dominated by the composition and combustion characteristics of the North Dakota lignite supplied solely from a surface mine adjacent to the plant. This mine is the only supplier of solid fuel for this station, as there are no railroad facilities provided to service the Milton R. Young plant. North Dakota lignite has high moisture and high sodium content, moderate higher heating values, and can have a widely variable and high ash content compared to other coals. These characteristics create difficulties in promoting consistent, steady combustion and slag formation in the cyclone burners. It also results in producing a flyash that has severe deposition characteristics.

Both boilers include a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boilers.

Ash deposition in each boiler and air preheater is a significant operational challenge for the facility. Significant equipment and manpower resources are devoted to on-going removal of fireside ash accumulations. Unit outages must be conducted at regular intervals to clean each boiler (approximately every 80-120 days). There are a number of issues that make selective catalytic reduction (SCR) technically infeasible for NO_X emission control for Milton R. Young Unit 2. The consistent long-term operation of SCR technology on lignite-fired cyclone boilers will be drastically inhibited by the susceptibility of the SCR catalyst to severe fouling, deactivation, and erosion resulting from the actions of the emitted flue gases and flyash, and ash deposit removal operations. SCR technology is considered technically infeasible for application on the cyclone boilers at the Milton R. Young Station.

Rich Reagent Injection has been demonstrated on boilers burning bituminous and subbituminous coal. However, it has not been commercially installed and placed in continuous operation on a cyclone-fired boiler burning lignite coal with high fouling and slag temperature sensitivities associated and a highly variable heat content. RRI adds urea reagent to the hot furnace gases near the cyclones, which must be devoid of free oxygen in order to avoid oxidation of the urea, and thus creating NO_X. While RRI is specifically intended for NO_X emissions control on cyclone boilers, RRI is considered technically infeasible for application on the lignite fired cyclone boilers at the Milton R. Young Station due to the variable heat content of the lignite fuel which allows the creation of oxygen-rich conditions in the boiler.

The application of separated overfire air (SOFA) for NOx emissions control on Milton R. Young Unit 2’s boiler was evaluated as part of the BACT analysis. A version of separated overfire air specifically designed for increased NO_X emission reduction performance for lignite-fired cyclone boilers, referred to as “Advanced SOFA” in this analysis, can be installed on both units at M.R. Young Station. This highest-performing form of SOFA can be applied alone and in combination with other technologies. Key aspects of successfully applying and operating a separated overfire air system on a cyclone-fired boiler are the ability to:

- Accurately measure the fuel heat input rate (BTUs) and combustion air inputs on a real-time, individual cyclone by cyclone basis, to allow the ability to determine and control the desired air/fuel ratio, especially when “starved air“ (i.e. substoichiometric) combustion conditions are required.
- Maintain adequate molten coal ash (slag) formation and flow within the barrels and slag taps.

The degree to which the individual cyclone furnaces can be operated with less-than-theoretical (substoichiometric) combustion air, which corresponds to operation of a SOFA system, directly contributes to less combustion-related NO_X formation and further in-furnace emission reduction but also risks solidification of the molten coal ash. This places great emphasis on achieving tight control over the air/fuel ratios on each cyclone during air-staged combustion operation with SOFA in order for air-staged combustion to be successful in producing significant additional NOx emissions reduction on lignite-fired cyclone boilers.

In the case of MRY Station Unit 2’s boiler, air-staged combustion must be sufficient to reduce NO_X emissions while releasing enough heat to continue to melt the fuel ash so that it flows effectively within and from the cyclone burners. Due to the short-term variability of the combustible and ash components of North Dakota lignite supplied from the current mine near Center, ND, and the complex behavior of lignite ash when exposed to high temperatures, the extent of air-staging and thus the level of NO_X control while operating the highest-performing version of SOFA system is expected to be modest.

Selective Non-Catalytic Reduction (SNCR) technology has been used to reduce NO_X emissions on numerous utility boilers burning eastern bituminous coal, midwestern bituminous coal, and, to a lesser extent, western subbituminous coal. SNCR has also been used on fuel oil and natural gas-fired units. SNCR does not appear to be dependent directly on the type of burners (wall-fired, tangentially-fired, and cyclone-fired) employed in the boilers where it has been installed, with or without air-staged combustion with overfire air in full operation.

There are significant concerns associated with effective long-term SOFA operation for Milton R. Young Station Unit 2‘s boiler. The ability of basic combustion equipment and improvements to precisely measure the boiler’s heat input rate in real-time on an individual cyclone by cyclone basis with compensation for the short-term variability of the combustible content of the Center lignite to consistently maintain substoichiometric operation of every cyclone during air-staged combustion is unproven.

Several other techniques and technologies were considered technically feasible for NOx emissions control at MRY Station: Fuel Blending/Switching; Basic Combustion Control Improvements; and various forms of Fuel Reburn. Fuel switching/blending was not evaluated further because of expected unreasonably high capital and operating costs and no additional emission reduction compared to continued lignite firing.

Other NOx emissions control techniques and technologies for MRY Station evaluated and determined to be technically infeasible were: Fuel Cleaning; Low NOx Burners (LNB); Flue Gas Recirculation; Oxygen-enhanced Combustion (OEC); Water/steam injection (combustion tempering); and Electro-Catalytic Oxidation (ECO®).

Step 3 – Rank Remaining Control Technologies by Control Effectiveness

The third step in the “top-down” BACT evaluation ranked the remaining control technologies by effectiveness. The purpose of ranking the control technologies was to establish a hierarchy that places at the “top” the control technology that achieves the lowest emission level. The technologies in order of their effectiveness, from highest to lowest, are: SNCR with ASOFA; Gas Reburn with ASOFA; Lignite Reburn with ASOFA; Fuel Lean Gas Reburn with ASOFA; and Advanced Separated Overfire Air (ASOFA). None of these control options has been installed on a cyclone-fired boiler burning North Dakota lignite. As such, the expressed control percentages reflect the use of engineering judgment, based on the listed technique or technology application.

Step 4 – Evaluate Most Effective Controls and Document Results

Additional criteria besides technical feasibility were utilized for technology selection in this BACT analysis. These included estimates of control effectiveness (i.e. percent pollutant removed), capital plus operating and maintenance costs, annual emission reduction (tons per year), energy impacts, average and incremental cost effectiveness ($/ton), and environmental impacts (other media and emissions of toxic and hazardous air pollutants).

The economic analysis examined the capital cost of each feasible BACT alternative evaluated and any other powerplant upgrade costs necessary to implement the alternative. In addition, the economic analysis examined the operating and maintenance cost associated with the highest-performing forms of each feasible BACT alternative evaluated. These costs were then combined into a levelized total annual cost for a comparative assessment of the total implementation cost of each alternative. Finally, as part of the top-down analysis, a dominant controls cost curve was plotted and the unit control cost for each alternative was evaluated.

Two alternatives were on the dominant controls cost curve and thus were identified as the more cost effective alternatives. The two BACT NO_X control alternatives evaluated for incremental cost, energy, and environmental impacts applicable to Milton R. Young Station Unit 2were:

- Selective Non-Catalytic Reduction (SNCR) combined with a special form of separated overfire air (SOFA) specifically for lignite-fired cyclone boilers (referred to as Advanced SOFA or ASOFA); and
- ASOFA alone.

The two most cost-effective feasible control alternatives for reduction of NO_X emissions were reviewed to determine if the use of the technique or technology would result in any significant or unusual energy penalties or benefits. Potential increase in power plant energy consumption or net generation reductions, for ASOFA alone, or ASOFA with SNCR were relatively small.

The predicted environmental impacts from implementation of the two most cost-effective feasible NO_X emissions control alternatives from slightly higher unburned carbon in the emitted fly ash, carbon monoxide, and excess ammonia ("slip") emissions was expected to be small in comparison with the significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NO_X emission reduction.

Step 5 – Select BACT

Taking into account technical feasibility, energy, environmental, and economic impacts and other costs, the recommended Best Available Control Technologies and associated emission rates for nitrogen oxides emissions produced by Milton R. Young Station Unit 2 boiler are provided in the table below.

NO_X Emission Control Technology and Rate Recommended as BACT

Control Technology and Emission Rate Recommended as BACT			
Unit	**Pollutant**	**Control Method**	**12-Month Rolling Average NOx Emission Rate (lb/ million Btu)**
2	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.330

This recommended BACT 12-month NO_X emission rate is based upon a historic pre-control 12-month baseline average annual NO_X emission rate used in the control and cost-effectiveness analysis of 0.786 lb/mmBtu for Unit 2. The baseline emission was determined from the 12 consecutive month period with the highest historic summation of NO_X mass emissions (pounds) reported for actual operation between January 1,2001 and December 31, 2005.

To complete the BACT determination process, the Consent Decree (CD) requires that “specific control technologies to be installed and a specific Phase II 30-day Rolling Average NO_X Emission Rate limitation (lbs/MMBtu)” must be established for each subject emission Unit [CD Paragraph 66, pg 20]. Because there are expected to be minor short term variations in operating conditions where Minnkota has not, in fact, materially changed any of their normal daily operating practices, a margin between the 12-month average operating conditions and the 30-day permit limit is proposed. This recommended emission rate should be suitably higher such that operation consistent with the technological limitations, manufacturer’s specifications, and good engineering and maintenance practices to the extent practicable for the recommended NOx BACT alternative would not result in an exceedance (violation) of an enforceable emission permit limit.

The Consent Decree also requires that the North Dakota Department of Health's (NDDH) NO_X BACT Determination address specific emission limitations during Unit startups at Milton R. Young Station [CD Paragraph 66, pg 20]. The type and duration of firing during startups, and the limited ability of available and feasible technologies to control startup NO_X emissions, both significantly influence the 30-day rolling average BACT NO_X emission rate limit recommended for Milton R. Young Station boilers. A 24-hour rolling average NO_X emission rate limit applied to startup periods is also recommended for Milton R. Young Station boilers.

The SEGU startup operating period is usually not defined in emission permits. However, for the purpose of this NO_X BACT analysis, Unit startup was defined as the period from initial fuel combustion to the point in time when:

- the measured Heat Input to the boiler on a 6-hour rolling average basis is greater than or equal to 4800 million BTU/hr for Unit 2; or
- the amount of time reported for the longest individual Unit 2 startup period during actual operation between January 1, 2001 and December 31, 2005 elapses, whichever occurs first; or
- fuel firing is discontinued prior to satisfying either previous criteria.

For MRYS Unit 2, the recommended 30-day rolling average NO_X emission permit limit rate that includes the impact of startups is based upon recognized operational factors and equipment designs that influence whether the startup emissions result in higher 30-day emissions compared to normal continuous operation excluding such startup periods:

- The uncontrolled emission rate (i.e. without separated OFA or SNCR in operation) and its variability during operation from a cold startup up to and including maximum continuous rated output;
- The operating conditions that are required to exist for the selected NO_X BACT control techniques to be initiated and be effective; and
- The effectiveness of these two particular control techniques if invoked at less-than-MCR steady-state operating conditions.
- The number of startups and their range of typical durations per 30-day period time frame.

The Consent Decree and the EPA's NSR Manual do not describe the method for determining a 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT applied to Milton R. Young Station Unit 2. The approach taken in this analysis was to establish a historic pre-control 30-day baseline average NO_X emission rate (lb/mmBtu) from the 30-consecutive day period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation between January 1,2001 and December 31, 2005. This reflects unit NO_X emissions that were generated during periods of high unit operations, not affected by unit shutdowns, startups, or malfunctions. This was then compared to the 12-month historic pre-control baseline average NO_X emission rate (lb/mmBtu) from the 12-consecutive month period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation during the same 5-year look-back period. An estimate of NO_X emission reduction for the proposed BACT NO_X alternative operating at the historic pre-control 30-day baseline average NO_X emission rate (lb/mmBtu) was made. This rate considered recognized operational factors and equipment designs applied to “steady state” conditions with sustained output close to maximum continuous capacity ratings. The potential impact of startups, recognizing operational and technical limitations on NO_X emission control performance, was then applied to the steady-state rate, to establish a recommended 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT for Milton R. Young Station Unit 2. This is summarized below.

Recommended NO_X BACT Control Method and 30-Day Rolling Average NO_X Emission Rate Limit Without Startups

Unit	Pollutant	Control Method	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)
2	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.350

This recommended BACT 30-day NO_X emission rate limit is based upon a historic pre-control 30-day baseline average NO_X emission rate of 0.874 lb/mmBtu for Unit 2. The baseline emission was determined from the 30-consecutive day period with the highest historic unit NO_X emissions rate reported for actual operation between January 1,2001 and December 31, 2005.

An incremental adjustment to the proposed 30-day rolling average steady-state unit NO_X BACT emission rate without startups of 0.35 lb/mmBtu for Unit 2 is recommended for the 30-day rolling average NO_X emission permit limit periods as defined and applied to Milton R. Young Station. This is summarized in the table below.

Recommended BACT 30-Day Rolling Average NO_X Emission Rate Limit and Startup Impact

Unit	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)	Impact on 30-day Rolling Average NOx Emission Rate Limit Due to Startups (lb/million Btu)
2	0.35	+0.102 per startup

This recommended adjustment to the proposed 30-day rolling average steady-state NO_X BACT emission rate limit without startups is based upon average historic pre-control NO_X emission rates of 0.959 lb/mmBtu for Unit 2 reported for the longest individual Unit 2 startup period during actual operation between January 1, 2001 and December 31, 2005. These emissions occurred during the 115-hour October 25-30, 2001 startup for Unit 2.

A 24-hour rolling average BACT NO_X emission rate limit applied to startup periods is also recommended for each of the Milton R. Young Station boilers.

This is summarized in the table below.

Recommended 24-Hour Rolling Average NO_X Emission Rate Limit During Startups

Unit	24-hour Rolling Average NOx Emission Rate Limit During Startups (lb/million Btu)
2	1.064

These emissions occurred during the 115-hour October 25-30, 2001 startup for Unit 2.

Compliance with these emission rate would be measured at the stack of the Unit, verified with Continuous Emission Monitoring (CEM) systems in accordance with the reference methods specified in 40 C.F.R. Part 75, and would be determined on a 30 consecutive Operating Day and 24-consecutive hour rolling average basis, respectively.

A trial demonstration period of 18 months after the completion of Consent Decree Phase II NO_X emission reduction system installation commissioning at Milton R. Young Station is recommended. It is proposed to allow Minnkota (for Square Butte) to demonstrate the actual control system capabilities of the combined NO_X BACT emissions reduction system. Operating experience during the trial period will:

- confirm steady-state control performance of the combined NO_X BACT emissions reduction system;
- allow determination of the ability to further control Unit start-up emissions;
- allow the determination of the permitted 30-day rolling average NO_X emission limit including startups, shutdowns, and malfunctions; and
- address the specific emission limitations during Unit startups at Milton R. Young Station and their impact on the proposed 30-day rolling average emission rate limit (without startups).

Based upon the information obtained during the trial period, final emission limits can then be determined.

The means that will be employed to minimize emissions during startup will primarily be based on operating procedures, both before and after the level of upper furnace gas temperatures and/or heat input rate are considered sufficient to start the NO_X controls and operating conditions are conducive for effective emissions reduction. These could be similar to Minnkota's current MRYS practices, or could be different, depending upon the capabilities of the NO_X controls and their impacts on Unit operations.

1.0 INTRODUCTION

The Milton R. Young Station of Minnkota Power Cooperative, Inc. (Minnkota) and Square Butte Electric Cooperative (Square Butte) includes two cyclone-furnace, lignite-fired boilers producing steam for electric generation. Both units fire North Dakota lignite supplied from an adjacent mine, near Center, North Dakota.

A Notice of Violation (NOV) from the United States Environmental Protection Agency (US EPA or EPA) was issued to Minnkota on June 21, 2002. The NOV alleged that modifications have been made at the Milton R. Young Station that would require a construction permit under New Source Review (Code of Federal Regulations 40CFR52.21, and North Dakota Administrative Code NDAC 33-15). As a result of this allegation, a civil complaint was filed by the United States of America and the State of North Dakota against Minnkota Power Cooperative Inc. ("Minnkota") and Square Butte Electric Cooperative ("Square Butte") in the United States District Court for the District of North Dakota. A Consent Decree[1] has been entered that represents a final negotiated settlement of the United States and North Dakota's claims against Minnkota and Square Butte. The Consent Decree requires Minnkota and Square Butte to perform a NO_X "Top-Down" Best Available Control Technology (BACT) Analysis to describe the emission limits for NO_X that will be required at Units 1 and 2, expressed as a 30-Day Rolling Average Emission Rate (lbs/million Btu)[2].

Burns & McDonnell was retained by Minnkota to conduct a "Top-Down" Best Available Control Technology (BACT) Analysis for nitrogen oxides (NO_X) at the Milton R. Young Station. Burns & McDonnell is a full service engineering, architectural, construction and environmental firm. The company plans, designs and constructs electric generating facilities and has been providing environmental services since the 1970s. As part of those services, Burns & McDonnell has extensive experience in permitting, Best Available Control Technology (BACT) studies and control technology analysis. The results of the BACT analysis are presented in this report.

[2] Ibid – footnote number 1, CD paragraph 65, page 19.

The primary guidance utilized in preparation of this BACT analysis is the U.S. EPA's New Source Review Workshop Manual: Prevention of Significant Deterioration and Nonattainment Area Permitting, Draft, October 1990[3] ("NSR Manual").

In the next section of the report, the approach to the BACT Analysis is described. Following that, a quick summary of the plant conditions and report basis is given and then the BACT Analysis begins. The impact portion of the report is broken down into separate subsections. Within the last section, the results of all of the BACT Analysis steps are summarized for NO_X control options for Unit 2's boiler at the Milton R. Young Station.

---

[3] Chapter B of the U.S. EPA's New Source Review Workshop Manual: Prevention of Significant Deterioration and Nonattainment Area Permitting, Draft, October 1990.

2.0 "TOP-DOWN" NO_X BACT ANALYSIS APPROACH

Best Available Control Technology (BACT) is an emissions limitation for each pollutant from a source determined to be achievable using control technologies(s) that provide the "maximum degree of emission reduction…taking into account energy, environmental, and economic impacts"[4]. A BACT review does not result in an emissions removal efficiency requirement. The generally accepted procedures for performing a BACT analysis are outlined in the EPA's draft NSR Manual. The BACT analysis for Milton R. Young Station Unit 2's boiler NO_X emissions was performed in accordance with this procedure. The EPA's draft NSR Manual outlines five basic steps that are to be followed in the "top-down" BACT evaluation. These steps are as follows:

Step 1 – Identify All Control Technologies
Step 2 – Eliminate Technically Infeasible Options
Step 3 – Rank Remaining Control Technologies by Control Effectiveness
Step 4 – Evaluate Most Effective Controls and Document Results
Step 5 – Select BACT

The predefined steps of a BACT analysis are described in this section, and results presented. Available NO_X control techniques and technologies are defined, identified, and a technical description of the emission reduction process and capabilities are reviewed in the following section. Subsequently, those techniques and technologies deemed feasible for retrofit application are ranked according to nominal NO_X control capability. An engineering analysis reviews the estimated capital and operations and maintenance (O&M) costs for each feasible alternative, including taking a look at Balance of Plant (BOP) requirements. Following the cost impact determination, the energy and environmental impacts are reviewed for each feasible technology. Finally, the results of the engineering analyses are tabulated and a NO_X BACT selection is recommended for each unit.

2.1 STEP 1 – IDENTIFY ALL CONTROL TECHNOLOGIES

The first step in a "top-down" NO_X BACT analysis is to identify, for the emissions unit in question, a comprehensive list of all "available" control options. In the EPA's draft NSR Manual,

> "available control options are those air pollution control technologies or techniques with a practical potential for application to the emissions unit and the regulated pollutant under evaluation. Air pollution control technologies and techniques include the application of

---

[4] Ibid footnote number 2, NSR Manual B.1

> production process or available methods, systems, and techniques, including fuel cleaning or treatment or innovative fuel combustion techniques for control of the affected pollutant"[5].

According to the EPA's draft NSR Manual, "a technology is considered "available" if it can be obtained by the applicant through commercial channels or is otherwise available within the common sense meaning of the term"[6]. Also, "a control technique is considered available, within the context presented above, if it has reached the licensing and commercial sales stage of development"[7].

In order to identify available NO_X emission control technologies and techniques appropriate for potential application to MRY Station units, the following information sources were reviewed for coal-fired electric generating unit powerplants:

- EPA's RACT/BACT/LAER Clearinghouse (RBLC) database and Control Technology Center (website).
- Federal (EPA) and State, including North Dakota Department of Health internet websites for air emission permits and recently-submitted applications, including BACT Evaluations following New Source Review procedures.
- Federal (EPA and Department of Justice) and State, including North Dakota Department of Health internet websites for Consent Decrees issued as a result of legal actions taken by the United States government for alleged violations of the Prevention of Significant Deterioration (PSD) provisions and New Source Review provisions of the Clean Air Act, and/or federally-approved and enforceable State Implementation Plans.
- Control technology vendor information.
- Published and available information from technical, engineering, and environmental consultants.
- Technical literature found in journals, reports, internet websites, newsletters, proceedings of technical seminars and conferences pertaining to studies, engineering, designs, and testing of air pollution controls.

---

[6] Ibid, NSR Manual B.17
[7] Ibid, NSR Manual B.18

2.2 STEP 2 – ELIMINATE TECHNICALLY INFEASIBLE OPTIONS

The second step of the "top-down" BACT process is to evaluate the available NO_X control technologies and techniques identified in Step 1 in terms of the specific factors that apply to the emissions unit in question. In accordance with EPA's draft NSR Manual, "an available technology is "applicable" if it can be reasonably installed and operated on the source type under consideration. A technology that is available and applicable is technically feasible[8]".

The EPA's NSR Manual states a technology may be determined to be not applicable if "a technical assessment considering physical, chemical and engineering principles and/or empirical data showing the technology would not work on the emissions unit under review or that unsolvable technical difficulties would preclude the successful deployment of the technique"[9]. Also, a "showing of unresolvable technical difficulty with applying the control would constitute a showing of technical infeasibility (e.g., size of the unit, location of the proposed site, and operating problems related to specific circumstances of the source)"[10]. After a determination is made that any of the processes are technically infeasible, options are eliminated if technical challenges would preclude or prevent the successful long-term use of the control option or technique on the emission unit under consideration. This is performed prior to any economic analysis.

However, the EPA's NSR Manual also states "…control options incapable of meeting an applicable New Source Performance Standard (NSPS) or State Implementation Plan (SIP) limit would not meet the definition of BACT under any circumstances. The applicant does not need to consider them in the BACT analysis"[11]. Also, it states "An NSPS simply defines the minimum level of control to be considered in the BACT analysis"[12]. The NSR Manual further states "When developing a list of possible BACT alternatives, the only reason for comparing control options to an NSPS is to determine whether the control option would result in an emission level less stringent than the NSPS. If so, the option is unacceptable"[13]. New Source Performance Standards (NSPS) for NO_X emissions from EGUs firing North Dakota lignite are 0.8 lb/mmBtu. The EPA Acid Rain Program's Title IV NO_X emission limit for Group 2, cyclone-fired coal boilers with outputs greater than 155 MWe is 0.86 lb/mmBtu.

---

[8] Ibid, NSR Manual B.17
[9] Ibid, NSR Manual B.20
[10] Ibid, NSR Manual B.19
[11] Ibid, NSR Manual B.12
[12] Ibid, NSR Manual B.12
[13] Ibid, NSR Manual B.12

EPA's draft NSR Manual also states "A source would not be required to experience extended time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required to experience extended trials to learn how to apply a technology on a totally new and dissimilar source type. Consequently, technologies in the pilot scale testing stages of development would not be considered available for BACT review"[14].

Also in the EPA's draft NSR Manual is a qualification for technical feasibility, as described by the statement "Commercial availability by itself, however, is not necessarily a sufficient basis for concluding a technology to be applicable and therefore technically feasible. Technical feasibility, as determined in Step 2, also means a control option may reasonably be deployed on or "applicable" to the source type under consideration"[15].

2.3 STEP 3 – RANK REMAINING CONTROL TECHNOLOGIES BY CONTROL EFFECTIVENESS

The third step in the "top-down" BACT evaluation is to rank the control technologies remaining after the feasibility analysis by control effectiveness. The purpose of ranking the control technologies is to establish a hierarchy that "places at the "top", the control technology that achieves the lowest emission level"[16].

Selecting common units in order to compare emissions performance levels amongst options is one of the two key issues that must be addressed in a BACT analysis. EPA's draft NSR Manual states "it is generally most effective to express emissions performance as an average steady state emissions level per unit of product produced or processed"[17]. For fossil fuel-fired boilers, pounds of nitrogen oxides per unit of fuel heat input (i.e. lb/mmBtu), is a common means of comparing and calculating NO_X emissions.

Many control techniques, including both add-on controls and inherently lower polluting processes can perform at a wide range of levels. The EPA's draft NSR Manual states "It is not the EPA's intention to require analysis of each possible level of efficiency for a control technique, as such an analysis would

---

[14] Ibid, NSR Manual B.18
[15] Ibid, NSR Manual B.18
[16] Ibid, NSR Manual B.25
[17] Ibid, NSR Manual B.22

result in a large number of options"[18]. Also, "manufacturer's data, engineering estimates, and the experience of other sources provide the basis for determining achievable limits"[19].

2.4 STEP 4 – EVALUATE THE MOST EFFECTIVE CONTROLS AND DOCUMENT RESULTS

The fourth step of a "top-down" BACT review is to evaluate the technically-feasible emission controls, beginning with the most effective. Economic, energy, and environmental impacts are to be assessed and quantified, where possible, in the control technology analysis. The purpose of the evaluation is to determine if there are any identified impacts that would eliminate the top control technology from consideration. In the case where the most effective control alternative is determined to incur or produce adverse energy, economic or environmental impacts, the basis of the determination is documented, and the next most stringent control alternative is evaluated. This analysis process continues until the control technology under consideration cannot be eliminated by identification of any source-specific adverse energy, economic or environmental impacts.

The economic impacts are based on estimates of capital equipment pricing, procurement, installation and estimated operating and maintenance costs. The total installed capital costs along with the operating costs for each control technology are summarized in the economics of each respective section. The Levelized Total Annual Cost (LTAC) represents the levelized cost of procurement, construction, operation and maintenance over an assumed service life. Cost effectiveness ($/ton) of a control technique or technology is calculated by dividing the LTAC ($/yr) by the annual amount of NO_X removed (tons/yr). Baseline pre-control emissions are calculated using realistic upper boundary operating assumptions, considering inherent physical or operational constraints on the source. Plotting of the annual amount of NO_X removed (tons/yr) versus the levelized total annual control cost ($/yr) for the various control options on an x-y graph allows visualization of the cost-effectiveness. A "least-cost envelope" can be readily identified to indicate the inferior control options which should not be considered in the subsequent analyses. The incremental cost-effectiveness (difference in $/ton) between control techniques or technologies can also be calculated and compared. This allows evaluation of the dominant controls included on the least-cost envelope (curve).

---

[18] Ibid, NSR Manual B.23
[19] Ibid, NSR Manual B.24

2.5 STEP 5 – SELECT BACT

The final step in the “top-down” evaluation process is to select BACT for the applicable pollutant and emission unit. Per the EPA guidance document, BACT is “the most effective control technology not eliminated in Step 4”[20]. The methodology described above was applied to the Milton R. Young Station Unit 2‘s boiler for emissions of nitrogen oxides.

3.0 BACT ANALYSIS for MRY STATION UNIT 2 NO_X EMISSIONS

The approach taken in this BACT analysis for Milton R. Young Station included a technical analysis of demonstrated control alternatives for NO_X emissions. This approach followed the predefined steps of a BACT analysis process as generally described in Section 2. Potential NO_X control techniques and technologies were identified, and a technical description of the emission reduction process and capabilities were provided. Subsequently, those techniques and technologies deemed available and feasible for retrofit application were ranked according to nominal NO_X control capability. The engineering analysis then developed the estimated capital and O&M costs for each alternative, including taking a look at Balance of Plant (BOP) requirements. Finally, the cost effectiveness points for each feasible technology were plotted, and those that comprise the dominant controls curve were identified.

For the feasible techniques and technologies considered for determining NO_X control cost-effectiveness for the two steam electric generating units at the MRY Station, estimates were produced for predicted NOx reductions that represent achievable long-term expectations of the alternative reduction techniques and technologies being presented in the technical analysis. Each were tabulated and graphed.

3.0.1 EMISSION UNIT DESCRIPTION

Milton R. Young Unit 2 is a Babcock and Wilcox steam generator installed in 1977. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation assisted with circulation pumps. Original unit design steam generating capacity is 3.20 million lbs/hr at 2,620 psi with a fuel heat input of 4,696 mmBtu/hr. The boiler is fired by twelve ten-foot diameter cyclone burners, arranged “three over three” across the front and rear walls of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Exhaust gases leave the air heater and pass through an ESP for particulate collection and removal followed by the two induced draft fans (installed in parallel) prior to a wet flue gas desulfurization (FGD) system which discharges to the stack. The current air pollution control system’s configuration allows a portion of the low dust flue gas to reheat the stack gas, thus bypassing the FGD system. Unit 2 has a nominal 439 MW net design output capacity rating, is capable of sustained output of approximately 462 MW gross, and has an ultimate short-term maximum gross output (URGE) of 512 MW.

The EPA's Technical Support Document[22] lists nameplate steam turbine-generator capacity of MRY Station Unit 2 as 477 MW (gross), which was assumed for calculating capital cost estimates for control alternatives.

The Unit 2 boiler at M.R. Young Station includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boilers.

Milton R. Young Station Unit 2's boiler design, combustion performance, and NO_X emissions are dominated by the composition and combustion characteristics of the North Dakota lignite supplied solely from a surface mine adjacent to the plant. This mine is the only supplier of solid fuel for this station, as there are no railroad facilities provided to service the Milton R. Young plant. North Dakota lignite has high moisture and high sodium content, moderate higher heating values, and can have a widely variable and high ash content compared to other coals. These characteristics create difficulties in promoting consistent, steady combustion and slag formation in the cyclone burners. It also results in producing a flyash that has severe deposition characteristics.

The design unit operating conditions for this study are presented in Table 3-1. The historical average lignite coal analysis is shown in Table 3-2.

Table 3-1 – Unit Design Parameters

Design Unit Operating Characteristics	**Unit 2 Design**
Boiler Type	Subcritical(1)
Combustion System	Cyclone

Higher Heating Value, Btu/lb	6,662

3.0.2 NITROGEN OXIDES EMISSION FORMATION

Nitrogen oxides (NO_X) are produced when nitrogen in the fuel and combustion air are exposed to high temperatures. There are two primary sources of NO_X emissions, referred to as "thermal" NO_X and "fuel" NO_X. Thermal NO_X emissions are produced when elemental nitrogen in the combustion air is admitted to a high temperature zone and oxidized. Fuel NO_X emissions are created during the rapid oxidation of the fuel containing nitrogen compounds. For most coal-fired units, thermal NO_X emission typically represents approximately 20% and fuel NO_X about 80% of the total NO_X formed. Nitrogen oxide (NO) is typically the most predominant form of NO_X emissions from fossil fuel combustion, along with nitrogen dioxide (NO_2). The formation of these compounds in utility powerplant boilers is sensitive to the method of firing and combustion controls utilized. The techniques employed for mixing the combustion air and fuel, which creates flames and high temperature combustion products, results from the rapid oxidization of carbon, hydrogen, and other exothermic reactions. Cyclone-fired boilers, by design, create intense heat release rates to melt and fluidize the coal ash introduced into the barrel-shaped furnaces. This produces high temperature flue gases and results in very high uncontrolled NO_X emissions. The amount of thermal NO_X emissions produced by cyclone boilers can be considerably higher than fuel NO_X emissions.

3.1 IDENTIFICATION OF NO_X CONTROL OPTIONS FOR MILTON R. YOUNG STATION

The first step in the BACT evaluation is to identify all "demonstrated and potentially applicable control technology alternatives"[23] according to the EPA's draft NSR Manual. In identifying control technologies, "the applicant needs to survey the range of potentially available control options"[24].

---

[23] Ibid, footnote number 2, NSR Manual page B.11

3.1.1 REVIEW OF RETROFIT INSTALLATIONS

The BACT determinations listed in the EPA's RACT/BACT/LAER Clearinghouse (RBLC) database are for new facilities. The Milton R. Young Station is an existing powerplant facility with two coal-fired EGUs. A BACT evaluation for retrofitting control equipment to coal-fired EGUs in an existing facility will be substantially different than an analysis for installing control equipment on coal-fired EGUs in a new facility. Consequently, in performing the BACT analysis for existing boilers at Milton R. Young Station, it is important to review powerplant facilities, especially cyclone-fired coal boilers, which have retrofitted NO_X control equipment in recent years.

In 1998, EPA issued a NO_X SIP (State Implementation Plan) call. Under the SIP call, utility boilers in the eastern United States were required to substantially reduce NO_X emissions during the "ozone season". The compliance date for the NO_X SIP call is May 31, 2004. A high percentage of the fired electric generation facilities in the eastern United States have or are in the process of retrofitting NO_X controls to comply with the NO_X SIP call. The EPA's NO_X SIP call was not applicable to North Dakota utility boilers.

There are a number of fossil fuel-fired EGU powerplants around the United States that have implemented or are planning to implement modifications to reduce NO_X emissions. The NO_X emission control system installations are in response to Acid Rain requirements, EPA's NO_X SIP call, the Clean Air Interstate Rule (CAIR), the Regional Haze Rule (RHR), and local regulations.

In addition to the facilities that have had to retrofit emissions controls as a result of the Title IV Part 76 Acid Rain requirements and/or EPA's NO_X SIP call, a few installations have had to retrofit controls in recent years as the result of court decisions resulting from litigation and regulatory action. None of the boilers associated with identified consent decrees are cyclone-fired. They are also located in a region requiring compliance with an EPA-approved State Implementation Plan for nitrogen oxides emissions controls (i.e. NO_X SIP call). As mentioned above, North Dakota utility boilers were not subject to the EPA's NO_X SIP call.

---

[24] Ibid, NSR Manual page B.11

3.1.2 POTENTIALLY FEASIBLE NOx CONTROL OPTIONS FOR MILTON R. YOUNG STATION

A review of available information on retrofit installations performed at utility and industrial coal-fired powerplants during the past fifteen years was undertaken. NO_X emission control technologies and techniques with potential application to Milton R. Young Station boilers were identified, and are listed in Table 3-3.

TABLE 3-3 – Potentially Available NO_X Control Technologies Identified for BACT Analysis

NOx Control Technology
Pre-Combustion Controls
Fuel Cleaning/Blending/Switching
Combustion Controls
Basic Combustion Control Improvements
Low NOx Burners (LNB)
Separated Overfire Air (SOFA)(1)
Flue Gas Recirculation
Fuel Reburn
Oxygen-enhanced combustion (OEC)
Water/steam injection (combustion tempering)
Post-Combustion Controls
Selective Non-Catalytic Reduction (SNCR)(2)
Selective Catalytic Reduction (SCR)
Electro-Catalytic Oxidation (ECO®)(3)

Notes: these are basic forms of the identified techniques.
Not all variations or combinations are included.
(1) – SOFA technologies include Boosted SOFA and Rotating Opposed Fired Air (ROFA)
(2) – SNCR technologies include Rich Reagent Injection, and Hydrocarbon-enhanced SNCR, commercially available as “NOxStar™”.
(3) – Multi-pollutant control technology currently under commercial development by Powerspan Corp.

A comprehensive literature search, with sources including technical papers and presentations made at conferences by nationally-recognized technical organizations, utilities and other parties involved with design, construction, and testing of NO_X control techniques, plus hardware supplier experience lists, was performed. The results of this search are presented in Appendix A2, which includes a summary of various selected U.S. NO_X emission reduction retrofit projects.

3.2 FEASIBILITY ANALYSIS

The second step of the "top-down" BACT process is to evaluate the control processes that have been identified and determine if any of the processes are technically infeasible.

An available technology is "applicable" if it can be reasonably be installed and operated on the source type under consideration. Also, a control technique is considered available if it has reached the stage of licensing and commercial availability. For the purposes of this analysis, the term "commercial" is further defined to mean "capable of establishing a full contractual agreement with commercial and performance guarantees supported by appropriate financial backing" for the implementation of full-scale, full-time systems of the technique or technology application. A technology that is available and applicable is technically feasible.

There are three basic categories of NO_X emission control techniques and technologies:

- Pre-combustion controls;
- Combustion controls; and
- Post-combustion controls

Uncontrolled NO_X emissions from a coal-fired electric generating unit are highly dependent on type of firing method, amount of solid fuel fired per unit time and furnace volume, and the fuel's basic combustion properties and elemental composition. The basic methods for reduction of such emissions:

- either prevent pollution, i.e. use inherently lower-emitting processes/practices which produce fewer NO_X emissions during the power generation process; or
- involve improvements to, or provide new add-on controls that, reduce emissions after they are produced before they are emitted from the facility; or
- are combinations of inherently lower-emitting processes and add-on controls.

Most of the identified control options have been commercially-available, installed, and operating in many full-scale, permanent coal-fired utility boiler installations in the United States for five years or more.

Pre-combustion controls, such as fuel switching, fuel blending, and fuel cleaning have been practiced and performed at numerous utility power plants, typically for operational and sulfur emissions control reasons.

Combustion controls, such as low-NO_X burners (LNBs) and overfire air systems, are very commonly applied to reduce NO_X emissions from fossil fuel-fired powerplants. Low-NO_X Burners are typically applied to pulverized coal, gaseous and liquid fuel-fired boilers. They are not applicable to cyclone-fired boilers. Flue gas recirculation (FGR) has been practiced and performed at numerous natural gas and fuel oil-fired utility and industrial powerplants for NO_X emissions control reasons. On large coal-fired utility boilers, FGR has primarily been applied for steam temperature control purposes, not for emissions control. Conventional Gas Reburn (CGR) with overfire air has been installed and placed in commercial operation on several cyclone-fired boilers, primarily in the eastern region of the United States. Coal Reburn (CR) with overfire air has been successfully demonstrated on two cyclone-fired boilers and commercially installed on three pulverized coal-fired boilers in the United States. Combustion tempering (water/steam injection) has been tested but has not been continuously practiced on cyclone-fired coal boilers. Oxygen-enhanced combustion has only been demonstrated and/or installed on a limited number of pulverized coal-fired powerplants, not on any coal-fired cyclone boilers.

Selective Catalytic Reduction (SCR) and Selective Non-Catalytic Reduction (SNCR) are post-combustion technologies that have been applied predominantly on eastern or midwestern bituminous coal-fired boilers. Others, mostly comprised of a combination of available emission reduction technologies, are often referred to as “hybrid” or “layered” controls. Variations of SNCR, such as Rich Reagent Injection (RRI) with and without SNCR, have only been installed or demonstrated on a limited number of cyclone-fired boilers. Other technologies, such as Fuel Lean Gas Reburn™ with SNCR, hydrocarbon-enhanced SNCR (commercially available as NO_XStar^{TM}), and Conventional Gas Reburn with SNCR have only been demonstrated and/or installed on a limited number of pulverized coal-fired power plants.

Emerging post-combustion multi-pollutant control technologies, such as Powerspan’s Electro-Catalytic Oxidation (ECO®), which include NO_X control, were also identified. These are typically in the large pilot-scale commercial development phase, and have not been successfully demonstrated on a full scale basis on any pulverized coal, cyclone, or circulating fluid bed boilers.

In most of the combination or “layered” and emerging control cases, the NO_X control technology has been demonstrated to be capable of controlling the targeted pollutant(s) on either:

- a full-scale basis, but only with temporary equipment; or
- a full-scale basis, with permanent equipment but in a limited number of installations; or

- with less than full-scale and full-time application.

3.2.1 SUMMARY OF RETROFIT INSTALLATIONS OF NO_X CONTROL TECHNOLOGIES

There are a number of facilities around the country that have implemented or are planning to implement modifications to reduce NO_X emissions. Table 3-4 summarizes the various NO_X emission control system installations currently installed, or that have been demonstrated on a full-scale, short-term basis, in response to Acid Rain requirements, EPA's NO_X SIP call and local regulations, or a utility investigating the technology.

TABLE 3-4 – Identified NO_X Control System Retrofits on Cyclone Coal-fired Boilers

No. of Units(1)	Cyclone NO_X Control Technology Description
1	Fuel Switching/Blending
39(2)	Separated Overfire Air (SOFA)
2	Selective Non-Catalytic Reduction, with or without SOFA
2(3)	Rich Reagent Injection, with SOFA
7(4)	Conventional fuel reburn (pulverized or micronized coal, gas), w/ SOFA
1(5)	Fuel lean gas reburn, with or without SOFA
22(6)	High-dust or low-dust SCR, with or without other technologies
1(6)	Tail-gas SCR, with or without other technologies

(1) – This list of known NOx control retrofit installations is primarily focused on units in the United States. There may be other installations that are similar but were not identified.
(2) – Installed for NOx control (without fuel reburn). A list of known cyclone boiler SOFA installations is included in Appendix A2.
(3) – RRI has only been demonstrated with temporary equipment for testing. See technical literature references in Appendix A1 and A2 for details.
(4) – Several conventional coal and gas reburn retrofits have discontinued reburn demonstration or routine operation. See Technical Literature Reference list and Appendix A3 for further details.
(5) – Only one example of fuel lean gas reburn retrofit (without OFA) on a cyclone-fired boiler has been demonstrated. This system was installed for short-term reburn testing and has been removed.
(6) – High-dust SCR technology has been retrofitted on sixteen U.S. cyclone-fired boilers, all believed to have SOFA. Low-dust SCRs in U.S. have only been installed only on pulverized coal-fired boilers, none on cyclones. One tail-gas SCR installation on a coal-fired cyclone boiler found in Germany; none in the U.S. See technical literature references in Appendix A1 and A2 for details.

A more detailed description of the various control technology retrofits and their claimed effectiveness is included in the technical descriptions and reference literature in the technical feasibility assessment of

Appendix A1, and Appendix A2, which includes a summary of various selected U.S. NO_X emission reduction retrofit projects.

3.2.2 SUMMARY OF FEASIBLE NO_X CONTROL TECHNOLOGIES FOR MRY STATION

One example of fuel switching applied to a cyclone-fired boiler was identified. Ottertail's Big Stone Unit 1 was originally designed to burn North Dakota lignite and was switched to western subbituminous (PRB) coal for reasons unrelated to NO_X emissions reduction. Big Stone Unit 1 and M.R. Young Station Unit 2 have similar boiler designs. Thus, conversion of Milton R. Young Station Unit 2's boiler to fire PRB coal or a lignite/PRB blend is technically possible. There are no railroad facilities provided to service the Milton R. Young plant. Additional operational and capital costs to bring in large quantities of PRB coal will be significant. Based on a comparison of available emission data between Ottertail's Big Stone Unit 1 and M.R. Station Young Unit 2, there is no expected reduction in baseline (i.e. uncontrolled) NO_X emissions from switching to PRB from lignite at Milton R. Young Station. Although fuel switching at Milton R. Young Station is technically feasible, this alternative will not be economically competitive with other NO_X control technologies that offer better results for a much lower combination of capital and operational costs. For these reasons, it has not been considered further as an effective NO_X emissions control option for MRY Station Unit 2 boiler.

Separated Overfire Air (SOFA) is the most commonly-applied, combustion-related NO_X emission reduction technology that has been proven effective on cyclone-fired boilers. A version of separated overfire air specifically designed for increased NO_X emission reduction performance for lignite-fired cyclone boilers, referred to as "Advanced SOFA" in this analysis, can be installed on both units at M.R. Young Station. The potential operational limitations mentioned in the detailed feasibility discussions included in Appendix A1 for deeply air-staged cyclones associated with separated overfire air are expected to limit the control effectiveness of this technique, alone and in combination with other feasible NO_X control options.

Selective Non-Catalytic Reduction (SNCR) technology is a form of post-combustion NO_X emission control that has been successfully applied on numerous utility boilers burning eastern bituminous coal, midwestern bituminous coal, and, to a lesser extent, western subbituminous coal to reduce NO_X emissions. SNCR has also been used on fuel oil and natural gas-fired units. SNCR does not appear to be dependent directly on the type of burners (wall-fired, tangentially-fired, and cyclone-fired) employed in the boilers where it has been installed, with or without air-staged combustion with overfire air in full operation. This control technology adds urea (or ammonia) reagent to the hot furnace gases in the upper furnace to chemically reduce nitrogen oxides. SNCR was considered technically feasible for application on both units at M.R. Young Station. SNCR can be operated with and without SOFA. Variations of SNCR technologies such as Hydrocarbon-enhanced SNCR (HE-SNCR) and “Rotamix” have been installed on pulverized coal-fired boilers but are not proven on cyclone boilers. This is described in detail in Appendix A1.

Rich Reagent Injection (RRI) is a form of SNCR under development specifically intended for NOx emissions control on cyclone boilers. As of October 2006, RRI has been demonstrated but has not been commercially installed and placed in continuous operation on a cyclone-fired boiler, especially one burning coal with high fouling and slag temperature sensitivities associated with lignite supplied from the Center mine. RRI adds aqueous urea reagent to the hot furnace gases near the cyclones, which must be devoid of free oxygen in order to avoid oxidation of the urea which will increase NOx emissions. RRI is considered technically infeasible for application on the cyclone boilers at the Milton R. Young Station at the present time. This is described in detail in Appendix A1.

Various forms of fuel reburn with and without overfire air are types of combustion-related technologies that have been demonstrated and commercially installed on pulverized coal, fuel oil-fired, and cyclone utility and industrial boilers. Natural gas-consuming variations such as Conventional Gas Reburn (CGR) and Fuel-Lean Gas Reburn (FLGR™) have been applied to cyclone boilers burning bituminous and subbituminous coals. High capital costs expected for installing a natural gas pipeline and high operating costs from consumption of large volumes of such fuel make these alternatives economically unfavorable for both units at M.R. Young Station. Pulverized or micronized coal reburn, in combination with SOFA, are technically feasible but will require extensive capital, operating and maintenance costs for fuel grinding equipment and facilities when installed and operated for both units at M.R. Young Station. This is described in detail in Appendix A1.

Fuel cleaning is a technique normally applied to reduce the sulfur or ash content of a fossil fuel prior to combustion. No examples of fuel cleaning of North Dakota lignite or western subbituminous coal strictly for NO_X emissions reduction were found in available technical literature. This technique is considered infeasible for NO_X emissions control of M.R. Young Station boilers at the present time.

High-dust, low-dust, and tail-gas variations of selective catalytic reduction (SCR) technology have been applied on pulverized coal and cyclone boilers as a post-combustion type of NO_X emission control throughout the world and in the United States, except on units firing North Dakota lignite. The severity of catalyst blinding and pluggage from particulate matter and flue gases emitted from cyclone-fired boilers burning North Dakota lignite precludes the technical feasibility for successful application of such SCR technology on the EGUs at the Milton R. Young Station. This is described in detail in Appendix A1 with supporting documentation in Appendix B.

The results of Step 2 of the NO_X BACT Analysis for determining the technical feasibility of potential control technologies, including various "layered" combinations, are listed in Tables 3-5 and 3-6.

TABLE 3-5 – Technically-Feasible Potential NO_X Control Technologies for M.R. Young Station Unit 2 Cyclone Boiler

Control Technology(1)	**In Permanent, Full-Scale Service on Existing Coal-Fired Cyclone Utility Boilers?**	**Technically Feasible on M.R. Young Station Unit 2 boiler?**
Selective Non-Catalytic Reduction (SNCR)	Yes(2)	Yes
Conventional Gas Reburn	Yes(3)	Yes(3); Requires SOFA or ASOFA
Coal Reburn	Yes(4)	Yes(4); Requires SOFA or ASOFA
Fuel Lean Gas Reburn	No(5)	Yes(5) (w/ or w/out SOFA or ASOFA)
Advanced SOFA	No(6)	Yes(6). Includes relocated lignite drying vent ports
Separated OFA (basic SOFA)	Yes(6)	Yes(6)
Combustion Improvements	Yes	Yes(7); typically included with separated OFA
Flue Gas Recirculation	Not for NOx control	Yes(8) (not expected to reduce NOx further)
Fuel Switching / Blending	Yes	Yes(9) (not expected to reduce NOx further)

See technical feasibility details and literature References in Appendix A for details.

(1) – All potential combinations of technologies not listed. See discussion of "layered" technologies.

(2) – Assumes use of urea for reagent. Limited number of active installations on cyclone-fired boilers burning western subbituminous (i.e. Powder River Basin or PRB) coal.

(3) – Limited number of active conventional gas reburn (CGR) installations on cyclone-fired boilers burning PRB coal.

(4) – Limited number of demonstrations or active installations of pulverized or micronized coal reburn on cyclone-fired boilers. One demonstration of pulverized coal reburning with PRB coal has been performed on a cyclone-fired boiler, no longer active. Only one active permanent coal reburn installation on cyclone-fired boiler burning eastern bituminous coal, none burning PRB coal or lignite.

(5) – Only one short-term test demonstration of FLGR™ on a cyclone-fired boiler burning coal with separated overfire air.

(6) – No cyclone boilers firing North Dakota lignite have installed basic or advanced SOFA. See Appendix A.

(7) – Considered part of SOFA installation for coal boilers without combustion controls for NOx reduction.

(8) – No examples of using recirculated flue gas on coal-fired boilers for NOx emissions control were found in available technical literature. Zero additional NO_X reduction potential expected from this technique alone for MRY Station Unit 2. Potential NO_X reduction improvement on MRY Unit 2 considered part of "advanced" SOFA.

(9) – Zero additional NO_X reduction potential expected from this technique (switching from lignite to lignite/PRB blends or 100% PRB) alone for MRY Station Unit 2.

TABLE 3-6 – Technically Infeasible Potential NO_X Control Technologies for M.R. Young Station Unit 2 Cyclone Boiler

Control Technology[(1)]	**In Permanent, Full-Scale Service on Existing Coal-Fired Cyclone Utility Boilers?**	**Technically Feasible on M.R. Young Station Unit 2 boiler?**
Selective Catalytic Reduction (SCR): conventional (high dust); Low-dust; Tail-gas	Yes(2) / No / Yes(3)	No(4) - Unresolvable fouling and catalyst deactivation problems expected. See discussion of SCR feasibility for ND lignite.
Electro-Catalytic Oxidation (ECO®)	No	No, has not been demonstrated full-scale nor reached commercial availability
HE-SNCR (using ammonia)	No(5)	No(5). Has not been demonstrated on cyclone.
Rotamix (ROFA + SNCR)	No(6)	No(6). Has not been demonstrated on cyclone.
Rich Reagent Injection (RRI) with ASOFA	No(7)	No(7). Requires oxygen-free furnace environment, varying air/fuel would increase NOx emissions.
RRI + SNCR with ASOFA	No(7)	No(7). See footnote and feasibility discussion.
Advanced Conventional Gas Reburn (ACGR) + SNCR	No(8)	No. Has not been demonstrated on cyclone.
Coal Reburn + SNCR	No(8)	No. Has not been demonstrated on cyclone.
Fuel Lean Gas Reburn + SNCR	No(8)	No. Has not been demonstrated on cyclone.
Rotating Opposed-Fired Air	No(6)	No. Has not been demonstrated on cyclone.
Oxygen Enhanced Combustion	No(9)	No. Has not been demonstrated on cyclone.
Water Injection	No(10)	No(10)
Fuel Cleaning	Not for NOx control	No(11) (not expected to reduce NOx further)

See technical feasibility details and literature References in Appendix A for details.

(1) – All potential combinations of technologies not listed. See discussion of "layered" technologies.

(2) – Limited number of active installations on cyclone-fired boilers burning western subbituminous coal.

(3) – No identified installations on coal-fired boilers in the United States. One tail-end SCR on cyclone boiler in Germany.

(4) – See discussion of SCR feasibility for ND lignite in Appendix A1 and Appendix B.

(5) – Hydrocarbon-enhanced SNCR has not been demonstrated on a cyclone-fired boiler, nor any boiler firing western subbituminous coal or lignite.

(6) – Rotating Opposed-Fired Air with or without SNCR has not been demonstrated on a cyclone-fired boiler. No apparent significant advantages over SOFA on cyclone-fired boilers.

(7) – Rich Reagent Injection has been successfully demonstrated for brief periods with SOFA with and without SNCR at two cyclone powerplants. There are no permanent RRI installations completed and operational as of May 2006. Difficulties in maintaining an oxygen-free furnace environment in MRY Station boilers where the urea reagent would be injected due to cyclone air/fuel imbalances during air-starved combustion would increase NOx emissions.

(8) – No known demonstrations or permanent installations of Advanced conventional gas reburn (CGR) or FLGR™ or pulverized/micronized coal reburn (PCR/mCR) in combination with SNCR on cyclone-fired boilers. CGR and PCR/mCR require separated overfire air. FLGR™ has been applied to pulverized coal firing with and without SOFA, with and without SNCR; FLGR™ with SNCR is also called amine-enhanced fuel lean gas reburn (AEFLGR™).

(9) – No known demonstrations or permanent installations of oxygen-enhanced combustion (OEC) on cyclone-fired boilers.

(10) – No permanently installed examples of using this technique continuously on coal-fired boilers were found in available technical literature. Not suitable for high-moisture lignite fuels.

(11) – No known demonstrations or permanent installations of using this technique continuously on coal-fired boilers for NOx emissions control were found in available technical literature.

Additional criteria besides technical feasibility are utilized for technology selection in a BACT analysis have been included in the following sections summarizing control effectiveness estimates, capital plus operating and maintenance cost estimates, energy impacts, and environmental impacts:

- Control effectiveness (i.e. percent pollutant removed)
- Expected emission rate (see Tables 3-7, 3-8) and emission reduction (tons per year)
- Economic impacts (total cost and incremental cost effectiveness)
- Energy impacts
- Environmental impacts (other media and emissions of toxic and hazardous air pollutants)

3.3 RANK OF TECHNICALLY FEASIBLE NO$_X$ CONTROL OPTIONS BY EFFECTIVENESS

The third step in the “top-down” BACT evaluation is to rank the remaining control technologies by effectiveness. The purpose of ranking the control technologies is to establish a hierarchy that “places at the “top” the control technology that achieves the lowest emission level.”

The emission reduction (control effectiveness) percentages developed for ranking the available NO$_X$ emission control options considered feasible for Milton R. Young Station Unit 2 are shown in Table 3-7. These are estimates based upon engineering judgments with considerations of:

- Boiler heat input rates associated with realistic upper boundary operating assumptions;
- baseline emission rates corresponding to the realistic upper boundary operating assumptions;
- the general combustion properties of North Dakota lignite;
- published and available emission reduction performance achieved at other similar utility powerplants (cyclone-fired boilers);
- computer-derived predictions; and
- inclusion of performance margins to allow for variations in fuel, weather, equipment condition, and other factors that prevent the ultimate peak short-term performance from being reliably sustained over the course of long-term operation.

These NO$_X$ emission level and reduction percentage estimates include adjustments of previously demonstrated or predicted performance that reflect differences between North Dakota lignite and eastern or midwestern bituminous and western subbituminous coals.

The numbers assume the estimated capability of the employed technique is achievable and sustainable (long-term) and that potential operational limitations mentioned in the feasibility discussions allow the successful practice of the technique or technology. None of the remaining control options has been installed on a cyclone-fired boiler burning North Dakota lignite. As such, the expressed control percentages reflect the use of engineering judgment, based on the listed technique or technology application. This is particularly pertinent to all control options that involve air-staged combustion associated with various forms of separated overfire air. SOFA-based controls for cyclone-fired coal-burning boilers have typically reduced NO_X emission levels significantly from the precontrol baseline, and which allow or enhance further reductions when combined with other control techniques and technologies.

3.3.1 ESTABLISHING BASELINE NO_X EMISSIONS FOR RANKING CONTROL OPTIONS

Before the various feasible NO_X emission control alternatives can be estimated and ranked in order of effectiveness, the precontrol baseline level of emissions and its basis must be determined. The EPA's NSR Manual provides general guidance for establishing estimated baseline emissions to be used for the purpose of calculating and comparing the control and cost-effectiveness of a control option:

> "The baseline emissions rate represents a realistic scenario of upper boundary uncontrolled emissions from the source. The NSPS/NESHAP requirements or the application of controls, including other controls necessary to comply with State or local air pollution regulations, are not considered in calculating the baseline emissions. In other words, baseline emissions are essentially uncontrolled emissions, calculated using realistic upper boundary operating assumptions. When calculating the cost effectiveness of added post-process emissions controls to certain inherently lower polluting processes, baseline emissions may be assumed to be the emissions from the lower polluting process itself. In other words, emission reduction credit can be taken for the use of inherently lower polluting processes"[25].

Also stated in the EPA's NSR Manual:

> "Estimating realistic upper bound case scenario does not mean that the source operates in an absolute worst-case manner all the time. For example, in developing a realistic upper boundary case, baseline emissions calculations can also consider inherent physical or operational constraints on the source. Such constraints should accurately reflect the true

---

[25] Ibid, NSR Manual B.37

> upper boundary of the source's ability to physically operate and the applicant should submit documentation to verify these constraints"[26].

Establishing estimated baseline NO_X emissions for a new or existing source involves determining the design or operational basis of the emission rate. A useful means of comparing such emission rates is to establish the unit emission rate, expressed in pounds of pollutant per unit of process output. For processes such as steam-electric generating powerplants utilizing combustion in boilers, the desired process output (kilowatts or megawatts) can be related to the pollutant-bearing flue gas created by the combustion of fuel. Units of fuel heat input (millions of BTUs) required to create a unit of desired electrical output (kW) and thus the efficiency of converting the fuel heat to such electrical output (unit heat rate, Btu/kW-hr) are important.

A review of reported hourly NO_X emissions for MRY Station Unit 2 boiler, including unit mass rates (lb/mmBtu and lb/hr), boiler heat input (mmBtu/hr), and gross electrical output in megawatts (MW_g), was performed for the operating periods in years 2001-2005 inclusive. A realistic upper bound emission case scenario for each boiler's baseline emissions at Milton R. Young Station determined the highest summation of any rolling 12-month period NO_X mass emissions (pounds), along with the summation of the gross heat input (mmBtus) and the boiler operating hours for the same rolling 12-month period corresponding to the highest NO_X pounds. Dividing the summation of the rolling 12-month NO_X pounds by heat input results in a average unit emission rates (lb/mmBtu). Likewise, the summation of the rolling 12-month gross heat input (mmBtus) divided by the boiler operating hours yields an average gross heat input rate (mmBtu/hr). This emission evaluation revealed that:

- Unit 2 at Milton R. Young Station is typically operated in a base-loaded manner;
- MRYS Unit 2's highest 12-consecutive month NO_X mass emissions summation divided by the summation of the same 12-month period's heat input averaged 0.786 lb/mmBtu at a corresponding average unit heat input rate of 4,885 mmBtu/hr and unit gross electrical output of 440 MW_g.

3.3.2 ESTIMATING CONTROL-EFFECTIVENESS OF NO_X EMISSIONS CONTROL OPTIONS

The degree of success in operation of separated overfire air alone and in combination with the other selected feasible alternatives is important to the amount of NO_X emission reduction achieved. The

---

[26] Ibid, NSR Manual B.37

emission control performance from the advanced version of separated overfire air (ASOFA) is highly dependent on the degree of success in admitting combustion air insufficient for complete combustion in the cyclones without causing related negative impacts. The control percentages estimated for firing North Dakota lignite in the MRY Station boilers reflect the belief that operating the existing cyclones much below an average cyclone stoichiometric ratio of approximately 0.95 (95% of the theoretical amount of combustion air required for complete combustion) will not be successful. This is due primarily to the expected "starved air" combustion causing a reduction in cyclone furnace gas temperatures, thus creating a strong potential for molten slag solidifying in the cyclone barrels, slag taps, and lower furnace floor openings. This would impose a great interruption to steam production since forced outages would be required to remove this physical obstruction before full load boiler operation could be reestablished. The EPA's draft NSR Manual states "It is not the EPA's intention to require analysis of each possible level of efficiency for a control technique, as such an analysis would result in a large number of options"[27].

The potential operational limitations for deeply air-staged cyclones associated with separated overfire air and coal reburn alternatives are expected to limit the amount of NO_X control potential possible from successful practice of the particular technique or technology. This is described in the detailed feasibility discussions included in Appendix A1.

The advanced form of separated overfire air is expected to be effective in NO_X emission reduction and can be combined with other feasible combustion-related and post-combustion control alternatives for these lignite-fired cyclone boilers. The basic form of SOFA in combination with coal reburn, gas reburn options, and SNCR, was not included in the detailed control effectiveness analysis in order to limit the number of options that were evaluated.

Using an advanced form of SOFA system, M.R. Young Station's Unit 2's boiler operating at MCR is expected to achieve a NO_X emission level of 0.49 lb/mmBtu when operating modestly air-staged cyclone furnaces with suitable combustion controls. This level of NO_X reduction from ASOFA operation, approximately thirty eight percent, is based on the expected ability to reduce emissions without incurring potential significant negative impacts of this technique. This reduction estimate includes the additional amounts of control potential available from operating with relocated lignite drying system vent ports (and FGR ports for Unit 2) associated with ASOFA operation with modestly air-staged cyclone furnaces.

---

[27] Ibid, NSR Manual B.37

Coal reburn with ASOFA is estimated to reduce NO_X emissions for M.R. Young Station's Unit 2's boiler operating at MCR slightly more than 54 percent from the pre-control baseline NO_X emission rate, considering similar control levels demonstrated by previous coal-reburn retrofits on cyclone-fired boilers and limitations previously discussed with ASOFA.

Conventional Gas Reburn and Fuel Lean Gas Reburn options were both assumed to be installed with ASOFA. NO_X reduction from CGR with ASOFA operation is expected to be approximately 55.4 percent. FLGR with ASOFA is expected to reduce NO_X emissions approximately forty five percent. Estimates for NO_X emissions for M.R. Young Station's Unit 2's boiler considered similar control levels demonstrated by previous gas-reburn retrofits on cyclone-fired boilers with modestly air-staged cyclone furnaces and limitations previously discussed with ASOFA.

The NO_X emission rate for Selective Non-Catalytic Reduction (SNCR) (using urea) with ASOFA is expected to be approximately 0.355 / 0.33, resulting from a reduction in NO_X emissions of approximately 58 percent from the 12-month average pre-control baseline NO_X emission rate.

Included in the feasible control option ranking of Table 3-7 are layered alternatives that were shown in Table 3-5. The highest-performing NO_X control alternatives remaining in consideration are ranked in declining order of expected emission reduction. These combined control options refer to "advanced" SOFA, which is expected to have significantly lower NO_X emissions than a typical SOFA system as applied to the Milton R. Young cyclone boilers.

TABLE 3-7 – Ranked NO_X Control Options Feasible for MRY Station Unit 2 Boiler with Expected Control Performance

Alt. Label[1]	NO_X Control Technique	Emission Rate (lb/mmBtu)	Control Percentage[2]
E	SNCR (using urea) w/ ASOFA	0.330	58.0
D	Gas Reburn with ASOFA	0.350	55.4
C	Lignite Reburn w/ ASOFA	0.360	54.2
B	Fuel Lean Gas Reburn with ASOFA	0.432	45.0
A	Advanced Separated Overfire Air (ASOFA)	0.489	37.7
-	Baseline	0.786	-

(1) - Alternative designation assigned from highest to lowest unit NOx emission rate.
(2) - Control percentages are relative to an average pre-control emission baseline of 0.786 lb/mmBtu based on annual operation at highest pre-control 12-month rolling NOx summation mass emissions divided by the 12-month heat input summation.

The annual emission levels developed for Table 3-7's ranking the feasible alternatives assume that the highest 12-month average pre-retrofit level of unit NO_X emissions for M.R. Young Station's Unit 2's boiler is a baseline of 0.786 lb/mmBtu. This was determined from the highest reported rolling 12 consecutive month period's summation of hourly NO_X emissions (lbs).

The hourly gross fuel heat input (mmBtu) was summed over that same 12-month time period, and divided by the number of boiler operating hours to yield an annual average gross fuel heat input rate (mmBtu/hr). Multiplying the 12-month average heat input rate (mmBtu/hr) by the baseline or control alternative's 12-month average unit emission rate (lb/mmBtu) equals a 12-month average hourly NO_X emissions rate (lb/hr). Annual NO_X emissions (tons) for the baseline pre-control condition were calculated by multiplying the 12-month summation for boiler operating hours during the same period as the highest NO_X emissions by the 12-month average emission rate (lb/hr). The annual tons for the control options were calculated by multiplying the alternative's average annual emission rate (lb/yr) by a reduction factor (if applicable) for heat input or running plant capacity and adjusting boiler operating hours by an annual uptime (availability) factor. Details for these adjustments are included in Appendix C3. Based on these calculations, the annual emissions for M.R. Young Station's Unit 2's boiler are shown in Table 3-8.

TABLE 3-8 – Expected Annual NO_X Control Performance for MRY Station Unit 2 Alternatives

		EMISSIONS				
Alt. Label[1]	**NOx Control Alternative**	**Emission Rate lb/mmBtu**	**Hourly Emission[2] lbs/hr**	**Annual Emission[3] tons/yr**	**Emission Reduction[4] tons/yr**	**NOx Removal Efficiency[5] %**
E	SNCR (using urea) w/ ASOFA	0.330	1,663	6,298	9,216	58.0
D	Gas Reburn w/ ASOFA	0.350	1,764	6,693	8,820	55.4
C	Lignite Reburn w/ ASOFA	0.360	1,815	6,806	8,707	54.2
B	Fuel Lean Gas Reburn w/ ASOFA	0.432	2,176	8,306	7,207	45.0
A	Advanced Separated Overfire Air (ASOFA)	0.489	2,466	9,451	6,063	37.7
-	Baseline	0.786	3,959	15,513	0	-

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.
(2) - Hourly NO_X emission estimates (lb/hr) were calculated based upon average annual unit emission rate (lb/mmBtu) x 4,885 mmBtu/hr MCR heat input.
(3) - Estimated annual emission tons assume an annual capacity factor specific to each alternative; 89.5% was assumed for the baseline case.
(4) - Estimated annual tons of emission reduction is the difference between annual baseline tons and each alternative’s annual emissions (tons).
(5) - Estimated NO_X control level percentage reductions relative to 0.786 lb/mmBtu emission baseline at 4,885 mmBtu/hr MCR heat input.

3.4 NO$_X$ CONTROLS ANALYSIS AND IMPACTS EVALUATION

The fourth step of a "top-down" BACT review is to evaluate the most effective emission controls. Energy, economic, and environmental impacts are to be considered in the control technology evaluation. The purpose of the evaluation is to determine if there are any energy, economic or environmental impacts that would eliminate the top control technologies from consideration.

3.4.1 NO$_X$ CONTROL ECONOMIC IMPACTS FOR MRY STATION UNIT 2

An evaluation was performed to determine the various cost impacts of installing feasible NO$_X$ control alternatives on Milton R. Young Unit 2. This evaluation includes estimated:

- Capital costs;
- Fixed and variable operating and maintenance costs; and
- Levelized total annual costs

to engineer, procure, construct, install, startup, test, and place into commercial operation the particular control technology. The results of this evaluation are summarized in Tables 3-9 through 3-13.

3.4.1.1 CAPITAL COST ESTIMATES FOR NO$_X$ CONTROL ALTERNATIVES

The capital costs to implement the various NO$_X$ control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. In the cases of SNCR, preliminary vendor budgetary cost information was obtained and used in place of, or to adjust, the published unit output cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

The unit nameplate output capacity (gross electrical output in megawatts) assumed for the NO$_X$ control technologies capital cost estimate basis was 477 MW$_g$ for MRY Station Unit 2[28].

A review of the unit capital cost factor range and single point factors applicable to MRY Station Unit 2 NO$_X$ control technologies are presented in Table 3-9. The estimated installed and levelized capital costs for the highest-performing form of the various feasible NO$_X$ emission reduction technologies evaluated for cost-effectiveness are shown in Table 3.10. These are listed in order of control effectiveness, with the highest ranked option at the top.

---

[28] Ibid footnote number 23.

TABLE 3-9 – Unit Capital Cost Factors of Feasible NO_X Control Options for MRY Station Unit 2

Alt. Label(1)	NO_X Control Technique	Range(2) ($/kW)	Single Point Unit Capital Cost Factor(3), ($/kW) MRYS Unit 2
E	SNCR (using urea) w/ ASOFA	20-35)6)	35.9(4),(5)
D	Gas Reburn w/ ASOFA	15-30(6)	74.4(5),(6),(7)
C	Lignite Reburn w/ ASOFA	30-60(6)	170.2(5),(8)
B	Fuel Lean Gas Reburn w/ ASOFA	--(9)	45.7(4),(5),(9)
A	Advanced Separated Overfire Air (ASOFA)	5-10(6)	21(5)

(1) – Alternative designation has been assigned from highest to lowest unit NOx emission rate.

(2) – Unit capital cost factors ($/kW) of these individual technologies combined by simple addition. Actual installed costs may differ this due to positive or negative synergistic effects. Range based on published values or vendor proposals.

(3) – Single point cost factor is best estimate for determination of total capital cost for a particular technology or combination, assuming maximum unit capacity is based on existing nameplate rating. Single point cost figures in 2006 dollars.

(4) – Estimated capital cost for SNCR point estimate and FLGR point estimate derived from December 2004 budgetary proposal by Fuel Tech. See Appendix C2 for details.

(5) – The single point unit capital cost factor shown for the “advanced” version of SOFA derived from Burns & McDonnell internal database and cost estimate for North Dakota lignite-fired cyclone boilers.

(6) – NESCAUM 2005 Technical Paper, posted at their website. See technical references in Appendix A1 for details.

(7) – The single point unit capital cost factor shown for a conventional gas reburn system includes the estimated capital cost to install a high-pressure natural gas supply pipeline (31.4 $/kW), and that both boilers share the capital cost in proportion to their respective rated MW gross output capacities.

(8) – The single point unit capital cost factor shown for a lignite reburn system is highly site-specific, and assumes that new pulverizers and building enclosures are required. The general cost range for pulverized coal-fired boilers is included in the NESCAUM 2005 Technical Paper; for cyclone boilers is included in the 2005 WRAP Draft Report, posted at their website. The single point unit capital cost factor for this alternative for increased PM collection capacity included in lignite reburn option is 75.5 $/kW. See technical references in Appendix A1 for details.

(9) – The unit capital cost factor range for FLGR applications on boilers without an existing a high-pressure natural gas supply was not found in available technical literature. The single point unit capital cost factor shown for a fuel lean gas reburn system includes the estimated capital cost to install a high-pressure natural gas supply pipeline (15.7 $/kW), and that both boilers share the capital cost in proportion to their respective rated MW gross output capacities.

TABLE 3-10 – Estimated Capital Costs for NO_X Control Alternatives - MRY Station Unit 2

Alt. Label(1)	**NOx Control Alternative**	**Installed Capital Cost(2) $1,000**	**Annualized Capital Cost(3) $1,000**
E	SNCR w/ ASOFA	17,128	1,493
D	Gas Reburn w/ ASOFA[4]	35,490	3,094
C	Lignite Reburn w/ ASOFA[5]	81,167	7,077
B	Fuel Lean Gas Reburn w/ ASOFA[4]	21,817	1,902
A	Advanced SOFA (ASOFA)	10,008	873
	Baseline	0	0

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Installed capital cost is estimated for determination of total capital cost for a particular technology or combination, assuming 477 MWg unit capacity rating. All cost figures in 2006 dollars.

(3) - Annualized capital cost = Installed capital cost x 0.08718 annualized capital cost factor.

(4) - Costs for gas reburn options include high-pressure natural gas supply pipeline installed capital cost of $14,988,000 for CGR and $7,494,000 for FLGR; and annualized capital cost of $1,307,000/yr for CGR and $653,000 for FLGR. See footnotes #8 and 10 under Table 3-9.

(5) - Costs for increased PM collection capacity included in lignite reburn option are $36,013,000 for installed capital cost, and $3,140,000/yr annualized capital cost.

3.4.1.2 Operating and Maintenance Cost Estimates for MRY Station NO_X Controls

The operational and maintenance costs to implement the various NO_X control technologies were largely estimated from cost factors (percentages of installed capital costs) established in the EPA's Air Pollution Control Cost Manual (OAQPS) for SNCR[29], and from published in technical papers discussing those control technologies. In the cases including various forms of SNCR, preliminary vendor quotes were obtained and used in place of, or to adjust the OAQPS cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy.

Fixed and variable operating and maintenance costs considered and included in each NO_X control technology's annual O&M costs are estimates of:

- Auxiliary electrical power consumption for operating the additional control equipment;
- Reagent consumption, and reagent unit cost for SNCR alternatives; and
- Reagent dilution water consumption and unit cost for SNCR alternatives.

---

[29] EPA Office of Air Quality Planning and Standards (OAQPS) publication EPA/452/B-02-001, Section 4.2, NO_X Controls – NO_X Post-Combustion, Chapter 1 - Selective Non-Catalytic Reduction, dated October 2000, posted at their website: http://www.epa.gov/ttn/catc/dir1/cs4-2 ch1.pdf

- Increases or savings in auxiliary electrical power consumption for changes in coal preparation equipment and loading, primarily for fuel reburn cases;
- General operating labor, plus maintenance labor and materials devoted to the additional emission control equipment and its impact on existing boiler equipment.
- Reductions in revenue expected to result from loss of unit availability, i.e. outages attributable to the control option, which reduce annual net electrical generation available for sale (revenue).

For economic evaluation purposes, an annual average running plant capacity factor of 95.2 percent compared to a nominal unit output capacity of 462 MWg combined with an average annual availability (uptime) of 8,229 operating hours (94.7 percent of 8760 hours per year) resulting in an annual unit capacity factor of 89.5% were assumed for Unit 2's pre-control baseline annual operation. A heat input rate of 4,885 mmBtu/hr and a NO_X emission rate of 0.786 lb/mmBtu were assumed for calculating control and cost-effectiveness from pre-control maximum rolling 12 month summation of nitrogen oxides' mass emissions for MRY Station Unit 2.

Table 3-11 show the estimated annual operating and maintenance costs and levelized annual O&M cost values for the highest-performing form of the various feasible NO_X emission reduction technologies. These are listed in order of control effectiveness, with the highest ranked options at the top. The cost methodology summarized in Appendix C3 provides more details for the levelized annual O&M cost calculations and cost factors.

TABLE 3-11 – Estimated O&M Costs for
NO_X Control Alternatives - MRY Station Unit 2

Alt. Label(1)	**NOx Control Alternative**	**Annual O&M Cost**(2) **$1,000**	**Levelized Annual O&M Cost**(3) **$1,000**
E	SNCR w/ ASOFA	7,937	9,911
D	Gas Reburn w/ ASOFA	48,680	60,789
C	Lignite Reburn w/ ASOFA	9,929	12,398
B	FLGR w/ ASOFA	21,951	27,411
A	Advanced SOFA (ASOFA)	2,805	3,503
	Baseline	0	0

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.
(2) - Annual operating and maintenance cost for a particular technology or combination is compared to unit baseline operation at nominal unit capacity (462 MWg) and assumes a 94.7% average annual availability, which is highest consecutive 12-months of operation from 2001-2005. All cost figures in 2006 dollars.
(3) - Levelized annual O&M cost = Annual O&M cost x 1.24873 annualized O&M cost factor.

(4) - Costs for increased PM collection capacity included in lignite reburn option are $3,358,000/yr for annual O&M cost, and $4,194,000/yr annualized O&M cost.

3.4.1.3 LEVELIZED TOTAL ANNUAL COST ESTIMATES FOR MRY STATION NO_X CONTROLS

In order to compare a particular NO_X emission reduction alternative during the initial engineering analysis portion of the BACT selection process, the sum of estimated annualized installed capital plus levelized annual operating and maintenance costs, which is referred to as "Levelized Total Annual Cost" (LTAC) of expected pollutant removal by implementing that alternative was calculated. The LTAC for all NO_X control alternatives was calculated based on the same economic conditions and a 20 year project life (see Appendix C1 for methodology). The unit control cost was then determined as the LTAC divided by annual tons of pollutant emissions that would be avoided by implementation of the respective alternative. The control alternatives were also compared by calculating the change in unit cost (incremental cost) per incremental ton removed for the next most stringent alternative. This identified which alternatives produced the highest increment of expected pollutant reduction for the estimated lowest average annual cost increment compared with the baseline emission rate. The expected annual number of tons of pollutant removed versus estimated LTAC for each remaining control alternative was then plotted.

The comparison of the cost-effectiveness of the remaining NO_X emission reduction technologies was made and is shown in Table 3-12 and Figures 3-1 and 3-2 for MRY Station Unit 2. These figures plot estimated annual amount of NO_X removal (emission reduction) in tons per year on the ordinate (horizontal axis) and the estimated levelized total annual cost in thousands of U.S. dollars per year on the abscissa (vertical axis), for each of the remaining NO_X control technologies. Points on the graph that are farthest to the right and closest to the horizontal axis are deemed more cost-effective, since they represent controls that achieve more NO_X removal per dollar required for total annual costs of operation, maintenance, and capital recovery (depreciation).

Although the NSR Manual repeatedly prescribes following a "top down" analysis approach for BACT determination, the development of a least cost envelope with dominant controls (as seen in NSR Manual Figure B-1, page B.42) clearly labels points with lower emissions reductions and total annual costs first, i.e. "A", "B", etc. then proceeding with labeling and connecting points plotted further away from the zero emission reduction point. This "bottom-up" approach is for plotting the least-cost (dominant) control curve. The labeling of each unit's NOx control technique alternative has followed this approach.

TABLE 3-12 – Estimated Annual Emissions and Levelized Total Annual Cost for NO_X Control Alternatives - MRY Station Unit 2

Alt. Label(1)	NOx Control Alternative	Annual NOx Emissions(2) Tons/yr	Annual NOx Emissions Reduction(3) Tons/yr	Levelized Total Annual Cost(4) $1,000	Average Control Cost(5) $/ton
E	SNCR w/ ASOFA	6,298	9,216	11,405	1,238
D	Gas Reburn w/ ASOFA	6,693	8,820	63,883(6)	7,243
C	Lignite Reburn w/ ASOFA	6,806	8,707	19,475(7)	2,237
B	FLGR w/ ASOFA	8,306	7,207	29,313(6)	4,067
A	Advanced SOFA (ASOFA)	9,451	6,063	4,376	722
	Baseline	15,513	0	0	

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Estimated annual emission tons assume an annual capacity factor specific to each alternative; 89.5% was assumed for the baseline case.

(3) - Estimated annual tons of emission reduction is the difference between annual baseline tons and each alternative's annual emissions (tons).

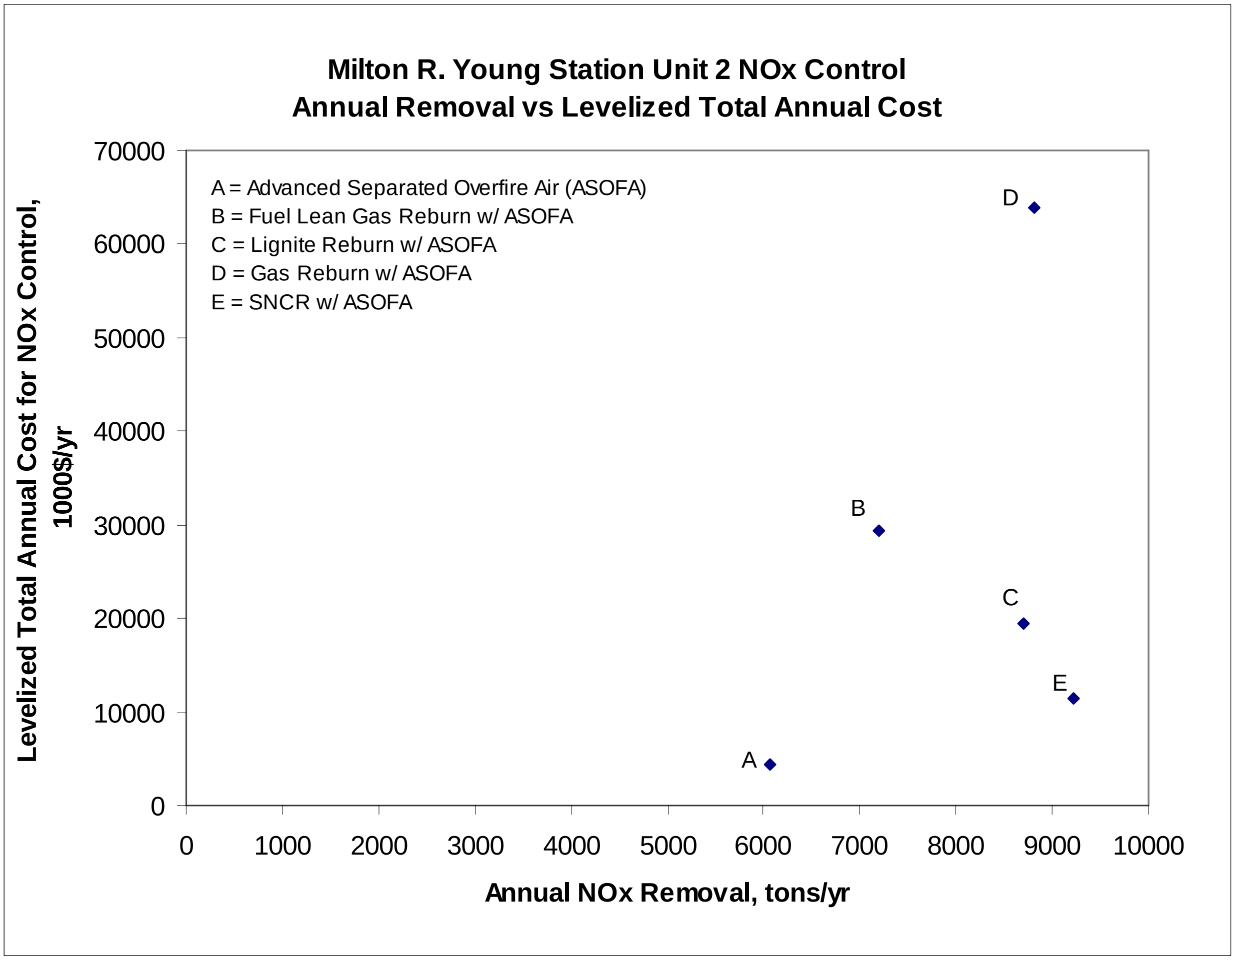
(4) - Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. See note #3 for Tables 3-10 and 3-11 for annualized cost factors. Emissions are calculated from unit emission rates, control percentage, hourly heat input, and annual hrs/yr operation compared to pre-control baseline based on annual operation at highest allowable pre-control NOx emission rate.

(5) - Average Control Cost Effectiveness ($/ton) is the Levelized Total Annual Cost (1000$/yr) divided by Annual Emission Reduction (tons/yr). All cost figures in 2006 dollars.

(6) - LTAC for gas reburn options include high-pressure natural gas supply pipeline annualized capital cost of $1,307,000/yr for CGR and $653,000 plus for FLGR. See footnotes #8 and 10 under Table 3-9

(7) - LTAC for increased PM collection capacity included in lignite reburn option are approximately $3,140,000 for annualized capital cost plus $4,194,000/yr for annualized O&M cost, for a LTAC subtotal of $7,333,000/yr.

Figure 3-1 – NO_X Control Cost Effectiveness - MRY Station Unit 2[(1)]



(1) - All cost figures in 2006 dollars. Numbers are listed and qualifiers are noted in Table 3-12.

The purpose of Figure 3-1 is to show the range of control and cost for all feasible NO_X reduction alternatives evaluated. A dominant set of control alternatives were determined by generating what is called the “envelope of least-cost alternatives”. The dominant controls cost curve is the best fit line through the points forming the rightmost boundary of the data zone on a scatter plot of the annual NO_X removal tonnage versus LTAC for the various remaining BACT alternatives. Following a “bottom-up” graphical comparison approach, each of the NO_X control technologies represented by a data point to the left of and above the least cost envelope are inferior control alternatives per the NSR Manual and should be excluded from further analysis on a cost efficiency basis.

Of the technically feasible NO_X control alternatives considered for MRY Station Unit 2, data points for conventional gas reburn (Point D) and fuel-lean gas reburn (Point B) with advanced separated overfire air, and lignite reburn with ASOFA (Point C), lay distinctly left and above the other points of the control cost points' scatter plot of Figure 3-1. These control options are inferior and therefore were eliminated from further control cost-effectiveness analysis.

Average and incremental annual costs and NO_X emission reductions for the dominant least-cost control alternatives remaining after the elimination of the obviously inferior options are listed in Table 3-13. The annual NO_X control tons per year, divided by the total levelized annual cost, yields an average unit cost ($/ton). Incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. The additional tons per year of NO_X control relative to the previous apparent least-cost curve point, divided by the increase in levelized annual cost, yields an incremental unit cost ($/ton). Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the envelope of least-cost control alternatives, also called the dominant controls cost curve or DCCC) between successively more effective alternatives which are considered technically feasible for Milton R. Young Station boilers.

TABLE 3-13 – Dominant Controls Cost Curve Points for Feasible BACT NO_X Alternatives - MRY Station Unit 2

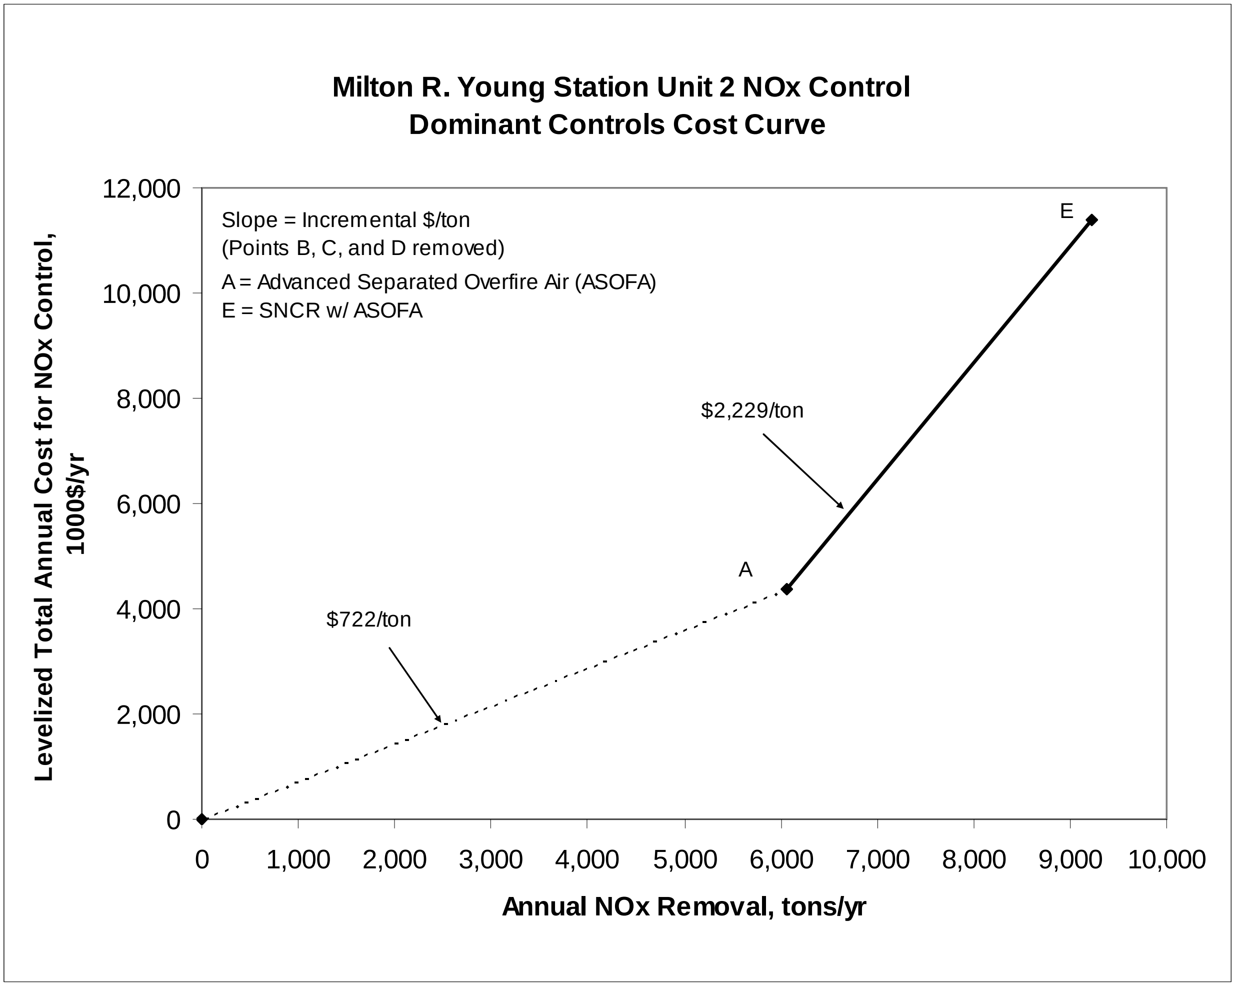
Alt. Label(1)	NOx Control Technique	Levelized Total Annual Cost(2),(3) ($1,000/yr)	Annual Emission Reduction(3) (tpy)	Incremental Levelized Total Annual Cost(2),(4) ($1,000/yr)	Incremental Annual Emission Reduction(4) (tpy)	Incremental Control Cost Effectiveness ($/ton)(2),(4)
E	SNCR w/ ASOFA	11,405	9,216	7,029	3,153	2,229
A	Advanced SOFA (ASOFA)	4,376	6,063	4,376	6,063	722

(1) – Dominant controls cost curve points from lowest (ASOFA) to highest (SNCR w/ ASOFA) are labeled the same as in Table 3-12, and on the graphs that accompany this table (Points B, C, and D were eliminated).
(2) – All cost figures in 2006 dollars.
(3) – Annual emission reduction and levelized control cost of these alternatives is relative to current costs and pre-control unit MCR baseline emission rate.
(4) – Increment based upon comparison between consecutive alternatives (points) from lowest to highest, except as noted.

The incremental cost analysis indicates that from a cost effectiveness viewpoint, the SNCR with ASOFA alternative incurs a significant annual (levelized) incremental cost compared to the ASOFA NO_X control technique (slope from zero baseline to ASOFA, Point A was $722/ton for MRYS Unit 2; the incremental cost (slope) from ASOFA, Point A to SNCR with ASOFA, Point E was $2,229/ton for MRYS Unit 2.

Figure 3-2 contains a repetition of the levelized total annual cost and NO_X control information from Figure 3-1 for MRY Station Unit 2, with Point B (FLGR™ with ASOFA) , Point C (Lignite Reburn with ASOFA) and Point D (conventional gas reburn with ASOFA) removed. This is the dominant controls cost curve for MRY Station Unit 2 NO_X emissions alternatives.

Figure 3-2 – MRY Station Unit 2 NO_X Control Alternatives BACT Dominant Controls Cost Curve(1)



(1) - All cost figures in 2006 dollars. Numbers are listed and qualifiers are noted in Table 3-13

In the U.S. EPA's NSR Manual, the EPA does not specify acceptable or unacceptable ranges for average (unit control costs) and incremental cost effectiveness values. As can be seen from a review of Table 3-14, the average levelized control cost effectiveness (called the unit control cost in this report) ranges from approximately \$722/ton to \$7,243/ton of MRYS Unit 2's NO_X emissions removed. It should be noted, however, that the highest estimated average control costs involve gas reburn technologies that were shown to be inferior options (not on the dominant controls cost curve) and thus were eliminated from further impacts analysis.

The incremental cost effectiveness is a measure of the increase in marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits (i.e., the slope of the least-cost envelope of dominant control alternatives or dominant controls cost curve) between successively more effective alternatives. The economic impact analysis indicates that from a cost effectiveness viewpoint, the highest performing alternative is SNCR with ASOFA (Point E). This control option is considered technically feasible for Milton R. Young Station Unit 2 boiler but incurs a significant annual (levelized) incremental cost relative to the next highest feasible NO_X control technique, ASOFA (Point A) when ASOFA is compared against the pre-control baseline. The Advanced Separated Overfire Air alternative has an average unit control cost (\$722/ton) approximately 58% of the highest performing feasible alternative on the dominant controls cost curve (SNCR with ASOFA, \$1,238/ton). ASOFA also has a much lower incremental cost per ton relative to the pre-control baseline (slope from zero to Point A, \$722/ton) compared to SNCR with ASOFA (Point E) versus ASOFA (Point A); the slope from Point A to Point E was \$2,229/ton.

The other elements of the fourth step of a BACT analysis following economic impacts are to evaluate the following impacts of feasible emission controls:

- The energy impacts.
- The environmental impacts.

TABLE 3-14 – Estimated Emissions and Economic Impacts Summary for NO$_X$ Control Alternatives - MRY Station Unit 2

Summary of Estimated Annual Emissions and Economics for NOx Control Alternatives Evaluated for Milton R. Young Station Unit 2

Alt. Label(1)	NOx Control Alternative	EMISSIONS(2)				NOx Removal Efficiency(2) %	ECONOMIC IMPACTS			
		Emission Rate lb/mmBtu	Hourly Emission lbs/hr	Annual Emission tons/yr	Emission Reduction tons/yr		Installed Capital Cost(3) $1,000	Annual O & M Cost(4) $1,000	Levelized Total Annualized Cost(5) $1,000	Average Control Cost(6) $/ton
E	SNCR w/ ASOFA	0.330	1,663	6,298	9,216	58.0	17,128	7,937	11,405	1,238
D	Gas Reburn w/ ASOFA	0.350	1,764	6,693	8,820	55.4	35,490	48,680	63,883(7)	7,243
C	Lignite Reburn w/ ASOFA	0.360	1,815	6,806	8,707	54.2	81,167	9,929	19,475(7)	2,237
B	FLGR w/ ASOFA	0.432	2,176	8,306	7,207	45.0	21,817	21,951	29,313(7)	4,067
A	Advanced SOFA (ASOFA)	0.489	2,466	9,451	6,063	37.7	10,008	2,805	4,376	722
	Baseline	0.786	3,959	15,513	0	0.0	0	0	0	

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Estimated NO$_X$ control level reductions relative to average annual emission baseline of 0.786 lb/mmBtu at 4,885 mmBtu/hr MCR heat input. Emissions are calculated from unit emission rates, control percentage, hourly heat input, and annual hrs/yr operation compared to pre-control baseline based on annual operation at a gross unit electrical output of 440 MWg and assumes a 93.9% average annual availability. Values from reported emission data for the 12 month operating period during 2001-2005 with the highest rolling summation of NOx pounds.

(3) - Installed capital cost is estimated for determination of total capital cost for a particular technology or combination, assuming 477 MWg unit capacity rating. All cost figures in 2006 dollars. Costs for gas reburn options include high-pressure natural gas supply pipeline installed capital cost of $14,988,000 for CGR and $7,494,000 for FLGR; and annualized capital cost of $1,307,000/yr for CGR and $653,000 for FLGR. Costs for increased PM collection capacity included in lignite reburn option are $36,013,000 for installed capital cost.

(4) - Annual operating and maintenance cost for a particular technology or combination is compared to unit baseline operation at a gross unit electrical output of 440 MWg and assumes a 95.2% average running plant capacity factor compared to nominal unit gross electrical output capacity of 462 MWg. All cost figures in 2006 dollars. Costs for increased PM collection capacity included in lignite reburn option are $3,155,000/yr for annual O&M cost.

(5) - Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. Annualized capital cost = Installed capital cost x 0.08718 annualized capital cost factor. Levelized annual O&M cost = Annual O&M cost x 1.24873 annualized O&M cost factor.

(6) - Average Control Cost Effectiveness ($/ton) is the Levelized Total Annual Cost (1000$) divided by Annual Emission Reduction (tons). All cost figures in 2006 dollars.

(7) - LTAC for reburn options include high-pressure natural gas supply pipeline annualized capital cost of $1,307,000/yr for CGR and $653,000 for FLGR; LTAC for increased PM collection capacity included in lignite reburn option are $3,140,000 for annualized capital cost plus $3,940,000/yr for annualized O&M cost, for a total of $7,080,000/yr.

3.4.2 ENERGY IMPACTS OF MRY STATION NO_X CONTROLS

Operation of the most cost-effective NO_X control technologies considered feasible for potential application at the Milton R. Young Station impose direct impacts on the consumption of energy required for the production of electrical power at the facility. The details of estimated energy usage and costs for the various NO_X control alternatives are summarized in Appendix C3.

Control alternatives for reduction of NO_X emissions were reviewed to determine if the use of the technique or technology will result in any significant or unusual energy penalties or benefits. There are several basic kinds of energy impacts for NO_X emissions controls:

- Potential increase or decrease in power plant energy consumption resulting from a change in thermal (heat) energy to net electrical output conversion efficiency of the unit, usually expressed as an hourly unit heat rate (Btu/kW-hr) or the inverse of pounds of pollutant per unit electrical power output (MW-hr). This may or may not change the net electrical output (MW) capacity of the EGU, depending on if there are physical or imposed limits on the total heat input to the boiler or electrical power output.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in physical operational limitations imposed on the ability to sustain a fuel heat input rate (mmBtu/hr) which results in a potentially lower or higher unit net electrical output (MW) capacity. This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in net electrical output of the unit, resulting from changes in auxiliary electrical power demand and usage (kW, kW-hrs). This is effectively a change in net electrical output (MW) capacity of the EGU.
- Potential increase or decrease in reliability and availability to generate electrical power. This results in a change to the number of hours of annual operation, not necessarily a change in net electrical output (MW) capacity of the EGU.

3.4.2.1 ENERGY IMPACTS OF SOFA TECHNOLOGY

There should not be a major impact on energy consumption resulting from the operation of the advanced variation of a separated overfire air system. SOFA does not significantly change the total amount of air introduced into the boiler, only the location where it is introduced. Damper resistance and supply pressure impacts of the SOFA system on fan power consumption should be insignificant. The amount of flyash emitted from the boiler is expected to be reduced (less than five percent) from the baseline level when the SOFA system is in full operation. Slightly higher levels of unburned carbon in the flyash may occur with the operation of a SOFA system. This could have a small negative impact on the plant heat rate (higher Btu/kw-hr). These changes are expected to be within the typical range of current operation.

There is a potential reduction in reliability and availability of a lignite-fired cyclone boiler to generate steam for production of electrical power as a result of installing and operating a separated overfire air system. Typical SOFA operation on bituminous or western subbituminous coal-fired cyclone boilers does not carry a significant additional risk of causing insufficient or excessive accumulation of slag within the cyclone barrels or furnace bottom compared with non air-staged combustion. Reliable boiler operation depends on avoiding such adverse conditions in the cyclones and lower furnace, which could require a forced outage to remove the solidified slag prior to returning the boiler to generation production service.

The challenges of maintaining adequate slag layer development and flow while firing lignite in MRY Unit 2’s cyclones under excess air conditions have been significant during the operating history of the powerplant. Minimizing forced outages resulting from cyclone slag issues have largely been successful through operational practices that do not affect day-to-day boiler reliability and availability. Due to the variability of combustion characteristics of lignite supplied from the Center mine, and the dependency of the slag flow on the temperature within the cyclone barrels or furnace bottom, conditions may occur during ASOFA operation that exceed the ability to adjust operational practices sufficiently to avoid forced outages to remove the solidified slag.

The potential impact on annual unit operating time due to cyclone slag issues associated with air-staged cyclones/ASOFA system operation was estimated to be approximately 2% reduction from the assumed pre-control baseline availability, i.e. 0.94-0.02=0.92. The estimated electrical generation production lost due to the reduction in MRY Unit 2’s annual availability is shown in Table 3-16.

3.4.2.2 ENERGY IMPACTS OF SNCR TECHNOLOGY

For SNCR, the injection of a diluted urea solution will require some additional auxiliary power for heating and pumping the liquid and using compressed air for atomization and cooling the reagent injection nozzles/lances, on the order of 100 to 300 kW. The injection of water (used for urea dilution) into the boiler flue gas also will have a small negative impact on the plant heat rate (higher Btu/kw-hr), although the vendor of SNCR systems advises that the heat released from the oxidation of a portion of the injected urea compensates for this impact. The impact of additional flue gas created by operation of an SNCR-related system on fan power consumption should be small.

There is a potential reduction in reliability and availability of a lignite-fired cyclone boiler to generate steam for production of electrical power as a result of installing and operating a SNCR-related system. Typical SNCR operation with low ammonia slip when firing low-sulfur western subbituminous coal in cyclone-fired boilers does not carry a significant additional risk of causing excessive fouling of the tubular air preheater compared with non-SNCR operation. Reliable boiler operation depends on avoiding adverse fouling conditions in the air preheater, which could require a forced outage to remove the ash deposits prior to returning the boiler to generation production service.

The challenges of maintaining open passages through the air preheater tubes while firing lignite in MRY Unit 2's cyclones under typical conditions have been minor during the operating history of the powerplant. Minimizing forced outages resulting from ash deposits within the air preheater have largely been successful through operational practices that do not affect day-to-day boiler reliability and availability. Due to the variability of fouling characteristics of lignite supplied from the Center mine, and the dependency of the fouling within the air preheater on sodium, sulfur, and ammonia slip emission levels, conditions may occur during SNCR operation that exceed the ability to adjust operational practices sufficiently to avoid forced outages to remove the air preheater deposits.

The potential impact on annual unit operating time due to air preheater fouling and other potential issues associated with SNCR system operation was estimated to be an incremental 1% reduction from the assumed pre-control baseline or ASOFA availability. The estimated electrical generation production lost due to the reduction in MRY Unit 2's annual availability is shown in Table 3-16.

TABLE 3-15 – Expected Auxiliary Electrical Power Impacts for NO_X Controls - MRY Station Unit 2

		Estimated Annual Average Auxiliary Electrical Power Demand and Consumption of NOx Control Equipment	
Alt. Label(1)	**NOx Control Technique**	**Gross Demand(2) kW**	**Power Usage(3) kW-hrs/yr**
E	SNCR w/ ASOFA	133	1,008,704
A	Advanced SOFA (ASOFA)	1	7,664

(1) – Alternative number has been previously assigned from least removal to highest removal percentage.

(2) – The APC NOx equipment gross auxiliary electrical power demand of alternatives is the sum of individual technologies combined by simple addition. Actual power demands may differ from this due to positive or negative synergistic effects.

(3) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.

TABLE 3-16 – Expected Electrical Power Generation Availability and Capacity Impacts for NO_X Controls - MRY Station Unit 2

Alt. Label(1)	NOx Control Technique	Estimated Annual Average Availability(2)	Estimated Annual Average Operating Time Reduction, hrs/yr(3)	Estimated Annual Average Running Plant Capacity Factor(4)	Estimated Annual Average Electricity Generation Reduction kW-hrs/yr(5)
E	SNCR w/ ASOFA	0.909	263	0.951	110,176,095
A	Advanced SOFA (ASOFA)	0.919	181	0.952	75,859.855

(1) – Alternative number has been previously assigned from least removal to highest removal percentage.

(2) – Baseline availability is assumed at 93.9 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

(3) – Annual lost operating time resulting from the implementation of the individual NOx control technique is the difference between the baseline and expected annual outage times.

(4) – Baseline running plant capacity factor is assumed at 95.2 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

(5) – Annual electricity generation reduction is annual reduction of operating time multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the MCR capacity rating of 462 MW (MCR gross unit electrical output capacity).

TABLE 3-17 – Expected Total Electrical Power Generation Impacts for NO_X Controls - MRY Station Unit 2

Alt. Label(1)	NOx Control Technique	Power Usage(2) kW-hrs/yr	Estimated Annual Average Electricity Generation Reduction(3) kW-hrs/yr	Est. Annual Change in Net Electrical Power Generation Available for Sale(4) kW-hrs/yr
E	SNCR w/ ASOFA	1,008,704	110,176,095	111,184,799
A	Advanced SOFA (ASOFA)	7,664	75,859.855	75,867,520

(1) – Alternative number has been previously assigned from least removal to highest removal percentage.

(2) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique. A negative reduction in generation is an increase in annual new electrical power available for sale.

(3) – Annual electricity generation reduction is annual reduction of operating time multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the MCR capacity rating of 462 MW (MCR gross unit electrical output capacity).

(4) – Annual change in net electrical power generation available for sale is arithmetic sum of annual power generation reduction due to a change in the auxiliary electrical power consumed plus the annual generation reduction from a decrease in annual operating time and average annual running plant capacity factor resulting from the implementation of the individual NOx control technique, compared with baseline.

3.4.3 ENVIRONMENTAL IMPACTS OF NOx CONTROLS - MRY STATION

Nitrogen oxides react with oxygen in the atmosphere to produce elemental nitrogen and ozone (O_3). This is one of the common causes of visible pollution in the atmosphere referred to as “smog”. Operation of the various NO_X control technologies considered for potential application at the Milton R. Young Station impose direct and indirect impacts on the environment. The most pronounced direct environmental impact expected from operation of any of the NO_X control options considered is the reduction of ozone and improvement in atmospheric visibility (i.e. reduced visibility impairment) downwind of the facility.

3.4.3.1 ENVIRONMENTAL IMPACTS OF SOFA TECHNOLOGY

The operation of a separated overfire air system is expected to slightly increase carbon monoxide concentrations in the stack flue gas. The advanced form of SOFA alternative is expected to slightly lower the amount of particulate matter emitted from the boiler and may raise the amount of unburned carbon in the flyash collected for land disposal and emitted to the atmosphere by small increments. Alternatives involving forms of gas reburn should experience lower particulate emissions, and a reduction in the amount of boiler bottom and flyash requiring disposal.

The environmental impact from potential reduction of annual unit operating time by approximately two percent due to cyclone slag issues associated with air-staged cyclones/ASOFA system operation will be to reduce the annual amount (tons) of nitrogen oxides emitted, and therefore the annual number of NO_X tons removed will increase, by approximately two percent.

3.4.3.2 ENVIRONMENTAL IMPACTS OF SNCR TECHNOLOGY

Operation of a conventional SNCR system is not expected to significantly impact emissions of CO or volatile organic compounds (VOCs).

Operation of an SNCR system will normally create a small amount of unreacted urea or ammonia to be emitted. The amount of ammonia slip produced by SNCR depends on the amount of reagent utilization and location of the injection points. Higher SNCR NO_X reduction performance involves greater amounts of reagent usage and ammonia slip. This is typically controlled to less than 10 ppmvd, especially when the possible formation of sulfates such as ammonium sulfate $[(NH_4)_2SO_4]$ and ammonium bisulfate $[NH_4HSO_4]$ will be more problematic at higher slip levels. Sulfur trioxide (SO_3) formed during combustion in the boiler can combine with ammonia during passage through the flue gas ductwork to form the sulfates.

Some of the unreacted ammonia from SNCR operation will be collected with the flyash in the electrostatic precipitator. Any remaining ammonia slip that is not collected or condensed in the air pollution control system will be emitted from the stack as an aerosol or condensable particulate. This has the potential to increase atmospheric visibility impairment downwind of the facility compared with a pristine condition. Although the predicted amount of such potential impact from ammonia slip emissions has not been determined, it is expected to be small in comparison with the significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NOx emission reduction.

Delivery of the urea reagent to the powerplant facility and storage of aqueous urea reagent on-site creates the potential for accidents, leaks, and subsequent releases to air, ground, and surface water immediately surrounding the facility. Urea is much less volatile than anhydrous or aqueous ammonia, and these risks are expected to be manageable. Emergency planning and community communications are part of the management plan requirements for such reagent usage.

The environmental impact from potential reduction of annual unit operating time by approximately one percent due to air preheater fouling issues associated with SNCR system operation will be to reduce the annual amount (tons) of nitrogen oxides emitted, and therefore the annual number of NO_X tons eliminated relative to the constant pre-control emission baseline will increase by approximately one percent.

3.4.4 SUMMARY OF ECONOMIC, ENERGY AND ENVIRONMENTAL IMPACTS OF MRY STATION NO_X CONTROLS

The economic, energy, and environmental impacts of each feasible BACT alternative evaluated for this study is summarized in this Section. Table 3-18 summarizes the various impacts discussed in Sections 3.4.1 through 3.4.3. The economic analysis examined the capital cost of each feasible BACT alternative evaluated and any other powerplant upgrade costs necessary to implement the alternative. In addition, the economic analysis examined the operating and maintenance cost associated with the highest-performing forms of each feasible BACT alternative evaluated. These costs were then combined into the levelized total annual cost for a comparative assessment of the total implementation cost of each alternative. Finally, as part of the top-down analysis, a dominant controls cost curve was plotted and the unit control cost for each alternative was evaluated. Two alternatives were on the dominant controls cost curve and thus were identified as the more cost effective alternatives. The two BACT NO_X control alternatives evaluated for incremental cost, energy, and environmental impacts applicable to Milton R. Young Station Unit 2 were:

- Selective Non-Catalytic Reduction (SNCR) combined with a special form of separated overfire air (SOFA) specifically for lignite-fired cyclone boilers (referred to as Advanced SOFA or ASOFA); and
- ASOFA alone.

TABLE 3-18 – Summary of Top-Down BACT Impact Analysis Results for Dominant NO_X Control Alternatives - MRY Station Unit 2

		EMISSIONS[2]				ECONOMIC IMPACTS					ENERGY IMPACTS		ENVIRONMENTAL IMPACTS	
Alt. Label[1]	NOx Control Alternative	Emission Rate lb/mmBtu	Hourly Emission lbs/hr	Annual Emission tons/yr	Emission Reduction tons/yr	Installed Capital Cost[3] $1,000	Annual O & M Cost[4] $1,000	Levelized Total Annualized Cost[5] $1,000	Average Control Cost[6] $/ton	Incremental Control Cost[7] $/ton	Incremental Aux. Power Demand[8], kW	Incremental Annual Aux. Power Usage + Generation Reduction[8], kW-hrs/yr	Non-Air Increase	Toxic Air Increase
E	SNCR w/ ASOFA	0.330	1,663	6,298	9,216	17,128	7,937	11,405	1,238	2,229	133	111,184,799	Flyash UBC	CO, NH_3
A	Advanced SOFA (ASOFA)	0.489	2,466	9,451	6,063	10,008	2,805	4,376	722	722	1	75,867,520	Flyash UBC	CO
	Baseline	0.786	3,959	15,513	0	0	0	0						

(1) - Alternative label has been assigned from highest to lowest unit NOx emission rate.

(2) - Estimated NO_X control level reductions relative to average annual emission baseline of 0.786 lb/mmBtu at 4,885 mmBtu/hr heat input. Emissions are calculated from unit emission rates, control percentage, hourly heat input, and annual hrs/yr operation compared to pre-control baseline based on annual operation at gross unit electrical output of 440 MWg and assumes a 93.9% average annual availability.

(3) - Installed capital cost is estimated for determination of total capital cost for a particular technology or combination, assuming 477 MWg unit capacity rating. All cost figures in 2006 dollars. Costs for increased PM collection capacity included in lignite reburn option are $36,013,000 for installed capital cost

(4) - Annual operating and maintenance cost for a particular technology or combination is compared to unit baseline operation at gross unit electrical output of 440 MWg and assumes a 95.2% average annual availability, which is the highest consecutive 12-months of operation from 2001-2005. All cost figures in 2006 dollars.

(5) - Levelized Total Annual Cost = Annualized Installed Capital Cost + Levelized Annual O&M cost. Annualized capital cost = Installed capital cost x 0.08718 annualized capital cost factor. Levelized annual O&M cost = Annual O&M cost x 1.24873 annualized O&M cost factor.

(6) - Average Control Cost Effectiveness ($/ton) is the Levelized Total Annual Cost (1000$/yr) divided by Annual Emission Reduction (tons/yr). All cost figures in 2006 dollars.

(7) - Incremental Control Cost Effectiveness ($/ton) is the difference in LTAC between the next most stringent alternative divided by the emissions reduction. All cost figures in 2006 dollars.

(8) - Energy impacts are incremental auxiliary electrical power demand (kW) and annual power usage plus generation lost due to negative unit reliability (fewer hours per year of operation) resulting from each control alternative (kW-hrs/yr).

(9) - Environmental impacts summarize expected non-air effects and potential toxic air emissions resulting from control alternative. Flyash unburned carbon content may increase with air-staging cyclones; carbon monoxide concentrations likely will increase with air-staging cyclones. Excess unreacted ammonia (slip) expected from SNCR technology.

3.5 BACT RECOMMENDATIONS AND CONTROL LEVELS – MRY STATION UNIT 2

This report presents the analysis of control technologies for nitrogen oxides (NO_X) for Minnkota Power Cooperative's (MPC's) Milton R. Young Station Unit 2 using the EPA's "top-down" BACT approach. BACT is an emissions limitation for each pollutant from a source determined to be achievable using control technologies(s) that provide the "maximum degree of emission reduction…taking into account energy, environmental, and economic impacts"[30]. A BACT review does not result in a percent removal efficiency requirement. The generally accepted procedures for performing a BACT analysis are outlined in the EPA's draft NSR Manual. The BACT analysis for Milton R. Young Station NO_X emissions was performed in accordance with this procedure. The EPA's draft NSR Manual outlines five basic steps that are to be followed in the "top-down" BACT evaluation. These steps were as follows:

Step 1 – Identify All Control Technologies
Step 2 – Eliminate Technically Infeasible Options
Step 3 – Rank Remaining Control Technologies by Control Effectiveness
Step 4 – Evaluate Most Effective Controls and Document Results
Step 5 – Select BACT

The final result of this analysis is a recommendation of the BACT alternative and the associated NO_X emission rate for Square Butte Electric Cooperative's Milton R. Young Station Unit 2. The emission limitations for a generation facility are expressed in a pounds per million British Thermal Units (lb/mmBtu) basis.

3.5.1 UNIT 2 NO_X BACT

In step one of the technology evaluation, three basic categories of NO_X controls for EGUs were-identified: pre-combustion, combustion, and post-combustion. Eleven basic types of NO_X control processes were identified within these three categories. Twenty four variations of these eleven processes were reviewed for availability and applicability to cyclone-fired EGUs burning North Dakota lignite. An "advanced" form of Separated Overfire Air, alone and in various combinations with Lignite Reburn, Selective Non-Catalytic Reduction (SNCR), Conventional Gas Reburn and

---

[30] Ibid, NSR Manual B.1

Fuel Lean Gas Reburn™, was evaluated for cost-effectiveness. The cost-effectiveness analysis indicated that ASOFA alone, and ASOFA with SNCR were cost effective alternatives for MRY Station Unit 2 NO_X control. The energy and environmental impacts analysis for MRY Station Unit 2's cost-effective NO_X control alternatives were generally insignificant.

Based upon the definition of BACT and the results of the BACT analysis, Selective Non-Catalytic Reduction (SNCR) in combination with a special form of separated overfire air (SOFA) specifically for lignite-fired cyclone boilers (referred to as Advanced SOFA or ASOFA) is recommended as the Best Available Control Technology for nitrogen oxides emissions from Square Butte Electric Cooperative's Milton R. Young Station Unit 2. The unit BACT NO_X emissions rate for MRYS Unit 2 is 0.330 lb/mmBtu , determined as a rolling 12-month average. This is shown in Table 3-19.

TABLE 3-19 – NO_X Emission Control Technology and Rate Recommended as BACT for Milton R. Young Station Unit 2

Control Technology and Emission Rate Recommended as BACT			
Unit	**Pollutant**	**BACT Control Method**	**12-Month Rolling Average BACT NOx Emission Rate (lb/mmBtu)**
2	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.330

3.5.2 EMISSION RATE LIMITATION RECOMMENDATION

To complete the BACT determination process, the Consent Decree (CD) requires that "specific control technologies to be installed and a specific Phase II 30-day Rolling Average NO_X Emission Rate limitation (lbs/MMBtu)"[31] (pounds per million Btu) must be established for each subject emission Unit. The CD also states that "a "30-day Rolling Average Emission Rate" shall be determined by calculating an arithmetic average of all hourly emission rates in lbs/MMBtu for the current Operating Day and the previous 29 Operating Days. A new 30-day Rolling Average Emission Rate shall be calculated for each new Operating Day. Each 30-day Rolling Average Emission Rate shall include startup, shutdown, and Malfunction periods within each Operating Day"[32].

---

[31] Ibid footnote number 1, Paragraph 66, page 20.

[32] Ibid footnote number 1, Paragraph 5, page 4.

The Consent Decree also states that the North Dakota Department of Health's (NDDH) NO_X "BACT Determination shall address specific emission limitations during Unit startups"[33] at Milton R. Young Station. The type and duration of firing during startups, and the limited ability of available and feasible technologies to control startup NO_X emissions, both significantly influence the 30-day rolling average BACT NO_X emission rate limit recommended for Milton R. Young Station boilers. A 24-hour rolling average NO_X emission rate limit applied to startup periods is also recommended for Milton R. Young Station boilers.

The Consent Decree and the EPA's NSR Manual do not describe the method for determining a 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT applied to Milton R. Young Station Unit 2.

In keeping with the establishment of a specific CD Phase II 30-day Rolling Average NO_X Emission Rate limitation, a relevant precontrol baseline level of emissions and its basis must be determined. The EPA's NSR Manual states:

> "The baseline emissions rate represents a realistic scenario of upper boundary uncontrolled emissions from the source. The NSPS/NESHAP requirements or the application of controls, including other controls necessary to comply with State or local air pollution regulations, are not considered in calculating the baseline emissions. In other words, baseline emissions are essentially uncontrolled emissions, calculated using realistic upper boundary operating assumptions"[34].

Also stated in the EPA's NSR Manual:

> "Estimating realistic upper bound case scenario does not mean that the source operates in an absolute worst-case manner all the time. For example, in developing a realistic upper boundary case, baseline emissions calculations can also consider inherent physical or operational constraints on the source. Such constraints should accurately reflect the true upper boundary of the source's ability to physically operate and the applicant should submit documentation to verify these constraints"[35].

---

[33] Ibid footnote number 1, Paragraph 66, page 20.

[34] Ibid footnote number 2, NSR Manual page B.37

[35] Ibid footnote number 2, NSR Manual page B.37.

The BACT Analysis was conducted based upon the highest historical 12-month rolling NO_X emission summation operating conditions for Milton R. Young Station boilers during years 2001-2005. However, a baseline reflecting a realistic upper bound case scenario based upon the highest historical 30-day rolling NO_X emission operating conditions during years 2001-2005 was established prior to recommending enforceable permit conditions for BACT to be applied to each Milton R. Young Station boiler.

The approach taken in this analysis was to identify pre-control 30-day baseline operating conditions from the 30-consecutive day period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation between January 1, 2001 and December 31, 2005. This reflects unit NO_X emissions that were generated during periods of high unit operations, not affected by unit shutdowns, startups, or malfunctions. MRYS Unit 2's highest reported 30-day rolling average NO_X unit emission rate during years 2001-2005 was 0.874 lb/mmBtu for the period ending April 5, 2002. The corresponding MRYS Unit 2 30-day average hourly NO_X mass emission rate was 3,726 lb/hr. The average unit heat input rate for MRYS Unit 2 was 4,264 mmBtu/hr, and the average gross unit electrical power output was 450.2 MW_g for the same 30-day period.

The operating conditions during the highest historical 30-day rolling NO_X emission for years 2001-2005 were then compared to the highest 12-month historic pre-control baseline conditions. The average unit NO_X emission rate (lb/mmBtu) from the highest historic pre-control 30-day baseline period was compared with the average NO_X emission rate (lb/mmBtu) from the 12-consecutive month period with the highest historic unit NO_X mass emissions (pounds) reported for actual operation during the same 5-year look-back period. An estimate of NO_X emission reduction for the proposed BACT NO_X alternative operating at the historic pre-control 30-day baseline average NO_X emission rate (lb/mmBtu) was made. This rate considered recognized operational factors and equipment designs applied to "steady state" conditions with sustained output close to maximum continuous capacity ratings. The potential impact of startups, recognizing operational and technical limitations on NO_X emission control performance, was then applied to the steady-state rate, to establish a recommended 30-day Rolling Average NO_X Emission Rate permit limitation (CD Phase II) that reflects BACT for Milton R. Young Station Unit 2. This is explained below.

NO_X emissions for cyclone-fired boilers are typically higher in pounds per million BTUs during start up events than during steady-state operation at maximum continuous rating (MCR) conditions. This is because hourly heat and combustion air input rates required to establish adequate molten slag formation within the cyclone barrels and promote slag tapping are typically produced from firing conditions that create high flame temperatures. NO_X emissions are sensitive to peak furnace gas temperatures, thus uncontrolled NO_X emissions can be high during cyclone boiler startups. Furnace exit flue gas temperatures (FEGTs) during cyclone boiler startups are less than those occurring during conditions of steady state MCR firing rates due to the high heat absorption of the boiler metal and water being raised from ambient or near-ambient temperatures. Until sufficient FEGT exists for a feasible and available post-combustion technology, such as SNCR, to be effective, NO_X emissions will be basically uncontrolled. There is a practical lower limit of boiler heat input for conventional combustion-based NO_X emission control techniques, such as the advanced version of separated overfire air, to be operated beyond the amount required for cooling the SOFA injection nozzles when it can be diverted from the cyclone burners and significantly control NO_X emissions. These limitations of the effectiveness of BACT controls on Milton R. Young Station boilers during startups and other reduced-load operating periods influence the recommended 24-hour and 30-day rolling average NO_X emission rate limits.

Startup procedures for steam electric generating units (SEGUs) comprising a fossil fuel-fired boiler and steam turbine-generator are specified by the original equipment manufacturers to follow guidelines for heat and pressure increases to provide protection of boiler and turbine equipment. Initial start up duration after an outage may be dictated by the need to gradually warm up burner port/cyclone refractory materials, steam drum shell, steam headers, and other boiler metal surfaces exposed directly or indirectly to furnace gases, and the steam turbine’s multiple casings and rotor shafts. This is normally accomplished with easy-to-ignite fossil fuel firing (such as natural gas, distillate fuel oil, or propane) of the boiler combined with coal to gradually increase firing until recommended boiler steam outlet temperature and pressure are reached. This is followed by supplying the steam turbine with sufficient inlet steam flow to reach conditions that allow the coupled generator to be synchronized and electricity to be generated above zero megawatts. From this point, boiler fuel firing is increased within prescribed rates until the desired operating load is achieved.

The SEGU startup operating period is usually not defined in emission permits. Startup is the period beginning with initiation of fuel ignition, and continuing until the powerplant equipment has reached operating conditions that include continuous fuel firing and sustained operating steam pressure and temperature levels within the guidelines of the designs for the boiler and turbine and their auxiliary systems for minimum sustainable levels without causing damage to the equipment.

A recent SEGU proposed PSD permit has included a definition of startup as "the period beginning with ignition and lasting until the equipment has reached a continuous operating level and operating permit limits"[36]. Similarly, a shutdown is defined as "the period beginning with the lowering of equipment from base load and lasting until fuel is no longer added to the boiler and combustion has ceased"[37]. Based on the referenced definitions of a startup period and a shutdown period, the amount of time required for a SEGU's load (boiler steam output or generator electrical output) to increase beyond such minimum sustainable operating levels can be considered part of startup events if the SEGU is typically base-loaded at full load or MCR output. This is the case with both MRY Station SEGUs.

Startups of SEGUs may be labeled as cold, warm, and hot to account for the amount of residual heat remaining in the boiler and steam turbine equipment. The various types of starts are dependent upon the amount of time the SEGU has been out-of-service (i.e. without boiler fuel firing or generator megawatt output). Cold starts have been defined as starts after the boiler has been without fuel firing for more than 72 hours, warm starts are more than 8 hours and less than 72 hours, and hot starts are less than 8 hours[38].

Although the definition of a startup event and the corresponding startup period is not required by the Consent Decree, defining start-ups is recommended. This helps to address the specific emission limitations during Unit startups at Milton R. Young Station and determine the impact of such operations on 30-day rolling average NO_X emissions. For the purpose of this NO_X BACT analysis, a Unit startup was defined as the period from initial fuel combustion to the point in time when:

- the measured Heat Input to the boiler on a 6-hour rolling average basis is greater than or equal to 4800 million BTU/hr for Unit 2; or
- the amount of time reported for the longest individual Unit 2 startup period during actual operation between January 1, 2001 and December 31, 2005 elapses, whichever occurs first; or
- fuel firing is discontinued prior to satisfying either previous criteria.

This startup definition for MRY Station Unit 2 accounts for conditions where cyclone refractory materials replaced during boiler overhauls must be cured by extended low-firing heating cycles,

unit controls are upgraded and must be adjusted during low-load operation, or for boiler feedwater quality to improve after boiler maintenance has been performed that affects the insides of the waterwall and superheated steam tubes. It also allows for a failed or interrupted start sequence which can require considerably less or more time to elapse than an average startup duration.

Analysis of MRY Station Unit 2 operations data from 2001 through 2005 revealed:

- There were 62 total startups in the five year period;
- Minimum startup was 14 hours for a "hot" start following a boiler master fuel interruption (Unit "trip");
- Maximum startup with an extended ramp-up period until full load was reached was 115 hours.

Unit 2 had a start-up that began on October 25, 2001 that lasted for 115 hours. This startup included initial firing in the 20th hour of 10/25 (2000 hours being the beginning of the startup period), and which ended at the end of the 14th hour (i.e. at 1500 hours) on October 30, 2001, upon reaching 451 MW (gross) output. The criteria of a 6-hour average heat input rate of more than 4800 million Btu per hour was not reached during this startup.

There are certain boiler operating conditions that need to exist before the BACT NOx control techniques and technologies can be effectively operated:

1. The furnace gas temperature in the region where a urea reagent solution is injected for SNCR-based NO_X control must be between 1700°F and 2100°F. This region is expected to be in the vicinity of the furnace exit, which is commonly defined as either the horizontal plane extending from the furnace rear wall arch ("nose") to the front wall of the boiler, or the vertical plane from the nose up to the furnace roof, upstream of the gas inlet to the superheater tube banks. The gas temperature (FEGT) range in this furnace region is dependent on boiler heat input rate and cleanliness of the firesides of the furnace walls, which affects the amount of radiant energy absorbed by the wall tubes and transferred to the water within.
2. The numbers of active cyclones and continuous coal firing rates must be enough to establish sufficient:
    a. coverage of molten slag on the actively-fired cyclone barrel surfaces and drainage of the slag from the bottom of the boiler; and

b. combustion airflow through the actively-fired cyclones to allow a portion to be diverted to the separated overfire air system above the amount required for idle cyclone cooling and SOFA nozzle cooling.

As previously discussed, furnace exit flue gas temperatures (FEGTs) will need to be measured or determined empirically during operation of the MRY Station boilers in order to be able to effectively control NO_X emissions using SNCR technology. The design and operation of the SNCR systems at MRYS for CD Phase II emissions control should include features that accommodate cyclone boiler startups and low-load operation with “clean” or “dirty” boiler heat transfer surfaces as soon as conditions occur that are technically practicable, i.e. within the SNCR system vendor’s recommended operating guidelines, as well as full-load conditions in order to minimize NO_X emissions.

The amount and duration of sustained boiler heat input required to establish the operating conditions described in item 2 above is more difficult to precisely determine. Lignite heat content variability and inability to accurately determine the actual air/fuel ratio on a cyclone-by-cyclone basis in real-time, and the slagging and fouling characteristics of the lignite ash, cause (and are expected to continue to cause) difficulties with stable combustion performance. The minimum firing rates of the MRY Station boilers required to successfully initiate the effective operation of the SOFA system are specific to each individual boiler, and are not currently known. Due to such operating problems and emission control limitations, the ability to effectively limit NO_X emissions during startup periods and low-load operation following implementation of advanced SOFA (CD Phase I control) and/or an SNCR system (CD Phase II control) is uncertain.

Because there are expected to be minor short term variations in operating conditions during startups where Minnkota has not, in fact, materially changed any of their normal startup operating practices and criteria, a margin between the 30-day rolling average steady-state NO_X emission rate (which does not include the impacts of startups) and the proposed 30-day rolling average NO_X emission permit limit that includes startup emissions is recommended. This rate considered recognized operational factors and equipment designs applied to steady state conditions with sustained output close to maximum continuous capacity ratings. The recommended 30-day Rolling Average NO_X Emission Rate permit limitation excluding the impact of startups that reflects BACT for Milton R. Young Station Unit 2 is shown in the table below.

TABLE 3-20 – Recommended NO_X BACT Control Method and 30-Day Rolling Average NO_X Emission Rate Limit Without Startups

Unit	Pollutant	Control Method	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)
2	NO_X	Selective Non-Catalytic Reduction with Advanced Separated Overfire Air (ASOFA)	0.350

This recommended BACT 30-day NO_X emission rate limit is based upon a historic pre-control 30-day baseline average NO_X emission rate of 0.874 lb/mmBtu for Unit 2. The baseline emission was determined from the 30-consecutive day period with the highest historic unit NO_X emissions rate reported for actual operation between January 1,2001 and December 31, 2005.

A recommended BACT 30-day NO_X emission rate limit that includes the impact of startup emissions should be suitably higher such that operation consistent with the technological limitations, manufacturer's specifications, and good engineering and maintenance practices to the extent practicable for the MRY Station boilers would not result in an exceedance (violation) of an enforceable 30-day rolling average NO_X emission permit limit.

For MRYS Unit 2, the recommended 30-day rolling average NO_X emission permit limit rate that includes the impact of startups is based upon recognized operational factors and equipment designs that influence whether the startup emissions result in higher 30-day emissions compared to normal continuous operation without or excluding such startup periods:

1. The uncontrolled emission rate (i.e. without separated OFA or SNCR in operation) and its variability during operation from a cold, warm, or hot startup up to and including maximum continuous rated output;
2. The operating conditions that are required to exist for the selected NO_X BACT control techniques to be initiated and be effective; and
3. The effectiveness of these two particular control techniques if invoked at less-than-MCR steady-state operating conditions.
4. The number of startups and their range of typical durations per 30-day period time frame.

The October 25-30, 2001 startup was chosen for additional evaluation as the start-up for MRY Station Unit 2.

An incremental adjustment to the proposed 30-day rolling average steady-state unit NO_X BACT emission rate without startups of 0.35 lb/mmBtu for Unit 2 is recommended for the 30-day rolling average NO_X emission permit limit periods as defined and applied to Milton R. Young Station. This is summarized in the table below.

TABLE 3-21 – Recommended BACT 30-Day Rolling Average NO_X Emission Rate Limit and Startup Impact

Unit	30-day Rolling Average NOx Emission Rate Limit Excluding Startups (lb/million Btu)	Impact on 30-day Rolling Average NOx Emission Rate Limit Due to Startups (lb/million Btu)
2	0.35	+0.102 per startup

This recommended adjustment to the proposed 30-day rolling average steady-state NO_X BACT emission rate limit without startups is based upon average historic pre-control NO_X emission rates of 0.959 lb/mmBtu for Unit 2 reported for the longest individual Unit 2 startup period during actual operation between January 1, 2001 and December 31, 2005. These emissions occurred during the 115-hour October 25-30, 2001 startup for Unit 2.

A 24-hour rolling average BACT NO_X emission rate limit applied to startup periods is also recommended for each of the Milton R. Young Station boilers.

This is summarized in the table below.

TABLE 3-22 – Recommended 24-Hour Rolling Average NO_X Emission Rate Limit During Startups

Unit	24-hour Rolling Average NOx Emission Rate Limit During Startups (lb/million Btu)
2	1.064

These emissions occurred during the 115-hour October 25-30, 2001 startup for Unit 2.

Compliance with these emission rates would be measured at the stack of the Unit, verified with Continuous Emission Monitoring (CEM) systems in accordance with the reference methods specified in 40 C.F.R. Part 75, and would be determined on a 30 consecutive Operating Day and 24-consecutive hour rolling average basis, respectively.

A trial demonstration operating period of 18 months after the completion of Consent Decree Phase II NO_X emission reduction system installation commissioning at Milton R. Young Station is recommended. It is proposed to allow Minnkota (for Square Butte) to demonstrate the actual control system capabilities of the combined NO_X BACT emissions reduction system. Operating experience during the trial period will:

- confirm steady-state control performance of the combined NO_X BACT emissions reduction system;
- allow determination of the ability to further control Unit start-up emissions;
- allow the determination of the permitted 30-day rolling average NO_X emission limit including startups, shutdowns, and malfunctions; and
- address the specific emission limitations during Unit startups at Milton R. Young Station and their impact on the proposed 30-day rolling average emission rate limit (without startups).

Based upon the information obtained during the trail period, final emission limits can then be determined.

The means that will be employed to minimize emissions during startup will primarily be based on operating procedures, both before and after the level of upper furnace gas temperatures and/or heat input rate are considered sufficient to start the NO_X controls and operating conditions are conducive for effective emissions reduction. These could be similar to Minnkota's current MRYS practices, or could be different, depending upon the capabilities of the NO_X controls and their impacts on Unit operations.

APPENDIX A

Technical Feasibility Assessment Details for NO_X Control Technologies (A1)

U.S. Coal Cyclone NO_X Reduction Projects Summary

With Retrofit NO_X Control Projects’ Technical Literature Summary (A2)

A.1 Technical Feasibility Assessment of NO_X Control Alternatives

A.1.1 Pre-Combustion Fuel Treatment/Switching

Fuel switching can be a viable method of NO_X emission reduction in certain situations. Often, coal combustion facilities are constructed to take maximum advantage of the particular combustion characteristics of a specific fuel. In the case of MRY Station, the Unit 1 and 2 boilers were designed and constructed specifically for firing North Dakota lignite, which has a fuel higher heating value (Btu/lb) approximately 20% lower than typical Powder River Basin (PRB) coal. A cyclone–fired boiler (Ottertail's Big Stone Unit 1) that is similar in geometry and steam generation design to MRY Station Unit 2 fires PRB coal. Based on a comparison of available emission data between Big Stone Unit 1 and MR Young Unit 2, there is no expected reduction in baseline (i.e. uncontrolled) NO_X emissions from switching to PRB from lignite at Milton R. Young Station.

Conversion of Milton R. Young Station Unit 2 boiler to fire PRB coal is technically possible. It is expected that major plant modifications will be required. Rail service is not presently installed at this site, so the additional operational and capital costs to bring in large quantities of PRB coal will be significant. Investigation of the specific source, distance, and costs for supplying necessary quantities of PRB coal via rail or trucks to M.R. Young station has not been performed. With zero baseline NO_X emissions reduction expected from application of fuel switching, this alternative will not be economically competitive with other NO_X control technologies that offer better results for a much lower combination of capital and operational costs. Although fuel switching is technically feasible, it has not been considered further as an effective NO_X emissions control option for MRY Station Unit 2 boiler.

A.1.2 Combustion Controls

Combustion controls comprise the most numerous category of NO_X emission reduction technologies. These techniques employ methods that reduce the amount of NO_X emissions created in the combustion zone of the boiler prior to exhausting the flue gases from the furnace (upstream of the convective heat transfer zones). These controls result in fewer emissions to atmosphere or that may require subsequent reduction from additional applicable combustion and/or post-combustion techniques.

As the boilers in question were designed for firing North Dakota lignite fuel, they were furnished with suitably-sized furnaces and limited back-end economizer heat transfer surfaces upstream of the air preheaters. This provides high temperature air to aid the evaporation of excess moisture from the crushed coal particles in the pre-combustion drying systems, and long residence times for solid and gaseous fuel particles to burn essentially to completion prior to leaving the furnaces. The latter feature is especially advantageous for applying various forms of combustion modifications which are conducive in reducing NO_X emissions.

A.1.2.1 Basic Combustion Improvements

Combustion improvements are commonly-applied techniques which may produce modest incremental NO_X emissions reductions. In their most basic form, these typically provide improvements to combustion air flow distribution, measurement, and pressure, together with fuel flow measurement and metering, to promote consistent combustion performance by burning fuel with more accuracy in maintaining a desired fuel/air ratio.

These improvements may allow, or be combined with, the practice of several other NO_X control techniques. Separated overfire air (discussed below), with or without “low excess air” (LEA), burners out-of-service (BOOS) and biased firing (BF) operation of the cyclones, cause a decrease in the ratio of combustion air to fuel supplied to the cyclones (burners), thus reducing the amount of thermal NO_X emissions produced during combustion. The amount of potential NO_X emission reduction achievable from these basic techniques is highly-dependent on the specific type of firing, fuel, and conditions which apply to the boiler(s) being reviewed.

Making lignite drying system air adjustments and adding improvements to the boiler combustion controls and reducing combustion air inputs have already reduced uncontrolled NO_X emissions at Milton R. Young Station Unit 2 boiler approximately 27%. Further incremental improvements from additional combustion controls that allow operation with modest amounts of cyclone air staging, similar to the effect of a separated overfire air system, are possible. Incremental NO_X emissions reductions are expected from such improvements being incorporated into another feasible alternative, such as separated overfire air. This alternative was not considered as a stand-alone option for additional NO_X reduction at Milton R. Young Station for the Unit 2 boiler.

A.1.2.2 Low NO_X Burners (LNB)

Low NO_X burners (LNBs) of various designs have been commonly applied to pulverized coal-fired utility and industrial boilers for more than ten years. However, they are not installed on cyclone-fired boilers. This technology is infeasible on cyclone boilers[1], and was eliminated from consideration for additional NO_X reduction at Milton R. Young Station Unit 2’s boiler.

A.1.2.3 Separated Overfire Air (SOFA)

Separated overfire air (SOFA) is a combustion-related NO_X emission reduction technology frequently-applied with and without low NO_X burners to utility and industrial boilers for more than twenty five years. Separated Overfire Air (SOFA) is an air-staging NO_X emission reduction combustion technique that is typically based on withholding 15 to 20 percent of the total combustion air conventionally supplied to the firing zone. The diverted combustion air is then injected in the upper furnace, where combustion is completed. For typical cyclone coal-fired boilers, this involves diverting approximately 20 percent of the secondary combustion air, forcing the cyclones to operate fuel-rich. Starved-air combustion causes fewer NO_X emissions to be produced.

At least thirty nine existing cyclone-fired boilers, firing eastern bituminous, midwestern bituminous, and western subbituminous ("Powder River Basin") coals in units ranging in size from 50 to 1150 MW, have been retrofitted with commercial SOFA since 1998. A summary of several of the first SOFA (and reburn) retrofits to cyclone-fired boilers is described in published technical papers[1,2]. Cyclone boiler retrofit SOFA installations are included in the EPA's BART technical support document[3] and listed later in Appendix A2.

A basic form of separated overfire air (SOFA) can be applied and installed on MRY Station Units 2. There are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application.

Key aspects of successfully applying and operating a separated overfire air system on a cyclone-fired boiler are the ability to:

- Accurately measure the fuel heat input rate (BTUs) and combustion air inputs on a real-time, individual cyclone by cyclone basis, to allow the ability to determine and control the desired air/fuel ratio, especially when "starved air" (i.e. substoichiometric) combustion conditions are required.
- Maintain adequate molten coal ash (slag) formation and flow within the barrels and slag taps.

The degree to which the cyclone furnaces can be operated with less than theoretical (substoichiometric) combustion air directly contributes to less NO_X formation and further in-furnace emission reduction but also risks solidification of the molten coal ash. In the case of MRY Station Unit 2 boiler, cyclone combustion must be sufficiently air-staged to reduce NO_X emissions while releasing enough heat to continue to melt the fuel ash so that it flows effectively within and from the cyclone burners.

In the case of MRY Station boilers, there is a significant amount of variability in the combustible and ash components of North Dakota lignite supplied from the current mine near Center, ND. Analysis of several hundred coal feed samples taken simultaneously from multiple cyclones of MRY Station Unit 2's boiler revealed that the maximum differential of the lignite heating values from cyclone-to-cyclone was just over 12% of the average heating value of all the samples. Assuming an operating case occurred where the maximum cyclone-to-cyclone differential heating value was for two cyclones at the opposite ends of the fuel heat content range, there would be a plus or minus 6% variation in fuel heat content for either of the individual cyclones from the overall average. If the desired average cyclone air/fuel (stoichiometric) ratio was 0.95 when operating with air-staged cyclones associated with separated overfire air, and the amount of secondary combustion air to each cyclone was equal, there would be a stoichiometric ratio of approximately 1.01 in one cyclone and a stoichiometric ratio around 0.89 in another cyclone at the same time. The modestly air-staged cyclone would produce higher than average NOx emissions. The deeply staged cyclone would produce less than average NOx emissions and potentially insufficient amounts of heat release, and raise the risk of solidifying the fuel ash so that it accumulates within the cyclone barrel. This could result in firing auxiliary fuel oil in the deeply-staged cyclone or taking the boiler out-of-service to remove the pluggage. Neither of these conditions is desirable because they result in lower emissions removal performance and higher operating costs. Thus, due to the variability of the fuel heat content and the complex behavior of lignite ash when exposed to high temperatures, the extent of air-staging and thus the level of NO_X control in MRY Station boilers is expected to be modest while firing lignite coals.

In order to potentially achieve lower NO_X emission rates with modestly air-staged combustion for MRY Station boilers, additional combustion improvements can be installed. One potential improvement is to implement a unique form of SOFA for North Dakota-lignite–fired cyclone boilers. This includes relocated lignite drying system vent ports, and in Unit 2's case, also involves blocked or relocated lower furnace flue gas recirculation ports. This will be referred to as "Advanced SOFA" (ASOFA). There are several design challenges anticipated for implementing the advanced version (with the described port relocations) of separated OFA. These are believed to be solvable.

Both forms of separated overfire air as a combustion-related NO_X control technique are considered feasible for application to Milton R. Young Station cyclone boilers. Since the advanced SOFA is the highest-performing form of this technology, only this ASOFA version of the alternative was considered for additional NO_X reduction at Milton R. Young Station boilers.

Another form of separated overfire air being marketed commercially is “Rotating Opposed Fire Air” (ROFA). For utility applications in the United States, this has only been applied to pulverized coal-fired boilers, primarily tangentially-fired units[4]. It is different than basic SOFA in that it includes a hot air booster fan, and injects the overfire air in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row. The vendor (Mobotec USA) claims ROFA maximizes air-staged in-furnace combustion NOx reduction while minimizing negative impacts on carbon monoxide and flyash unburned carbon.

While this variation of separated overfire air could potentially be applicable to cyclone boilers, it has not been marketed to serve such applications. Because cyclone boilers do not require the addition of hot air booster fans for SOFA, this technique is not distinct enough from basic SOFA from functional and air-staged cyclone NO_X reduction performance standpoints to warrant individual consideration. ROFA technology lacks demonstrated cyclone-fired boiler experience, and thus was considered infeasible and not included in the control effectiveness and cost-effectiveness sections of the main report.

A.1.2.4 Oxygen-Enhanced Combustion

A supplier of liquid oxygen (Praxair) has developed a method of replacing some of the combustion air supplied to the burners with pure oxygen. Combustion air, which is normally input through the secondary air system ductwork downstream of the forced draft (FD) fan and air heater, is supplemented with pure oxygen directly injected into the burners. Oxygen-enhanced combustion (OEC) can reduce boiler NO_X emissions resulting from “ thermal NO_X“, a reaction of the nitrogen in the combustion air admitted to the burners with the available oxygen in the air in the flame or peak temperature regions of the fuel combustion process. The use of pure oxygen instead of air reduces the availability of nitrogen from the air to be oxidized in the high temperature regions, thus reducing formation of thermal NO_X. This technique has only been demonstrated in a boiler with pulverized fuel burners firing bituminous coal[5].

The lack of adequate experience on any cyclone-fired coal-burning boiler, on a temporary demonstration or permanent full-scale basis, and for a coal-fired facility of this size, precludes consideration of oxygen-enhanced combustion at MRY Station Unit 2’s boiler. This is deemed to be infeasible technology at this location at the present time.

A.1.2.5 Flue Gas Recirculation

Flue gas recirculation (FGR) has been commonly applied to coal-fired boilers, primarily to inject into the lower furnace, just above the burners, supplied from the boiler's economizer flue gas outlet via a hot gas booster fan. This modifies the amount and temperature of hot furnace gas either in the lower-middle or upper furnace and convection heat transfer zones. As this flue gas typically has an oxygen content around 2-5%, it limits the availability of oxygen in a high temperature, possibly fuel-rich lower furnace zone. Flue gas recirculation for NO_X control is most commonly applied with gaseous or liquid fossil fuels to reduce the high temperatures which convert nitrogen in the combustion air to nitrogen oxides. No examples of using or installing FGR on cyclone-fired boilers strictly for NO_X emissions control were found in available technical literature.

FGR is already practiced at MRY Station in the Unit 2 boiler, primarily for furnace gas temperature and lower wall slagging reduction reasons. For this boiler, FGR could aid in potentially providing some small additional NO_X emissions control if it were modified from its current configuration, as part of an advanced form of separated overfire air. Complete elimination of the use of FGR could also slightly reduce NO_X emissions from Unit 2's boiler during air-staged cyclone combustion with separated overfire air system operation. There is uncertainty whether elimination of the use of FGR in the lower furnace of MRY Station's Unit 2 boiler could be successful in controlling lower furnace wall fireside ash deposition.

A.1.2.6 Water/Steam Injection (Combustion Tempering)

When applied to older gas-fired and oil-fired utility and industrial boilers, water and/or steam injection adds moisture into the lower furnace, concurrent with or near (to the side or slightly above) the burners, supplied from the boiler's treated feedwater or auxiliary steam systems via a metering pump or valve. There has been some limited testing of water injection for NO_X emissions control on natural gas-fired and coal-fired cyclone boilers[6,1]. For coal-fired cyclones, this technique is most effective on boilers burning bituminous coal; however, it has not been permanently installed and continuously operated in such applications. Successful long-term operation of water injection would be difficult for lignite-fired cyclone boilers, due to the high moisture levels in the coal and the need to readily ignite and sustain stable combustion and molten slag formation in the cyclone furnaces. For these reasons, water/steam injection is considered technically infeasible for NO_X control application at Milton R. Young Station.

A.1.2.7 Fuel Reburn

Another combustion technology that may be applicable to control NO_X emissions from the Milton R. Young Station units is fuel reburn. In a similar manner that overfire air diverts a portion of the combustion air input to the main firing zone, the reburning process involves supplying a portion of the fuel heat input to the boiler at a higher elevation in the furnace. This creates an upper furnace atmosphere where the reburn fuel's combustion products causes some of the NO_X formed in the main burner combustion zone and reburn zone to be converted into molecular nitrogen. Depending on the amount of reburn fuel added and the amount of oxygen available in the furnace gases to combine with the reburn fuel introduced, additional combustion air may be supplied as supplemental or overfire air. Downstream of the air injection elevation, the intention is to complete the reaction of any remaining carbon monoxide (CO) to carbon dioxide (CO_2), plus reduce the amount of combustible matter remaining in the entrained flyash.

The most common forms of reburn technology applied to utility powerplant boilers are:

- Pulverized or micronized coal reburn (PCR or MiCR); and
- Gas reburn (GR).

Pulverized coal reburning and micronized coal reburning have been applied to pulverized coal and cyclone-fired boilers. NO_X reduction efficiencies of 50 to 60 percent have been demonstrated on eastern bituminous coal and midwestern bituminous and Powder River Basin (PRB) western subbituminous coals while supplying up to approximately 20-30% of the boiler's total fuel heat input to the reburn zone[7,8].

For utility powerplant boiler applications, natural gas has been utilized as reburn fuel most often, demonstrated in two basic approaches:

- Conventional gas reburn (CGR); and
- Fuel-lean gas reburn (FLGR™).

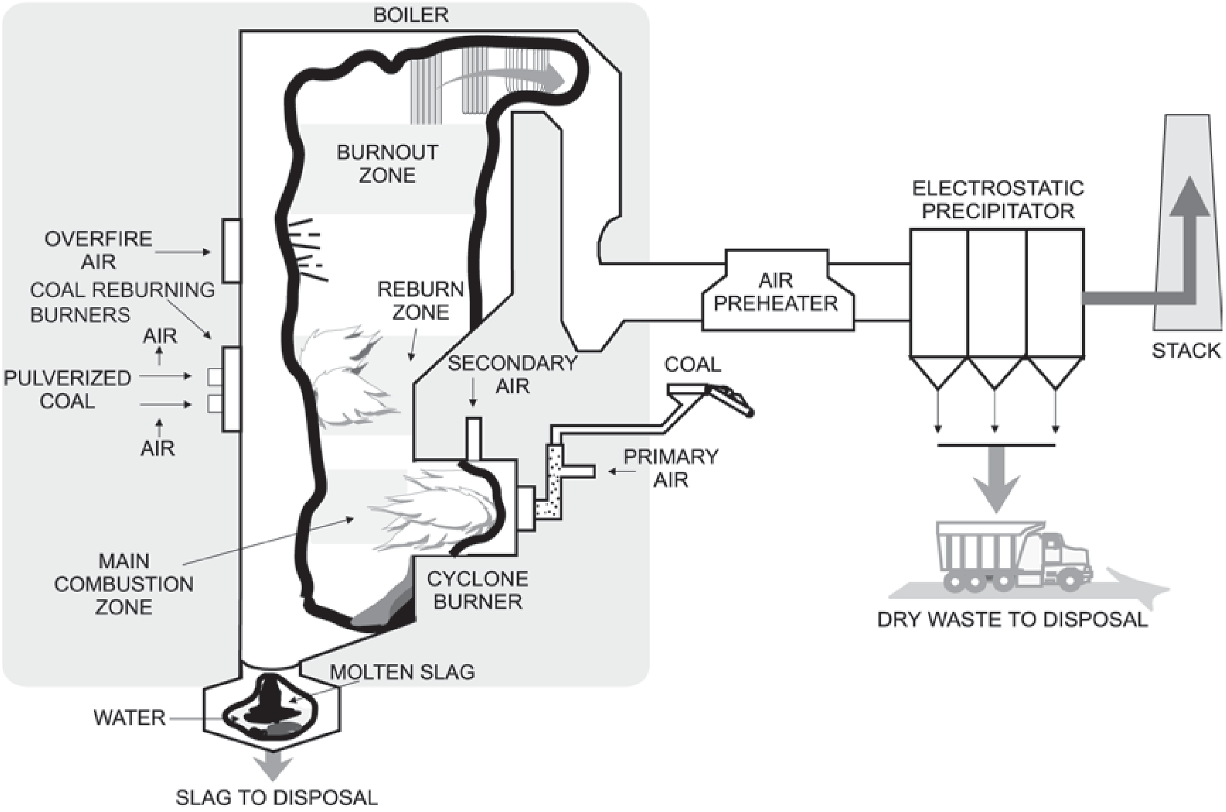
Either natural gas or pulverized coal (lignite) can be used as the reburn fuel. A sufficient quantity of natural gas is not currently available at the Milton R. Young Station plant site. Supplying enough natural gas to provide 6 to 25% of the total heat input to either or both boilers at MRY Station is expected to be technically feasible, although transport pipeline installation capital costs, and current and predicted unit natural gas costs and operating economics, are likely to be unfavorable.

Various forms of fuel reburning have been demonstrated and operated routinely on cyclone boilers for NO_X emission controls. This has been applied to units firing eastern bituminous coal, and western subbituminous or PRB/bituminous coal blends, using pulverized or micronized coal or natural gas as the most common reburn fuel. Reburning for NO_X emissions reduction has not been demonstrated on a unit firing high moisture, low heat content North Dakota lignite. Pulverized/micronized coal, along with conventional and fuel lean gas reburn technologies, are discussed below.

A.1.2.7.1 Coal Reburn

In the case of applying conventional coal reburn to cyclone boilers, the existing cyclones are supplied with the majority of the fuel, with either natural gas or pulverized coal (lignite) used as the reburn fuel such that the total heat input to the boiler is essentially the same as without fuel reburn. Separated OFA ports are located above the reburn fuel injection section of the furnace. These SOFA ports provide sufficient oxygen in a conventional fuel reburn installation to complete the combustion process that begins in the main combustion zone and is supplemented in the reburn and burnout zones. This is shown schematically for a pulverized coal reburn application on a cyclone-fired boiler with SOFA in Figure A.1-1.

Figure A.1-1 Pulverized Coal Reburn Application on Cyclone Boiler With Overfire Air[8]



In the United States, pulverized coal reburning and micronized coal reburning techniques for utility powerplant NO_X emissions reduction have been applied on a very limited full-scale, full-time basis to cyclone-fired boilers in field demonstration tests and longer-term demonstration operation, respectively. There have been only two known pulverized or micronized coal reburn installations in the United States on cyclone boilers, one on a utility boiler in Wisconsin, and one on a small industrial-size cyclone boiler in New York state[7,8,9,10,11,12,13,14]. NO_X emissions reduction efficiencies of 57 percent have been demonstrated on cyclone boilers firing eastern bituminous coal, or midwestern bituminous and Powder River Basin (PRB) western subbituminous coals while supplying up to approximately 20-30% of the boiler's total fuel heat input to the reburn zone. With the exception of the U.S. Department of Energy's (DOE) Clean Coal Technology Program demonstration projects[7,8,9], no known commercially-available coal reburn systems have been installed and are routinely operated on cyclone boilers in the United States to date. The DOE-CCTP projects for coal reburn applied to cyclone boilers are described below.

Pulverized coal reburning for NO_X emissions reduction in a cyclone-fired boiler was demonstrated on the 110 MW Nelson Dewey Unit 2 for Wisconsin Power & Light in 1991-1992. Reburn fuel preparation and handling, reburn burners with flue gas recirculation, and a separated overfire air system were added. Coal reburn tests were conducted on this unit while firing bituminous and PRB coals. NO_X emission control efficiencies of 50 to 60 percent, with reductions from 0.75-0.83 lb/mmBtu baselines to around 0.38 lb/mmBtu, but as low as 0.29 to 0.32 lb/mmBtu, with PRB coal at full load with approximately 25-30% of the total fuel heat input from reburn fuel were demonstrated[9,11,12]. The reburn system is no longer operated on Nelson Dewey Unit 2.

Micronized coal reburning has been demonstrated in 1997-1998, and continues to operate year-round on a small industrial cyclone boiler (400,000 lb/hr steam output, 50 MW gross equivalent) for Eastman Kodak Company at their Kodak Park facility in Rochester, NY. This unit (Boiler #15) achieves a NO_X reduction efficiency of approximately 57 percent on eastern bituminous coal, involving limited cyclone air-staging (cyclones believed to be slightly above 0% excess air) and a modest amount of overfire air injection downstream of the micronized reburn fuel input nozzles. Approximately 17% of the boiler's total fuel heat input is typically supplied to the reburn zone. This coal reburn system continues to operate routinely at this facility. This installation is reported to use a Fuller MicroMill to produce micronized coal with 80% passing through a 325 mesh screen[7,9,13].

If a coal reburn system was applied to MRY Station boilers, the existing cyclones would be supplied with the majority of the fuel in the form of crushed coal, and the balance of fuel would be supplied to a pair of dedicated pulverizers to feed the reburn injection ports, such that the total heat input to the boiler is essentially the same as without fuel reburn. In a conventional fuel reburn installation, OFA ports located above the reburn section of the furnace provide sufficient oxygen to complete the combustion process that begins in the main combustion zone and is supplemented in the reburn and burnout zones.

Similar to the application of separated overfire air, there are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. As a reburn fuel, lignite is expected to behave appropriately upon introduction in the lower middle furnace to help reduce NO_X emissions. The concerns are that the diversion of a significant amount of heat input from the cyclone barrels to use as a source of reburn fuel in the form of pulverized or micronized lignite may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction as part of this reburn technique will further risk slag “freezing” in the barrels and lower furnace. Reducing the number of active cyclones which are air- and fuel-staged to accommodate reduced firing rates while operating a coal-fired boiler with reburn and separated overfire air is the typical approach to avoid slag tapping problems.

Potential NO_X emissions reduction performance is expected to be limited on lignite-fired cyclone boilers with a basic form of separated overfire air system, since the reburn fuel injection location is expected to coincide with the existing lignite pre-drying system vent ports. The amount of oxygen introduced by the vent ports will be disruptive to any conventional reburn process in that it would require much higher reburn fuel injection rates to create a substoichiometric atmosphere in the lower secondary furnace that is conducive to promoting in-furnace NO_X reduction.

Significant additions to the fuel preparation equipment in the existing plant facilities will be required. The coal reburn system expected to be applied to MRY Station boilers may use two new fine-grind pulverizers and dynamic classifiers to achieve the level of coal particle size distribution required.

Higher unburned carbon levels in the flyash exhausted from the boiler may occur, especially when the reburn fuel is coal, and the regular burners are fired with less than theoretical amounts or combustion air commonly practiced with the use of overfire air. Lowering the reburn fuel injection elevation, decreasing the amount of reburn fuel, and grinding the reburn coal to a greater degree of fineness can help to offset some of the increase in flyash unburned carbon content. Flue gas opacity from the stack may increase if the particulate removal equipment is an electrostatic precipitator, due primarily to reduced resistivity and smaller particle sizes of the flyash.

An issue that affects the feasibility of lignite reburning is the uptime required for the lignite reburn fuel pulverizing system, and impact of the reburn system on effectiveness in reducing NO_X emissions during load changes and lower loads. Typically, one new pulverizer is dedicated to prepare reburn fuel in existing pulverized fuel-fired boiler applications. Cyclones may be fired with less fuel or deactivated during boiler operation in order to accommodate changes in fuel combustion characteristics, boiler load, and for scheduled or unscheduled individual crusher maintenance. Milton R. Young Station Unit 2 has twelve crushers for cyclone coal grinding, each dedicated to one of the twelve cyclone furnaces. Diverting as much as 30% of the total heat input as reburn fuel could require four existing cyclones to be deactivated, and two new MPS-89 pulverizers to be dedicated to reburn fuel preparation. As each of these mills requires periodic maintenance, boiler emissions and/or load could be negatively impacted during individual reburn mill outage periods while the boiler remained in service. A high level of fineness of coal particles from the reburn mills is important to achieve and maintain in order to limit increases in flyash combustibles. A minimum of 60 percent passing through 200 mesh fineness is recommended by one of the reburn technology vendors (B&W) for pulverized lignite reburn. Micronized coal reburn requires even greater fineness: 70-80 percent passing through a 325 mesh screen.

Pulverized or micronized coal reburn with the advanced form of separated overfire air (ASOFA) can be applied and installed on MRY Station Unit 2's boiler. These combined techniques are expected to reduce NO_X emissions approximately 54% from current pre-control baseline levels (down to 0.36 lb/mmBtu) for the MRY Station Unit 2 boiler. These levels of NO_X reduction depend on the advanced form of separated overfire air technique to achieve the expected NO_X reduction percentages when applied to lignite-fired cyclone boilers, which may not be successful given the concerns expressed about the potential impacts of this technique. Using finely pulverized lignite for reburn fuel is considered technically feasible for NO_X emissions control under evaluation for application to MRY Station Unit 2's boiler.

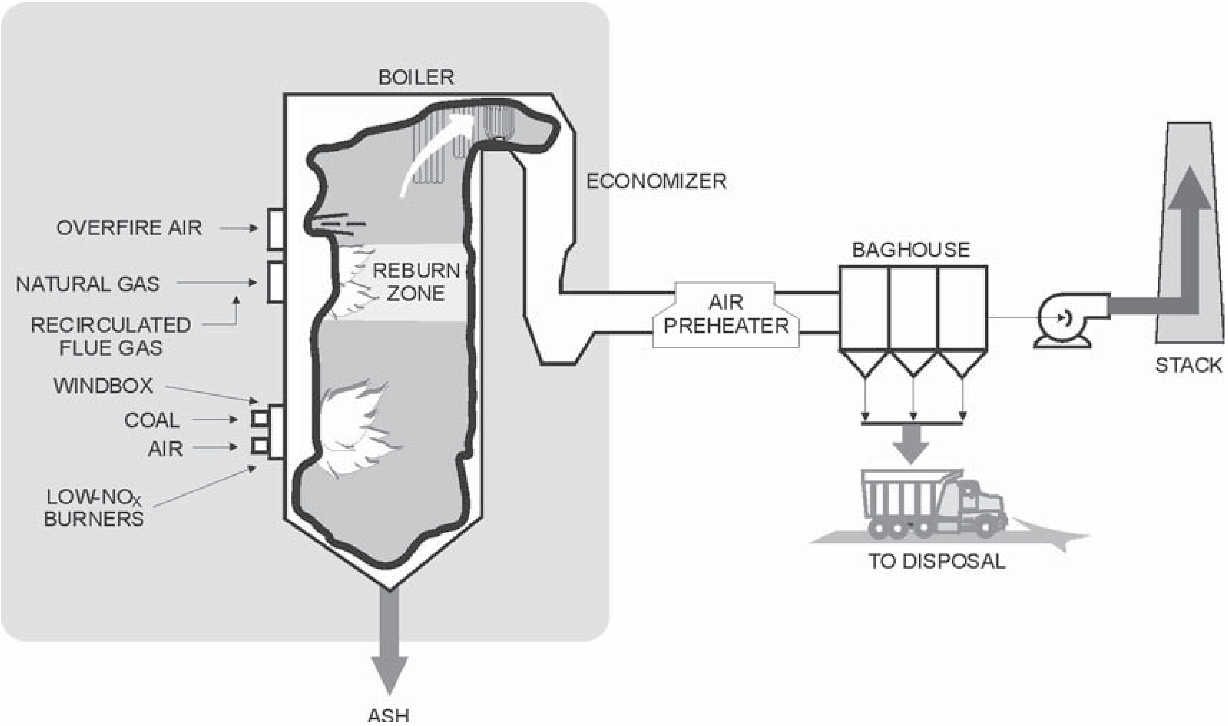
A.1.2.7.2 Conventional Gas Reburn

Natural gas has been preferred as the reburn fuel of choice. Natural gas has been utilized for reburn fuel in two basic approaches: conventional reburn and fuel-lean gas reburn. In the conventional approach, up to 30% of the boiler's total fuel heat input is supplied to the reburn zone, followed by a significant amount of overfire air for completion of combustion prior to flue gases exiting the boiler.

Conventional gas reburning in a cyclone-fired boiler has been available at Tennessee Valley Authority's Allen Station Boiler #1 (300 MW) since 1998. The reburn technology provider (vendor) claims NO_X emissions were reduced 67% from a full-load baseline of 1.29 (down to 0.42) lb/mmBtu when firing a blend of western bituminous and PRB coals[14]. Conventional gas reburn fuel input rates were not available from the technology vendor's literature. Another reference source of information stated NO_X emissions were reduced 65% from a full-load baseline of 0.86 (down to 0.30) lb/mmBtu with 7 percent of the total fuel heat input supplied as reburn fuel[9].

A schematic graphic of conventional gas reburn on a pulverized coal-fired boiler is shown in Figure A.1-2.

Figure A.1-2 Natural Gas Reburn Application on Wall-Fired Pulverized Coal Boiler with Overfire Air[8]



Similar to the application of separated overfire air, there are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. For the most effective NO_X reduction by applying the various available forms of fuel reburn, the injection of fuel is usually performed using recirculated flue gas as a diluent and carrier media to aid dispersion and avoid completely oxidizing the carbon and nitrogen components in the fuel and furnace gases from staged burners/cyclones. Improved gas reburn designs have reduced or eliminated FGR with higher gas injection pressures. For lignite-fired cyclone boilers, reburn fuel firing with a basic form of separated overfire air is expected to be much less effective in reducing NO_X emissions than previously demonstrated elsewhere. This is related to the likelihood that the injection of reburn fuel will be near the elevation of the existing lignite drying system vent ports, and that the oxygen introduced with the lignite drying system's vented moisture will disrupt the desired in-furnace nitrogen oxides reduction process.

It should be recognized that application of air-staged cyclones with basic or advanced forms of SOFA with reburn techniques will require the overfire air injection ports to be located at a somewhat lower elevation of the furnace compared with air-staged cyclones without reburning. This means that less air-staging of the cyclones may be practiced, or that less residence time will be available for the in-furnace NO_X reduction process to occur.

Similar to coal reburning, there are concerns that withholding a significant amount of heat input from the cyclone barrels to use natural gas as a source of reburn fuel may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Air-staging the cyclones for use of separated overfire air to further complement combustion NO_X reduction as part of this reburn technique will further risk slag "freezing" in the barrels and lower furnace. Reducing the number of active cyclones which are air- and fuel-staged to accommodate reduced firing rates while operating a coal-fired boiler with conventional reburn and separated overfire air systems is the typical approach to avoid slag tapping problems. Natural gas reburn with the advanced form of separated overfire air (ASOFA) can be applied and installed on Milton R. Young Station's Unit 2 boiler.

Although the unit operating and capital costs to supply large quantities of gaseous fuel not currently available at this site are economic disadvantages, using high-pressure natural gas for reburn fuel is considered technically feasible for NO_X emissions control under evaluation for application to MRY Station Unit 2's boiler.

A.1.2.7.3 Fuel Lean Gas Reburn

Another approach to gas reburning is “fuel-lean gas reburn” (FLGR™) technology, which injects limited amounts of natural gas (approximately 3-10 percent of the total fuel heat input) above the burners (or cyclones) with or without significant air-staging of the burners (cyclones) or the addition of overfire air upstream of the fuel injection elevation. FLGR’s first field-test on a cyclone-fired boiler was at Commonwealth Edison’s Joliet Unit 6 (327 MW), a 9-cyclone-furnace boiler[15]. NO_X emissions reduction with FLGR (without SOFA) was believed to be approximately 35-40% with 7% of the boiler’s total fuel heat input supplied in the reburn zone. This test yielded 0.59 lb/mmBtu NO_X emissions from a baseline of 0.98[16]. One other cyclone boiler has been modeled using computational fluid dynamics (CFD) as part of a study looking at applying FLGR at Owensboro Municipal Utilities’ Elmer Smith Station Unit 1 (150 MW single-wall, eastern bituminous coal-fired boiler). This model predicted that NO_X emissions could be reduced by 25-30% over that achievable from overfire air and SNCR[17].

More commonly, FLGR™ has been applied on medium to large pulverized coal wall-fired boilers burning eastern bituminous or western subbituminous coals. On Wisconsin Electric Power Company’s (WEPCO’s) Pleasant Prairie Unit 1, a 620 MWg Riley turbo-fired wet-bottom (slagging) boiler, FLGR™ alone was predicted to reduce NO_X emissions by 35-39 percent at a gas reburn rate of 7-8 percent but only achieved 20% from a baseline of 0.45 lb/mmBtu[16,18]. This is presumably without burner air-staging or SOFA. It has also been applied in combination with SNCR at this WEPCO site.

A potential advantage of FLGR™ over conventional gas reburn is that the former is generally compatible with, but does not require, the installation and operation of SOFA. The staged reburn fuel is introduced into an oxygen-rich atmosphere downstream of the burners and any OFA injection points. The amount of reburn fuel injected is typically limited by acceptable carbon monoxide levels in the boiler exit flue gas.

There are potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application. This is significant, especially for alternatives with FLGR™ technology when combined with basic or advanced SOFA to allow the natural gas introduced above the SOFA ports to burn completely prior to the furnace exit plane. In either case, the amount of additional potential NOx reduction possible with FLGR™ is limited, since the reburn fuel injection location is expected to coincide with the existing lignite pre-drying system vent ports. The amount of oxygen introduced by the vent ports will be disruptive to the fuel-lean reburn process in that it would require much higher reburn fuel injection rates in the lower secondary furnace to promote in-furnace NO_X reduction. There are reduced concerns that the withholding of a modest amount of heat input from the cyclone barrels to use natural gas as a source of reburn fuel may reduce cyclone temperatures enough to inhibit slag formation and flow, especially as boiler load is reduced. Air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction is an optional part of this reburn technique which will further risk slag "freezing" in the barrels and lower furnace.

Fuel lean gas reburn can be applied and installed on MRY Station Unit 2's boiler with or without SOFA/ASOFA. This technique is considered technically feasible for application to MRY Station Unit 2's boiler. Expected NO_X reduction will be modest for FLGR™ without SOFA and FLGR™ with a basic form of SOFA. Unit operating and capital costs to supply large quantities of gaseous fuel not currently available at this site are economic disadvantages. Because of these factors, these variations of this technology will not be cost-effective compared to other alternatives with similar control effectiveness. FLGR™ without SOFA and FLGR™ with a basic form of SOFA were not included in the control effectiveness and cost-effectiveness sections of the main report.

Other demonstrated forms of fuel lean gas reburning in combination with post-combustion technologies, such as amine-enhanced fuel lean gas reburn (FLGR™ with SNCR), are discussed under the layered technologies section.

A.1.2.7.4 Fuel Oil Reburn

Fuel oil has been substituted for natural gas in a conventional reburn application. This is much less common in the United States than using natural gas as a reburn fuel, due to the general lack of demand and difficulties in supplying the volume of fuel oil which would be required. It has been installed commercially on three 350 MW oil-fired boilers in New Brunswick (Canada) at the Coleson Cove plant. NO_X emissions reduction with reburn and SOFA was 78% with 25% of the boiler's total fuel heat input supplied in the reburn zone. This yielded 0.22 lb/mmBtu NO_X emissions from a baseline of 1.0 lb/mmBtu[9]. No examples of conventional fuel oil reburn applied to a coal-fired cyclone boiler were found in available literature.

Fuel oil reburn could potentially be considered for application to MRY Station Unit 1 and Unit 2 boilers. Investigation of the specific source, distance, and costs for supplying significantly increased quantities of fuel oil via transport trucks hauling tanker trailers or underground pipeline to M.R. Young station has not been performed. The unit operating and capital costs to supply large quantities of high-volume liquid fossil fuel at this site are economic disadvantages. The concerns regarding potential impacts and limitations unique to the firing of North Dakota lignite in cyclone-fired boilers that should be recognized as part of this emission reduction technology application are similar to those expressed for conventional gas reburn. It is believed that potential NO_X control with oil reburn would be slightly less than comparable conventional gas reburn systems.

Although fuel oil reburn could potentially be considered for application to MRY Station Unit 2's boiler, the lack of any distinct potential NO_X reduction advantages and demonstration on cyclone-fired boilers does not appear to support its consideration. This alternative was not included in the NO_X control and cost-effectiveness analysis.

A.1.3 Post-Combustion Controls

Post-combustion controls deal with techniques that thermally or chemically-treat the flue gases to reduce NO_X emissions after they have exited the boiler's lower furnace. In the case of Milton R. Young Station Unit 2, this primarily involves forms of selective catalytic reduction (SCR) and selective non-catalytic reduction (SCR) technologies. Another emerging technology that has recently entered the commercial market is Powerspan's Electro Catalytic Oxidation®, which treats utility boiler flue gas for removal of nitrogen oxides, sulfur oxides, and mercury. Another emerging technology that has recently entered the commercial utility air pollution control market is Powerspan's Electro Catalytic Oxidation®, which treats boiler flue gas for removal of nitrogen oxides, sulfur oxides, and mercury.

A.1.3.1 Selective Non-Catalytic Reduction (SNCR)

Selective Non-Catalytic Reduction (SNCR), and variations such as hydrocarbon-enhanced SNCR (sold under the trade name of NOxStar™), and Rich Reagent Injection (RRI), are all post-combustion types of boiler NO_X emission controls. While these technologies are insensitive to the specific fuel types whose combustion products are being treated, the large majority of boiler applications to date have been on pulverized coal-fired units burning eastern bituminous fuels. SNCR has been used to reduce NO_X emissions on numerous utility boilers burning eastern bituminous coal, midwestern bituminous coal, and, to a lesser extent, western subbituminous coal. SNCR has also been used with fuel oil and natural gas-fired units. SNCR (and hydrocarbon-enhanced SNCR) technologies can each be applied to cyclone boilers with or without the use of a SOFA system. SNCR does not appear to be dependent directly on the type of burners (wall-fired, tangentially-fired, and cyclone-fired) employed in the boilers where it has been installed, with or without overfire air in full operation. Operation at these plants has demonstrated that SNCR can decrease NO_X emissions as much as 15-40% at full load, most typically between 25-35 percent[19].

In the conventional SNCR process, urea or ammonia is injected into the boiler in a region where the combustion gas temperature is in the 1700 to 2100 degrees F range. Under these temperature conditions, the urea reagent [$CO(NH_2)_2$] or ammonia [NH_3] reacts with the NO_X, forming N_2 and water, reducing NO_X emissions.

Long-term examples where SNCR has been used to reduce NO_X emissions on two cyclone-fired boilers are on a 138 MW unit and 160 MW unit burning eastern bituminous coal at Conectiv's B.L England Station (Units 1 and 2) since 1995 and 1996, respectively. Tests at these plants demonstrated that SNCR can decrease NO_X emissions as much as 30-36% at full load, from around 1.3-1.4 lb/mmBtu respectively to as low as 0.85 lb/mmBtu (without overfire air)[18,19,20]. These boilers, located near Atlantic City, New Jersey, continue to operate SNCR (with OFA) for annual NOx emissions around 0.55 and 0.45 lb/mmBtu, respectively.

SNCR can be applied and installed on MRY Station boilers. Estimated NO_X emission rates for using SNCR with North Dakota lignite considered published levels achieved by cyclone-fired units firing western subbituminous coal, and vendor predictions. SNCR alone is expected to reduce NO_X emissions approximately 37% from MCR baseline levels (down to around 0.5 lb/mmBtu) for the MRY Station Unit 2 boiler with ammonia slip limited to approximately 5 ppmvd. Because of the operating costs of the consumed reagent, this technology will not be cost-effective compared to other alternatives with similar control effectiveness (i.e. SOFA), SNCR alone was not included in the control effectiveness and cost-effectiveness sections of the main report.

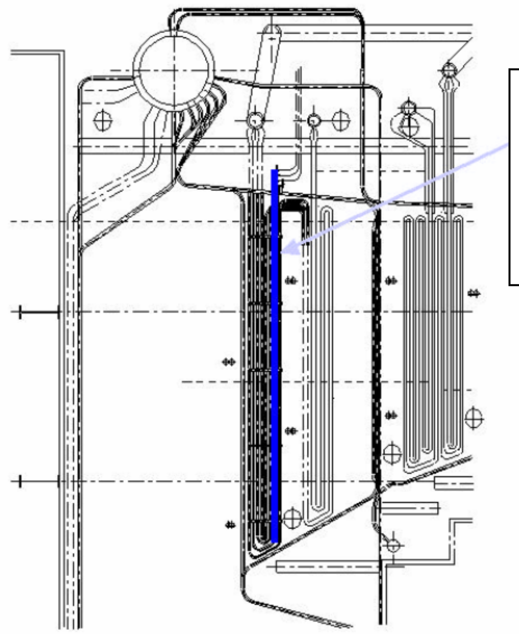
Other demonstrated forms of SNCR-related technologies, such as Rich Reagent Injection with SNCR, and amine-enhanced fuel lean gas reburn (FLGR™ with SNCR), are discussed under the layered technologies section.

A.1.3.2 Hydrocarbon-enhanced SNCR (NOxStar™)

Hydrocarbon-enhanced SNCR technology, commercially marketed as NO_XStar™, is offered by a single vendor (Mitsui Babcock) as a post-combustion type of enhanced SNCR technology, whereby an ammonia-based reagent is continuously injected into the superheater/reheater pass of an operating boiler with small amounts of gaseous hydrocarbon (typically either natural gas or propane) and air or steam to provide lance cooling and aid reagent dispersion. The targeted combustion gas temperature range is between 1500°F and 2000°F. The amount of gaseous hydrocarbon introduced is small enough (0.1 to 0.2% of total fuel heat input) that this is not intended to act as a form of reburn or staged fuel combustion. An array of permanently-installed injection lances are located within the boiler convection pass, divided into numerous discrete zones across the full width and height of the duct. The hydrocarbon auto-ignites, forming hydroxyl (OH) radicals which react with the NO_X and ammonia to produce elemental nitrogen (N_2) and water vapor (H_2O).

NO_XStar™ was demonstrated at Tennessee Valley Authority's Kingston Power Station Unit 9 (tangentially-fired 200 MW twin-furnace boiler firing eastern bituminous coal) in 2002[21]. This technology was subsequently permanently-installed at TVA's Colbert Station Unit 4 in late 2003 on a 192 MW wall-fired boiler burning eastern bituminous coal[22]. NO_X reduction was stated as 68-80% for these applications, which included the impact of overfire air and air-staged combustion upstream of the ammonia and propane injection locations.

An example of a hydrocarbon-enhanced SNCR installation on a wall-fired pulverized fuel boiler is shown as a sectional side elevation view of the upper furnace in Figure A.1-3.



NOxStar™ ammonia/hydrocarbon/steam injection lances (vertical lances behind secondary superheater inlet tubes

Figure A.1-3 Hydrocarbon-enhanced SNCR Application on PC-fired Boiler[22]

The supplier (Mitsui Babcock) of hydrocarbon-enhanced SNCR technology claims there is little sensitivity to the type fuel (coal) or burners this technique can be potentially applied to in order to reduce NO_X emissions. The chemical reagent injection for hydrocarbon-enhanced SNCR (NO_XStar™) NO_X control technology must be precisely located and carefully controlled to be effective. Operation outside of the required operating ranges can even result in increased NO_X emissions. Extensive computational fluid dynamic (CFD) model simulations are needed to determine the optimum injection points and spray patterns. Boiler operating conditions change with unit load and varying fuel characteristics. The NO_XStar™ process control system must be able to adjust for these changing conditions in order to be effective throughout the intended load range and firing conditions encountered. Non-retractable ammonia injection lances arranged in a parallel-series manner are permanently mounted inside the upper furnace zone, attached to convective tube elements. Different sections of the injection "grid" can be turned off or on, depending on load and firing conditions and amount of NO_X reduction required. Injection nozzles are continuously purged and cooled by extracted superheated steam from the boiler's main steam outlet, whether ammonia reagent is being introduced into the flue gas stream or not. Ammonia slip can be minimized by injecting less reagent, although NO_X control performance will be reduced.

There are a number of issues with firing North Dakota lignite that make the applicability of hydrocarbon-enhanced SNCR infeasible compared to previous experience in other coal-fired powerplants. These issues include:

- Hydrocarbon-enhanced SNCR (NOxStar™) technology has not been applied to cyclone boilers (with or without the use of a SOFA system). It has been only applied to date on pulverized coal-fired boilers burning eastern bituminous fuels.
- There is no successful demonstrated full-scale experience in continuous service of hydrocarbon-enhanced SNCR (NO_XStar™) technology on units firing high-slagging coals such as western subbituminous (PRB) and lignite. The heat transfer surfaces in the convective heat transfer zone where the reagent mixture is injected are prone to severe fouling from flyash constituents common in North Dakota lignite coals. Flyash deposit accumulation on the outside of the NO_XStar™ lances in Milton R. Young Station Unit 2 boiler's upper furnace is expected to be significant, potentially occurring within a matter of a few weeks from startup and nearly impossible to prevent or remove effectively during boiler operation. Such buildup is expected to cause maldistribution of the NO_X reduction chemical reagent from the injection nozzles. Effective on-line removal of these deposits from the injection nozzles is anticipated to be insufficient to maintain effective injection distribution and volume control. It is anticipated that this would significantly reduce the NO_X emission reduction performance consistently achieved on a sustainable basis.

The lack of experience with cyclone boilers, especially those firing coal with severe deposition characteristics such as North Dakota lignite, makes this technology technically infeasible for application on the Milton R. Young Station Unit 2 boiler.

A.1.3.3 Rich Reagent Injection (RRI)

Rich Reagent Injection (RRI) is a NO_X control process that has been developed and demonstrated specifically for use on cyclone boilers. Rich Reagent Injection is an SNCR process that involves the injection of aqueous urea into the lower furnace between the cyclones and the SOFA ports. RRI targets a high temperature, fuel-rich zone within the boiler-furnace environment immediately adjacent to the cyclone burners, and requires temperatures in the range of 2400 to 3100 degrees F.

The three zones of a Rich Reagent Injection SNCR application on a boiler with separated overfire air are shown as a sectional side elevation view of the furnace in Figure A.1-4.

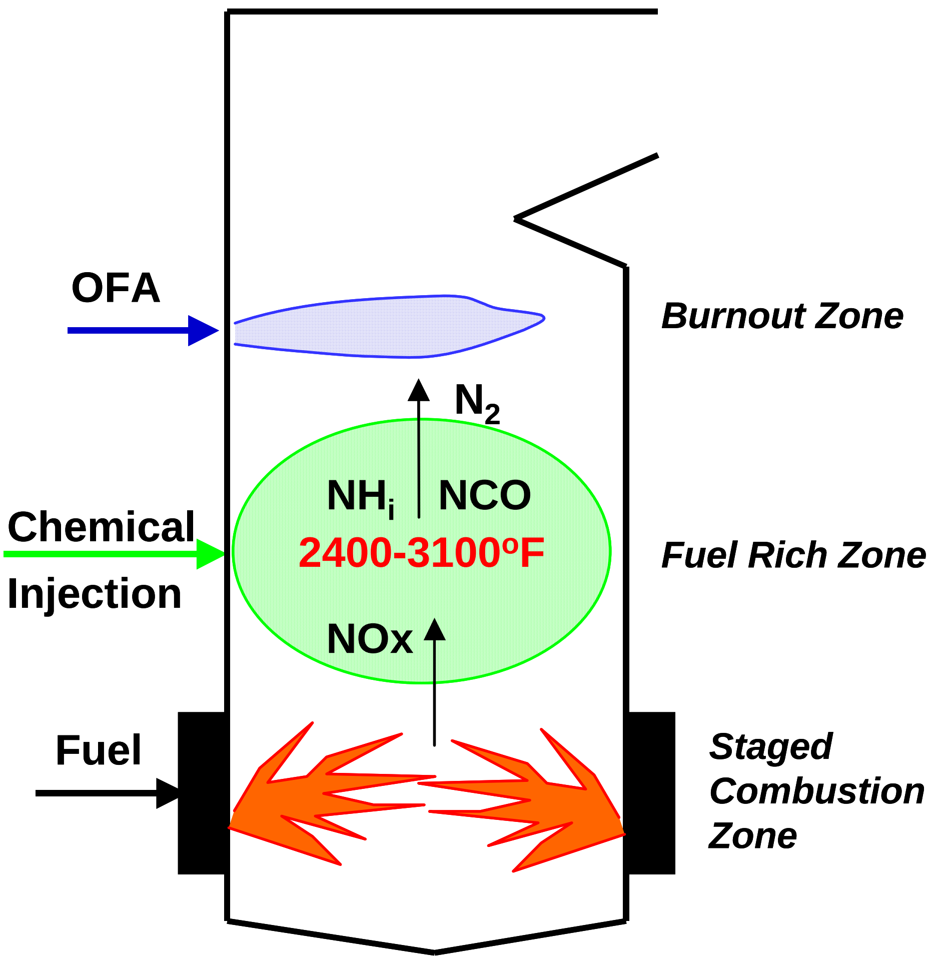


Figure A.1-4 Rich Reagent Injection Application on Boiler With Overfire Air[23]

The Rich Reagent Injection (RRI) process has been successfully demonstrated on at least two cyclone-fired boilers, with the most recent installation at Ameren's Sioux Unit 1, a 500 MW boiler firing a blend of PRB and midwestern bituminous coals. Generally, the heat content of these coals typically varies very little. Short-term testing of the RRI process has been performed alone and in combination with SNCR on B.L. England Unit 1 in 1999[24,25], and more recently at Ameren's Sioux Unit 1 in 2002[23,25], in 2004[26] (alone), and in the first half of 2005[27] (alone, and with SNCR).

The RRI process is intended to be used only with air-starved (substoichiometric staged-air) cyclone combustion, in conjunction with the installation and operation of an OFA system. The RRI process has not been demonstrated on any unit that fires North Dakota lignite. As of October 2006, no commercial installation of a permanent Rich Reagent Injection system has been made at any cyclone-fired boiler.

There is only one holder of a commercial license for modeling and conceptually designing RRI (Reaction Engineering International), with two vendors sub-licensed to design and sell RRI equipment (Fuel Tech and Combustion Components Associates). Since these license agreements are in place, and considering that successful demonstration testing has been performed at two cyclone-fired boiler powerplants, this technology is considered to be applicable and commercially available for potential application on cyclone boilers which burn coals with heat contents that are relatively constant. However, due to the variable heat content of lignite coal, RRI is considered to be technically-infeasible for application on North Dakota lignite-fired boilers. Technical feasibility and expected NO_X emissions from RRI for application on the Milton R. Young Station Unit 2 boiler are included in the “Layered NO_X Reduction Technologies” section.

A.1.3.4 Selective Catalytic Reduction (SCR)

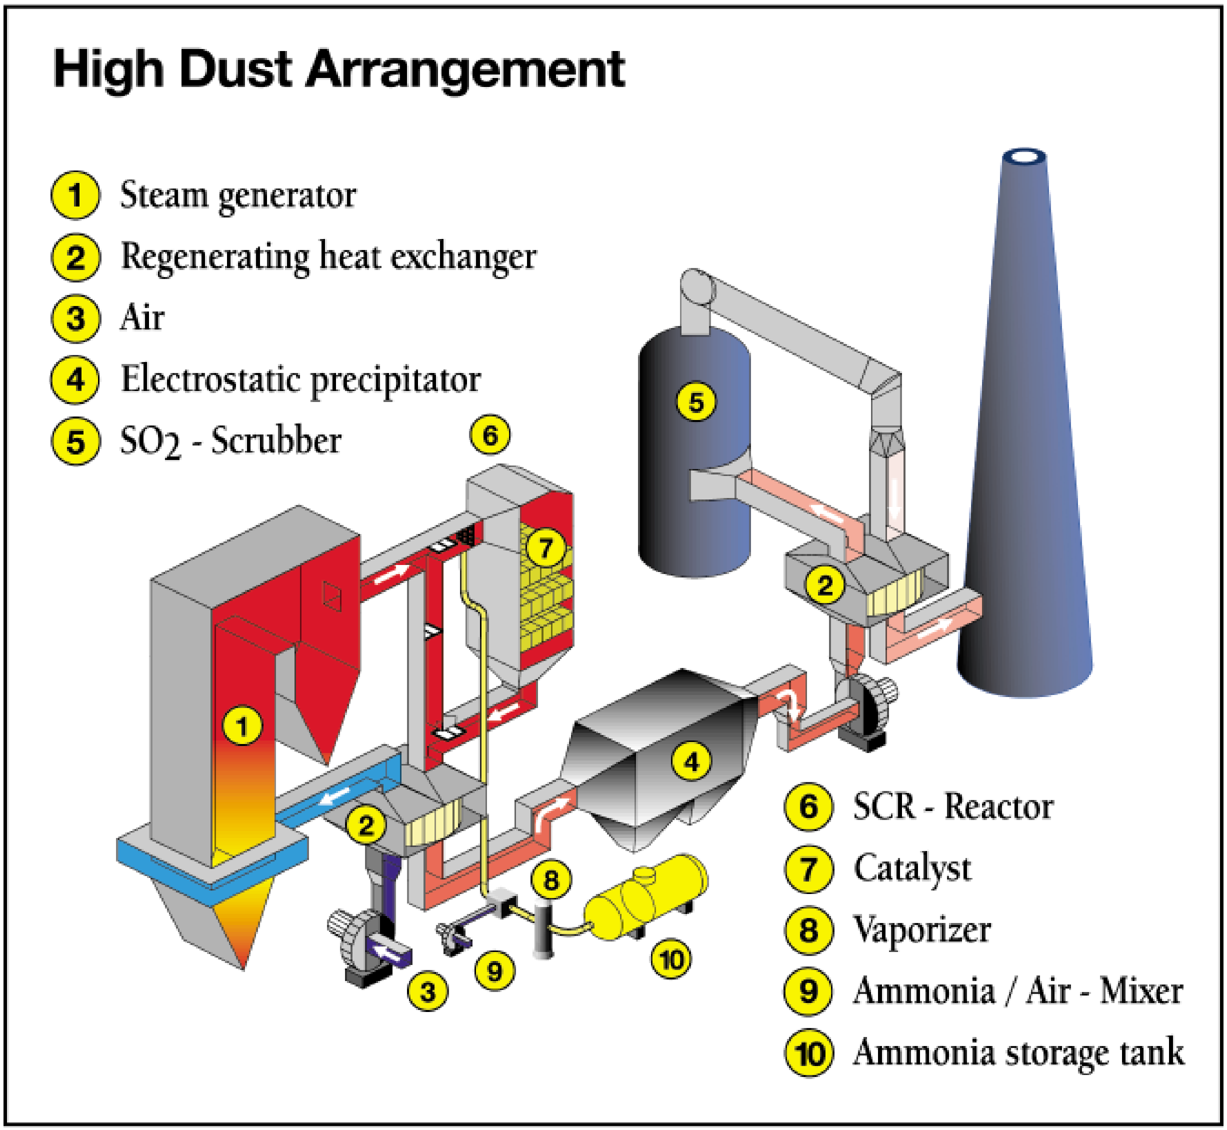
The lowest NOx emission levels from coal-fired utility boilers are typically achieved by installing and operating selective catalytic reduction (SCR) technology. In the SCR process, the gas stream is passed through a catalyst bed in the presence of ammonia to reduce NO_X to molecular nitrogen and water. The process is termed “selective” because the ammonia preferentially reacts with the NO_X rather than with the oxygen in the flue gas. A catalyst is used to enhance NO_X reduction and ammonia utilization at appropriate flue gas temperatures. SCR is usually applied to flue gas in the 600°F to 750°F temperature range. There are variations in the SCR process for coal-fired boilers that mostly involve locations in the flue gas path where the catalyst is placed in order to promote the desired NO_X emission reduction effect. These are described below.

A.1.3.4.1 High-Dust Selective Catalytic Reduction (HD-SCR)

For coal-fired boilers, a conventional SCR reactor utilizes readily-available catalyst materials and reagent in the form of ammonia. A conventional SCR reactor is commonly installed in a high-dust, hot-side arrangement, located between the economizer outlet and air heater inlet, where the flue gas temperature is within the desired operating range for the SCR catalyst. The conventional SCR reactor arrangement is preferred for most coal-fired applications in utility boilers because it avoids the added expense of reheating the flue gas if placed after the air heaters which cool the flue gas, and downstream of any flue gas treatment to remove acid gases. Conventional SCR technology uses an ammonia injection grid (AIG), which consists of multiple nozzles, for distributing the reagent into the flue gas at the boiler’s economizer flue gas outlet.

A schematic graphic diagram for a conventional high-dust, hot-side SCR system on a boiler with a flue gas desulfurization system and stack gas reheat is provided in Figure A.1-5.

Figure A.1-5 Conventional High-Dust SCR Arrangement with FGD Scrubber Outlet Reheat



(figure copied from Wheelabrator Air Pollution Control literature)

Conventional high-dust, hot-side SCR technology has been installed on several pulverized coal and cyclone boilers firing bituminous and subbituminous coal in the United States. There are also a limited number of European SCR installations on steam electric generating units (SEGUs) firing lower grade (brown) coal. There are, however, no existing full-scale SCR installations on units that fire North Dakota lignite. There are approximately 50 cyclone-fired units located in the states affected by EPA's NO_X SIP call. Over half of these units are planning to install conventional high-dust, hot-side SCR systems in response to the SIP call. The installation of conventional high-dust, hot-side SCR systems has been completed on approximately 22 of these units. Appendix A2 lists several conventional high-dust hot-side U.S. SCR installations on pulverized coal and cyclone-fired utility boilers, along with measured NO_X emissions. Initial data from these units indicate that conventional high-dust, hot-side SCR systems operated on suitable cyclone-fired units may be able to reduce NO_X emissions to as low as 0.07 lbs/mmBtu. Several SCR installations have been retrofit on existing cyclone-fired boilers burning western subbituminous coal (or PRB blended with midwestern bituminous coal). For cyclone coal-fired utility boilers retrofitted with SCR technology, all were originally designed to burn bituminous coal.

The EPA NO_X SIP call only applies to units in the eastern United States. There are no facilities firing North Dakota lignite in the EPA NO_X SIP call region. SCR system operation is currently only needed during the ozone season (June – September) for units installing control equipment solely to meet the EPA NO_X SIP call requirements. Limited annual operation is a significant factor with respect to SCR equipment reliability, maintenance, operational costs, and catalyst life. The demands on the SCR system are much more severe if the equipment is required to operate on a full-time, annual basis.

Two byproducts from the high-dust, hot-side SCR process are ammonia slip and SO_3:

- Ammonia Slip: Slip is ammonia that is unreacted in the NO_x emission reduction process. Maximum ammonia slip for a gas fired unit is usually 10 ppmvd whereas, on a coal fired unit, ammonia slip below 5 ppm is desired. For certain applications, this concentration can be problematic, therefore requiring more catalyst to reduce slip. Most new SCR applications have ammonia slip guaranteed at a 2 ppmvd maximum for an initial operating period.
- SO_3: Due to the composition of typical SCR catalysts, a small percentage of inherent SO_2 will be oxidized to SO_3. This oxidation can be controlled by catalyst selection and can be less than one percent. SO_2 to SO_3 oxidation must be carefully controlled to avoid creating SO_3 levels sufficiently high to raise the possibility of air heater fouling. A unit firing high-sulfur coal with SCR technology is especially vulnerable to SO_3 oxidation and ammonia slip-related fouling problems. The deposition and fouling is due to formation of solid ammonium sulfate ($(NH_4)_2SO_4$) and liquid ammonium bisulfate (NH_4HSO_4). The most important design variable is optimizing the catalyst selection and amount of catalyst that will reduce NO_X emissions, control ammonia slip, and minimize SO_2 oxidation.

Recent technology has allowed catalyst suppliers to make more rigorous and lengthy guarantees. A reasonable initial operating period for conventional catalysts in high-dust reactor arrangements on boilers firing eastern or midwestern bituminous coal is around 24,000 active operating hours (i.e. when ammonia reagent is being injected). Factors that need to be taken into account in design of a high-dust, hot-side SCR application that affect the need for catalyst replacement are:

- Pressure drop: The amount of restriction to flue gas flow through the SCR inlet, ammonia injection grid, SCR reactor, and downstream ductwork directly increases induced draft fan horsepower required to maintain adequate boiler draft. This is an important parameter to consider and minimize during the design stage. Pressure drop is a function of the average and maximum SCR reactor duct velocities, the amount of restriction caused by flow distribution correction devices (baffles or vanes), and the number and geometrical aspects of the catalyst layers. Many retrofit SCR installations require a booster fan or upgraded induced draft fan to overcome the added flow resistance. This increases operating cost for the increase in auxiliary power consumption and loss of saleable electric power. The type and pitch of the catalyst are factors most influential in determining the amount of pressure drop.
    - Catalyst type: The most common types or forms of catalyst material are honeycomb or plate. The former offers more surface area per volume, but can be more restrictive and prone to pluggage from ash deposits. The latter is usually less restrictive but requires more catalyst per layer or more layers to achieve the active surface needed to achieve the intended NO_X emission reduction.
    - Catalyst pitch: The pitch of the catalyst, a term used to describe the size of the gas path openings through the catalyst, varies depending on the manufacturer and design dust loading. Pitch is generally on the order of 5 to 7 millimeters. Potential pluggage of flow channels within the catalysts layers is therefore an issue that must be dealt with during design.
- Catalyst performance: The amount of NO_X emission reduction expected is a function of the specific activity level of the catalyst material and the amount of catalyst installed, over a given period of time. Catalyst formulation selection and features of construction have a significant impact on long-term NO_X emission reduction and subsequent costs for reagent and catalysts replacement. The frequency of catalyst replacement is influenced strongly by:
    - Catalyst erosion: Erosion of the catalyst material in coal fired units from entrained flyash or sootblowing action reduces the amount of active surface available for reacting with the reagent and flue gas, and can cause distortions in gas distribution (“channeling”) through the

SCR reactor. Catalyst material is fragile and can be easily damaged. Some catalyst is provided with erosion-resistant top edges to mitigate this tendency.

- Moisture absorption: Many types of catalyst are damaged by absorption of moisture. The reactor must be kept above ambient dewpoint temperatures or protected from freezing during outages in order to protect the catalyst from moisture damage. Spare catalyst must be carefully packaged to keep it dry and must be handled delicately to prevent damage.
- Thermal degradation: The specific active elements of the catalyst surface, or the matrix structure itself upon which the catalyst material is applied, can degrade when exposed to flue gas temperatures greater than the intended design of the formulation. High flue gas temperatures within the reactor causes sintering, leading to a permanent loss of catalyst activity due to a change in the pore structure of the catalyst. Proper selection and manufacturing control of the catalyst structure and formulation can minimize thermal degradation.
- Catalyst poisoning: The loss of performance or activity of the catalyst over time can be due to chemical damage or poisoning. Two elements especially detrimental to the life of common titanium-supported vanadium pentoxide SCR catalyst are arsenic and zinc. Vanadia/tungsten-based catalysts are particularly susceptible to rapid deactivation due to gaseous arsenic poisoning. In some German SCR installations, a 50% loss of activity has been reported within 10,000-15,000 operating hours. Addition of molybdenum to a vanadia-titanium SCR catalyst on similar applications shows relative activity reductions of 20-25%. Progressive loss of SCR NO_X reduction performance from catalyst deactivation due to poisoning is not possible to restore without effective cleaning to remove the deposits, or eventual replacement.
- Catalyst fouling: The surface area potentially exposed to the reagent (ammonia) and nitrogen oxides in the flue gas can become fouled with flyash or sulfur-related compounds. The presence of excess calcium oxide in the presence of sulfur in the flue gas can form a calcium sulfate surface coating that can be extremely dense, masking the pores of the catalyst. Progressive loss of SCR NO_X reduction performance from catalyst deactivation due to fouling is difficult to restore without effective cleaning to remove the deposits, or eventual replacement.

SCR technology has been installed on numerous coal-fired utility boiler facilities around the world and there are a large number of manufacturers that market the catalysts. The question is whether SCR is a feasible technology for a unit firing North Dakota lignite. There are serious concerns whether installation of SCR technology on a North Dakota lignite-fired unit can be successful, especially in a conventional "hot-side, high-dust" configuration. The effectiveness of the SCR process is highly dependent upon the ability of the nitrogen oxides in the flue gas being able to contact the active sites within microscopic pores of the catalyst in the presence of ammonia reagent with minimal interference from contaminants.

A recent technical paper "Ash and Mercury Behavior in SCR Catalysts When Firing Subbituminous and Lignite Coals" by the Energy & Environmental Research Center (EERC) of the University of North Dakota was published in the February 2005 issue of Fuel Processing Technology magazine[28]. This paper summarized the results of SCR slipstream testing at two PRB-fired plants and one North Dakota lignite-fired powerplant. The evaluation included determination of impacts of ash on SCR plugging and blinding. Flue gas was isokinetically extracted from the convective pass of the boiler upstream of the air heater. Pressure drop across the catalyst was measured during the initial two-month test period, and the two consecutive two-month test periods following the initial trial, while holding flue gas flow and temperatures constant. Ammonia was injected downstream of a screen, upstream of a flow straightener and air pulse section. Compressed air was injected ahead of the reactor, and was periodically pulsed to simulate sootblowing to minimize ash deposit accumulation.

This slipstream SCR testing examined the significance of ash accumulations on SCR catalyst on both the macroscopic and microscopic levels. Very small flyash particles were found bonded together by a matrix of sodium-, calcium-, and sulfur-rich materials, likely in the form of calcium sulfate. North Dakota lignite coal contains many alkali and alkaline-earth elements, and sulfur. The firing of lignite coal which produces fine (less than 5-µm diameter) flyash particles creates conditions that enter the pores of the catalyst, react with SO_3 in the flue gas, and form sulfates which bind other ash particles into the matrix.

As posted on Electric Power Research Institute Inc.'s (EPRI's) website regarding the impact of coal type on SCR catalyst life and performance, a recent EPRI study[29] produced field data analyzed from an "In-Situ Mini SCR Reactor" system installed in a typical "high-dust" location at seven different test sites, including four firing PRB coal, one firing Texas lignite, one firing high-sulfur eastern bituminous coal, and one firing a PRB/eastern bituminous coal blend. The PRB/bituminous coal blend test was performed at AmerenUE's Sioux Station, on one of the two 500 MW cyclone-fired boilers. This study found that the cyclone unit firing the PRB/bituminous coal blend exhibited the fastest rate of catalyst activity degradation. Also, the higher deactivation rates seen at this site were due to economizer exit flue gas temperatures being significantly higher than at the other sites. A comparison of the Texas lignite and one of the PRB-fired sites with two different catalysts, deactivation was more a function of trace elements in the flue gas and flyash than the specific catalyst type or formulation.

North Dakota lignite produces an ash that is very sticky and creates severe ash deposition problems. There have been no installations of SCR systems (full-scale) on units that fire North Dakota lignite. A technical assessment was conducted for the installation of SCR technology on a North Dakota lignite unit. In order to further evaluate the feasibility of installing a conventional SCR system on a North Dakota lignite fired unit, the Energy & Environmental Research Center (EERC) at the University of North Dakota was consulted. EERC has extensive experience investigating the deposition characteristics of North Dakota lignite ash.

Technical difficulties and anticipated operating problems that are unresolved with respect to installing conventional SCR technology at Milton R. Young Station include the impacts of erosion, severe ash deposition, and "popcorn ash" on the catalyst. According the EERC's study (see Appendix B), "the most significant problems that prohibit the successful operation of SCR catalysts to lignite coal is the formation of low-temperature sodium-calcium-magnesium sulfates and phosphates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency". For these reasons, application of available conventional high-dust SCR technology is considered technically infeasible for Milton R. Young Station Unit 1 and Unit 2 boilers. These concerns can be divided into four categories. Each category is addressed below. An explanation of the factors that make conventional SCR technology infeasible for these boilers follows:

1. Ash Deposition: North Dakota lignite contains a variable and complex variety of inorganic compounds that contribute to ash deposition. This fuel produces ash with severe deposition characteristics that are not typical with other coals. When exposed to the heat of the combustion process inside the cyclone burners, the majority of the fuel ash becomes molten and flows into the bottom of the furnace. A significant portion of the fuel ash is entrained into the flue gas exiting the cyclone barrels at high velocity, where it comes into contact with the lower furnace waterwalls. The portion that is carried with the rising flue gas cools and some is deposited on heat transfer surfaces in the upper furnace and boiler convection pass. Ash deposition on heat transfer surfaces is a substantial problem for units that fire North Dakota lignite. The problem is so severe at Milton R. Young that the Unit 2 boiler must be shut down at 80 to 90-day intervals to

allow for cleaning of ash deposits from the boiler heat transfer surfaces in order to restore reasonable furnace exit gas velocities and temperatures.

Sodium is a significant contributor to the "stickiness" of the ash produced from firing North Dakota lignite. Sodium content of the lignite ash averages approximately 4.4%, and can nearly double this value for some of the lignite produced from the Center mine. PRB coal typically averages around 1.5% sodium content. Boilers firing North Dakota lignite typically have a 2.5% higher heat rate (million Btu per kilowatt of electric generation) than a typical boiler firing PRB coal, thus requiring more heat input and firing more fuel per megawatt of electricity output. A cyclone boiler firing North Dakota lignite also converts approximately 50% of the fuel ash to flyash, compared with a 35% conversion rate for PRB coal-fired cyclone boilers. Overall, this results in an amount of sodium emitted from a cyclone boiler firing North Dakota lignite of approximately 7.3 lbs/MW-hr compared with 0.9 lbs/MW-hr for a PRB-fired cyclone boiler.

The catalysts in coal-fired boiler SCR reactors are highly susceptible to ash deposition. In a typical conventional high-dust SCR reactor, the flue gas typically passes through two to four layers of catalyst modules. The catalyst modules have numerous narrow passages to provide intimate contact between the flue gas, ammonia and catalyst. The clearance (pitch) in these passages is typically 6-10 millimeters. A typical catalyst layer is approximately 1 to 1.5 meters deep. The catalysts in coal-fired boiler SCR reactors must be cleaned frequently using soot blowers and/or sonic horns. This is true even on units firing fuels that do not produce a sticky ash that contributes to ash deposition. Ash deposition on the catalyst in a high-dust SCR application would be severe for a unit firing North Dakota lignite.

Sulfur in the coal is oxidized during excess air combustion to form sulfur dioxide (SO_2), and a small amount of sulfur trioxide (SO_3). Some of the ammonia-based reagent injected upstream of the SCR reactor will combine with SO_3 to form ammonium bisulfate. The catalyst in the SCR reactor will also oxidize a portion of the SO_2 to SO_3. Excess unreacted ammonia reagent carryover ("ammonia slip") from the SCR reactor will also react with these sulfuric acid compounds in a similar fashion. The deposition characteristics for a unit burning North Dakota lignite will create difficult-to-remove ash deposits and pluggage of a conventional high-dust catalyst, and increase the probability that the air preheater downstream and flue gas ductwork will be prone to accumulations which could be severe. High-dust SCR performance and catalyst life will be severely impacted. It is anticipated that a high-dust SCR's catalyst life will be shortened from 3-6 years (typical) to as little as 2-12 months, requiring extended, frequent outages for replacement.

Hot-side air preheaters are susceptible to fouling. Tubular air pre heaters originally supplied with all cyclone boilers also tolerate moderate dust loadings, since their height and size make them difficult to maintain cleanliness. Leak tightness of the air preheater is important on cyclone-fired boilers with relatively high forced draft fan discharge (combustion air supply) pressures. A high-dust SCR installation will be prone to air preheater tube fouling and pluggage, requiring extended, frequent outages for cleaning.

2. "Popcorn Ash": A second consideration in the application of conventional high-dust SCR technology on a lignite-fired unit is the potential of the SCR reactor catalyst pluggage resulting from carry over of "popcorn ash" from the boiler. Boilers firing North Dakota lignite have severe problems with ash deposition on boiler surfaces. North Dakota lignite has a high propensity to form deposits on the boiler's furnace and convection pass fireside surfaces. For lignite-fired units, the boiler's heat transfer surfaces must be cleaned by sootblowing and other methods (e.g. water lances) frequently to maintain satisfactory boiler operation. Some of the removed deposits released by the cleaning action within the boiler and convection passes form "popcorn ash", which will be entrained in the flue gas. Carry over of boiler ash deposits will contribute to pluggage of the "popcorn ash" screen ahead of the top layer of SCR reactor catalyst. This can cause distortions in gas distribution ("channeling") through the SCR reactor, which will aggravate erosion in the high velocity areas and ineffective performance of the catalyst.

3. Temperature: A third issue that impacts the feasibility of installing high-dust SCR technology on the North Dakota lignite-fired units is catalyst operating temperature. The performance of any SCR catalyst is highly dependent on the temperature of the flue gas passing through the reactor. Typically, a temperature of 600 – 750 degrees F is required to obtain satisfactory operation of an SCR reactor. Operation of commonly supplied catalyst suitable for a high-dust SCR reactor at temperatures above 750 degrees results in severe and rapid deterioration of the catalyst and SCR reactor's NO_X emission reduction performance. For bituminous and sub-bituminous coal-fired units, boiler flue gas passing between the economizer outlet and air heater inlet is generally

within a temperature range acceptable for conventional SCR catalysts without additional heating or cooling of the flow stream.

North Dakota lignite-fired cyclone boilers, including those at Milton R. Young Station, have high temperatures at the economizer's flue gas outlet by design. The highest gas temperatures downstream of the convection pass economizer sections and upstream of the air heater inlets in Milton R. Young Unit 2's boiler are much higher than 750 degrees.

High gas temperatures at the air heater inlet are required to produce the high air temperatures (700°F) needed for the pre-combustion lignite drying system, along with primary and secondary combustion air supplied to the cyclones. Such air preheater arrangements and capabilities have been taken into account in the design of the North Dakota lignite-fired cyclone boilers. Reducing this high gas temperature to accommodate conventional catalysts for a conventional high-dust SCR reactor would result in pre-combustion air temperatures that are too low to provide satisfactory drying and rapid ignition of the high-moisture fuel. This will seriously impact reliable combustion, slag formation and tapping in the cyclone burners. Consequently, it is not feasible to modify the Milton R. Young Unit 2's boiler to operate with the lower economizer outlet flue gas temperature.

Catalysts for a conventional high-dust, hot-side SCR system have not been installed nor successfully demonstrated in a full-scale installation of an operating solid fuel-fired unit that are designed to continuously operate at the high temperatures (above 750 degrees F) that exist between the convection pass economizer and air heater on the Milton R. Young Unit 2's boiler.

4. Erosion: A final consideration on whether hot-side, high-dust SCR technology can be successful on a North Dakota lignite-fired unit is the potential for erosion of the SCR catalyst. North Dakota lignite supplied from the Center mine has an average fuel ash content of 10.5%, and can have an ash content up to 25.5 percent. PRB coal fuel ash content typically averages approximately 5 percent. As previously stated, a cyclone boiler firing North Dakota lignite converts a significantly greater amount of flyash than a PRB-fired cyclone boiler. Overall, this results in a flyash output rate from a cyclone boiler firing North Dakota lignite of approximately 83 lbs/MW-hr compared with 21 lbs/MW-hr for a PRB-fired cyclone boiler. High ash contents in the flue gas stream can result in physical erosion of the catalyst. In addition, effective on-line cleaning of the

high-dust catalyst will likely require steam or compressed air sootblowing. Cleaning cycles of the catalyst will be required much more frequently than a typical conventional SCR installation due to the ash deposition characteristics of the North Dakota lignite and the expected buildup and pluggage resulting from the carry over of “popcorn ash”. Frequent sootblowing of the catalyst to remove fouling deposits and ash accumulations will contribute to erosion and decreased catalyst life. There is some European experience with high ash brown coals that catalyst manufacturers will be able to draw upon. This experience, however, will not be directly applicable to these United States units because of the severe deposition characteristics of the North Dakota lignite ash compared to brown coal.

The EPA’s NSR Manual states that for a technology to be feasible it must “available and applicable”. SCR technology is an available technology which has been installed on numerous powerplant facilities around the world and there are a large number of manufacturers that market the technology. The question is whether SCR technology is “applicable” for a unit firing North Dakota lignite.

In accordance with EPA’s NSR Manual, a technology is “applicable” if it has been installed on a “similar unit”. Hot-side, high-dust SCR technology has been retrofit on coal-fired units featuring cyclone boilers. However, there are no SCR installations in operation or planned on units that include cyclone burners firing North Dakota lignite with severe slagging and fouling tendencies combined with such high boiler economizer outlet gas temperatures (over 750°F) required for high-moisture fuel pre-drying systems and tubular air preheaters.

The EPA’s NSR Manual also states a technology may be determined to be not applicable if “a technical assessment considering physical, chemical and engineering principles and/or empirical data showing the technology would not work on the emissions unit under review or that unsolvable technical difficulties would preclude the successful deployment of the technique.” In this SCR technology application, it appears that a facility utility powerplant firing North Dakota lignite would experience extended time delays or be required to devote significant internal resources and engage outside research, followed by extended field trials to learn how to apply a conventional high-dust, hot-side SCR technology on a such a fuel source.

Based upon this technical assessment that looked at the various design and operational issues associated with the installation of hot-side, high-dust SCR technology on a North Dakota lignite-fired steam-electric generating unit, this control option is considered technically infeasible for Unit 2's boiler at Milton R. Young Station.

A.1.3.4.2 Low-Dust Selective Catalytic Reduction (LD-SCR)

Low-dust SCR (LD SCR) technology could potentially be applicable to North Dakota lignite-fired boilers for NOx emission control. Low-dust SCR refers to the location of the SCR system downstream of a particulate collection system, such as an electrostatic precipitator or a fabric filter. If the low-dust SCR is downstream of a hot-side electrostatic precipitator and prior to the air preheater, flue gas reheating is unnecessary. This has been the prevalent form of alternative retrofit SCRs in the United States for coal-fired utility boilers. There are ten known hot-side low-dust SCR installations (without flue gas reheat) operating in the United States as of July 2005. These are listed in Appendix A2. If applied to MRY Station Unit 2's boiler, the low-dust SCR equipment would be downstream of a cold-side electrostatic precipitator; flue gas reheat prior to the LD SCR reactor inlet would be required for proper NO_X emission reduction performance.

For a cold-side LD SCR, the ESP outlet flue gas passes through a low-dust gas-to-gas heat exchanger (LD GTG-HE), prior to passing to the low-dust SCR reactor. After the LD GTG-HE, the flue gas will travel through the new duct, receiving hot flue gases from a direct-fired gas burner or set of high-pressure steam coils, leading to an ammonia injection grid, turning vanes and then into the LD SCR reactor. The flue gas entering the inlet to the LD GTG HE is expected to be near the air heater outlet temperature (330-340°F) in a cold-side LD SCR application. The supplemental heat added downstream of the LD GTG-HE can be supplied from high temperature steam coils (indirect heat exchange) or directly from natural gas-fired duct burners. The flue gas must be heated to a minimum of approximately 600°F for the LD SCR NO_X–ammonia reaction to be effective. The LD gas-to-gas heat exchanger is used to recover part of that supplied heat, prior to exhausting to the FGD system (if applicable) and stack. The use of rotary regenerative-type heat exchangers has been applied in European LD SCRs. With this design, there will be leakage between the untreated and treated gas streams such that the exit flue gas has higher NO_X concentrations than the LD SCR outlet gas. The direct-fired flue gas reheat duct burners will also create NO_X emissions, which will add to the amount emitted from the boiler and input into the LD SCR reactor. The LD SCR reactor, GTG HE, and connecting ductwork will increase the pressure drop through the flue gas system. This normally requires an induced draft fan upgrade or a booster fan addition.

The factors that make low-dust SCR technology infeasible for the Milton R. Young Station Unit 2's boiler with existing particulate collection via electrostatic precipitators are as follows:

- Catalyst Fouling and Deactivation: An existing electrostatic precipitator upstream of a low dust SCR reactor will still expose the catalyst to the acid gas content and fine particulate containing trace metals and the high alkali mineral content of the entrained lignite flyash not removed by the ESP upstream. Although the total amount of flyash carryover into the LD-SCR reactor is greatly reduced compared with a high-dust design, it is anticipated that the low-dust SCR catalyst life will still be unacceptably short. The small particle flyash passing into the reactor will be sufficient to cause pluggage of the catalyst pores, resulting in deactivation of the catalyst. The firing of lignite coal produces fine (less than 5-µm diameter) flyash particles, which are also least likely to be removed by the existing particulate collection equipment (e.g. ESP) upstream of a low-dust SCR. This creates conditions that allow these small flyash particles to enter the pores of the catalyst, react with SO_3 in the flue gas, and form sulfates which bind other ash particles into a matrix of sodium-, calcium-, and sulfur-rich materials (likely in a form of calcium sulfate). Once such a matrix forms within the catalyst, it can be extremely tenacious and difficult to remove. One catalyst vendor's has stated it is their "experience that low-dust catalyst is more difficult to clean than that from high-dust"[30]. Low-dust SCR performance and catalyst life could be severely negatively impacted. Shortened lifespans of the LD SCR catalyst will require premature, extended, frequent outages for replacement.
- Site Space Constraints: The installation of a low-dust SCR system with flue gas reheat requires a substantial amount of space for installation and operation. A low-dust SCR system will likely use a regenerative gas-to-gas heat exchanger (reheater) to raise the temperature of the flue gas at the SCR inlet. A GTG HE will transfer heat from the flue gas at the SCR reactor outlet to the flue gas entering the SCR reactor in order to minimize the supplemental SCR energy usage. The gas-to-gas heat exchanger dictates the footprint of the cold-side low-dust SCR system. Space is required for the GTG HE and for ductwork in and out of the reheater. Sufficient free space around the reheater and SCR is also required for maintenance.

  The area around Units 1 and 2 at the M.R. Young station is extremely congested in the areas where low-dust SCR systems must be located. The situation is particularly severe for Unit No. 2. Equipment that impacts the feasibility of installing a low-dust SCR system on Units 1 and 2 includes the Unit 2 absorbers, Unit 2 flue gas desulfurization (FGD) dewatering equipment, fly ash handling equipment, fuel storage and transfer equipment, stacks, fans and ductwork. It would be extremely disruptive to the continued economic operation of both boilers to relocate all the mentioned equipment to create space for the low-dust SCR systems at the M.R. Young Station. Stacks, fans and ductwork and the Unit 2 FGD system cannot be readily relocated due to adjacent structures and the need to continue operation while constructing the retrofit installations. The fuel handling equipment includes a coal storage barn and the main conveyors supplying lignite to the units. Relocating the coal handling equipment currently occupying space needed for the low dust SCR systems would be quite difficult given the site configuration. It is conceivable that the fly ash equipment located west of Unit 1 could be relocated to provide some of the space needed for the low-dust SCR. However, the availability of this space is doubtful, since avoiding the likelihood of severe SCR catalyst sulfate fouling will require a new Unit 1 FGD system to be installed. If a new FGD system is installed for Unit 1, the FGD system would need to occupy the space that can be made available by relocating ash handling equipment. This space subsequently would not be available for a low-dust SCR system.

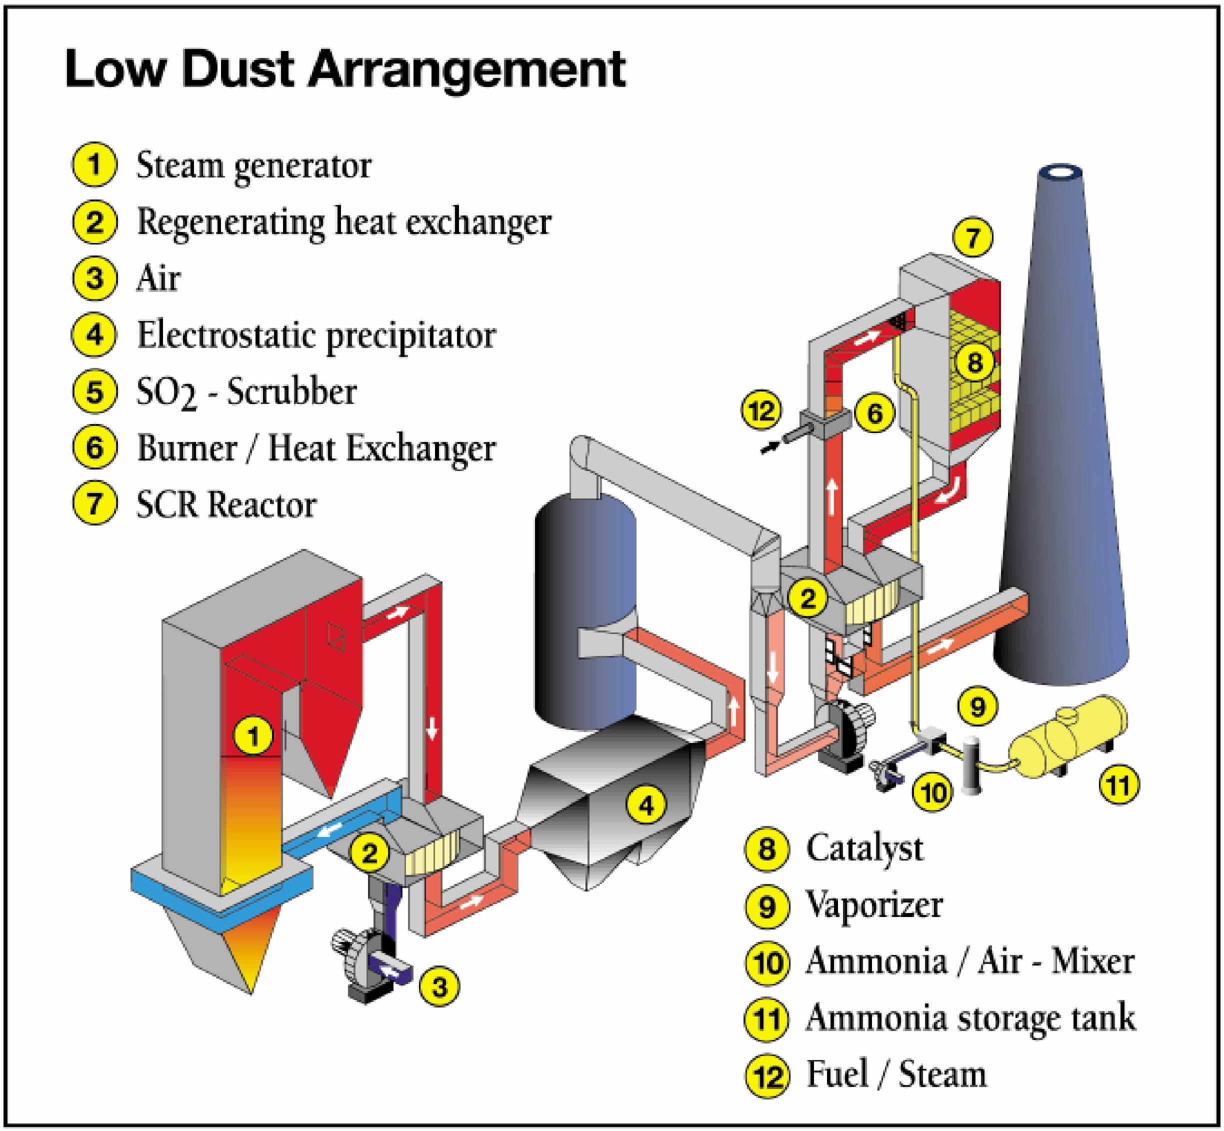
Based upon a technical assessment that looked at the various design and operational issues associated with the installation of low-dust SCR technology on a North Dakota lignite-fired steam-electric generating unit, this control option is considered technically infeasible for the Milton R. Young Station Unit 2's boiler.

A.1.3.4.3 Tail-Gas Selective Catalytic Reduction (LD-SCR)

A tail-gas (TG) SCR is a low-dust SCR system where the LD SCR reactor is installed downstream of a FGD scrubber. The FGD outlet flue gas passes through a gas-to-gas heat exchanger (GTG-HE), prior to passing to the tail-gas SCR reactor. The flue gas will travel through new or modified ductwork leading to an ammonia injection grid, turning vanes and then into the TG SCR reactor. The TG SCR reactor, GTG HE, and connecting ductwork will increase the pressure drop through the flue gas system. This normally requires an induced draft fan upgrade or a booster fan addition.

A schematic graphic diagram for a low dust arrangement is shown in Figure A.1-6.

Figure A.1-6 Tail-Gas SCR Arrangement



(figure copied from Wheelabrator Air Pollution Control literature)

The flue gas from a wet FGD scrubber outlet entering the inlet to the gas-to-gas heat exchanger is expected to be near the saturation temperature (140°F) in a cold-side TG SCR application. The supplemental heat added downstream of the TG GTG-HE can be supplied from high temperature steam coils (indirect heat exchange) or directly from natural gas-fired duct burners. The flue gas must be heated to a minimum of approximately 600°F for the TG SCR NO_X– ammonia reaction to be effective. The TG gas-to-gas heat exchanger is used to recover part of that supplied heat, prior to exhausting to the stack. With a rotary regenerative-type gas-to-gas heat exchanger, there will be internal leakage between the untreated and treated gas streams such that the stack exit flue gas has higher NO_X concentrations than the

TG SCR reactor outlet gas. Using direct-fired flue gas reheat duct burners will also create NO_X emissions, which will add to the amount emitted from the boiler and input into the TG SCR reactor.

There is limited technical information published in English for coal-fired steam-electric generating units (SEGU) with low-dust/tail-gas SCR technology in applications requiring full flue gas reheat prior to the reactor inlet. There is no experience with TG SCR on eastern bituminous, western subbituminous coal or lignite-fired SEGUs in the United States. As of 1997, there was one low-dust/tail-gas SCR on a 220 MWe German cyclone-fired boiler with a 1988 retrofit installation. This boiler was reported to be operating without combustion controls or FGD, burning low sulfur, low ash, moderate moisture bituminous coal with an average pre-SCR NO_X emission rate of approximately 1.07 lb/mmBtu, and was meeting a 30-day rolling average emission limit of approximately 0.16 lb/mmBtu (85% reduction)[31].

Milton R. Young Station Unit 1 does not currently incorporate any flue gas desulfurization equipment, which would place the reactor catalyst in a low-dust SCR configuration, which is considered infeasible when burning North Dakota lignite. A new FGD system for Unit 1 would be required in order to avoid or significantly reduce expected sulfate formation within the catalyst and gas-to-gas heat exchanger when combined with ammonia required for the TG SCR. Unit 2 currently employs a wet scrubber which currently treats approximately 83% of the total flue gas flow from the boiler. Flue gas reheat is currently provided by the FGD bypass (i.e. warm, untreated flue gas is mixed with the cool scrubbed gas).

The factors that make tail-gas SCR technology infeasible for both Milton R. Young Station boilers with existing particulate collection via electrostatic precipitators are as follows:

- Catalyst Fouling and Deactivation: The TG SCR reactor downstream of a flue gas desulfurization (FGD) scrubber will still be susceptible to fouling, contamination, pluggage, and catalyst deactivation.
    - An existing electrostatic precipitator (ESP) upstream of a tail-gas SCR reactor will still expose the catalyst to fine particulate containing trace metals and the high alkali mineral content of the entrained lignite flyash not removed by the ESP upstream. Although the total amount of flyash carryover into the TG-SCR reactor is greatly reduced compared with a high-dust design, it is anticipated that the tail-gas SCR catalyst life will still be unacceptably short.
    - The firing of lignite coal produces fine (less than 5-µm diameter) flyash particles, which are also least likely to be removed by the existing particulate collection equipment (e.g. ESP) upstream of

a TG-SCR. Flue gas with entrained fine particulate matter, including some involving sodium and sulfur-containing compounds, will pass through and be carried-over from a wet FGD scrubber. This treated gas stream will carry sodium sulfate particles, formed by homogenous condensation after exiting the boiler and not removed by the FGD system, into the catalyst layers of the TG-SCR reactor. A dry FGD system followed by a fabric filter upstream of the TG-SCR will still allow sulfur-bearing flue gas and fine particles to enter the catalyst. There is serious concern that fine particles passing into the reactor will accumulate within the catalyst, and be resistant to removal by conventional sootblowers and other cleaning technologies. This creates conditions that allow these small flyash particles to enter the pores of the catalyst, react with SO_2 and/or SO_3 in the flue gas, and form sulfates which bind other ash particles into a matrix of sodium-, calcium-, and sulfur-rich materials (likely in a form of calcium sulfate). Once such a matrix forms within the catalyst, it can be extremely tenacious and difficult to remove. Catalyst that is exposed to such conditions will be ineffective at maintaining adequate activity upon which the performance of the TG-SCR's NO_X removal is based.

  - These entrained particles will also deposit on the gas-to-gas heat exchanger ahead of the tail gas SCR reactor. This deposition will decrease heat transfer between the incoming (cool) flue gas and the outgoing (warm) flue gas. Sootblowers could be used to remove the accumulated deposits from the GTG HE, but the SCR reactor could still suffer catalyst fouling from the deposits dislodged from the GTG HE cleaning cycle becoming reentrained in the reheated flue gas. Tail-gas SCR performance and catalyst life could be severely negatively impacted. Shortened lifespans of the TG SCR catalyst will require premature, extended, frequent outages for replacement.

- Site Space Constraints: The installation of a tail-gas SCR system with flue gas reheat requires a substantial amount of space for installation and operation. A tail-gas SCR system will likely use a regenerative gas-to-gas heat exchanger (reheater) to raise the temperature of the flue gas at the SCR inlet. A GTG HE will transfer heat from the flue gas at the TG SCR reactor outlet to the scrubbed flue gas entering the SCR reactor in order to minimize the supplemental SCR energy usage. The gas-to-gas heat exchanger dictates the footprint of the TG SCR system. Space is required for the GTG HE and for ductwork in and out of the reheater. Sufficient free space around the reheater and SCR system is also required for maintenance.

  The area around Units 1 and 2 at the M.R. Young station is extremely congested in the areas where TG SCR systems must be located. A flue gas desulfurization system will be needed for Unit 1 in the near future to comply with the Consent Decree. When a new FGD system is installed for Unit 1, the FGD system would need to occupy the space that can be made available by relocating ash handling equipment. This space subsequently would not be available for a tail-gas SCR system. Thus, the availability of adequate space for all the new FGD and TG-SCR system equipment and structures while accommodating existing coal storage and handling needs for both existing boilers at Milton R. Young Station is doubtful.

The challenges for installation of new ductwork, SCR reactors, and flue gas reheating equipment and the lack of pertinent experience with all aspects of design, construction, operation and maintenance of tail-gas SCRs on such high-fouling coals as North Dakota lignite are significant. The flue gas conditions that the TG-SCR catalyst will be exposed to will create unresolvable fouling and blinding that makes successful application of this technology difficult, expensive, and uncertain.

The risk of failure and uncertainty of successfully applying low-dust, tail-gas SCR technology to a cyclone-fired utility powerplant firing North Dakota lignite appear substantial.

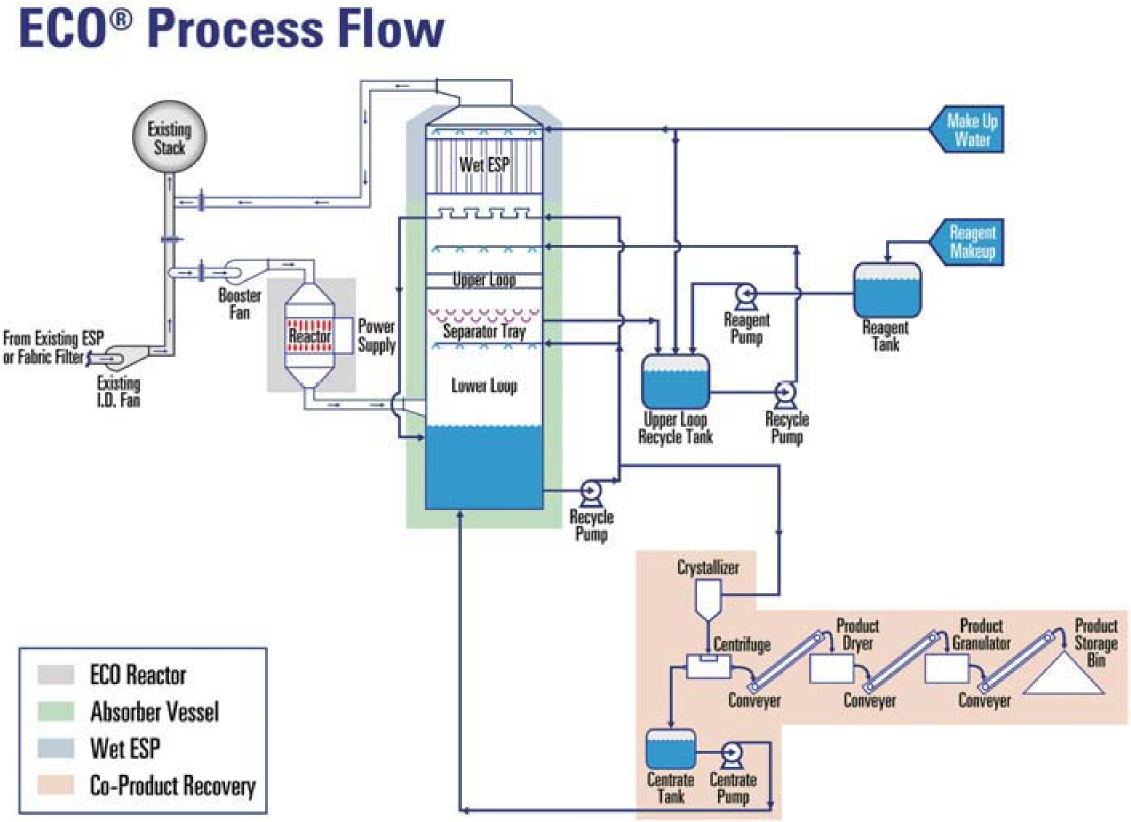
Based upon a technical assessment that looked at the various design and operational issues associated with the installation of tail-gas SCR technology on a North Dakota lignite-fired steam-electric generating unit including a cyclone boiler, this control option is considered technically infeasible for the Milton R. Young Station Unit 2's boiler.

A.1.3.5 Electro-Catalytic Oxidation (ECO®)

Powerspan's Electro-Catalytic Oxidation (ECO®) system is a multi-pollutant technology designed to control emissions of NO_X, SO_2, fine particulate, mercury and certain Hazardous Air Pollutants (HAPs). The ECO® process has two main process vessels, a barrier discharge reactor, and a multi-level wet scrubber. The barrier discharge reactor utilizes an electrical discharge to create oxygen and hydroxide radicals which then react with NO_X, and other constituents in the flue gas stream. The flue gas stream then enters the bottom of the ECO® scrubber where the lower loop cools the flue gas and removes a portion of the acid gasses [sulfur trioxide (SO_3), sulfuric acid (H_2SO_4), nitric acid (HNO_3)] produced in the barrier reactor and oxidized metals such as mercury, with a low pH aqueous ammonia reagent. A second scrubbing loop is then entered where additional SO_2, NO_2, acid gases and oxidized metals are removed with an aqueous ammonia reagent, though at a higher pH. Above the second scrubber loop is an absorber section for absorbing fugitive ammonia from the first and second scrubbing loops. The final step in the ECO® process is a wet electrostatic precipitator (WESP) which collects fine particulate matter, aerosols generated in the scrubber and additional mercury. An updated schematic process flow diagram for the basic ECO® process is shown in Figure A.1-7.

Figure A.1-7 – Electro-Catalytic Oxidation (ECO®) Process Flow Diagram

(copied from http://www.epa.gov/appcdwww/aptb/EPA600R03110.pdf)



Powerspan has been involved in an extended ECO® process demonstration using a 28 MW Commercial Demonstration Unit (CDU) at R.E. Burger Station Units 4&5. The ECO® CDU project treated a slipstream and demonstrated performance, reliability and economics for approximately one year. The demonstration program started in January, 2004. NO_X removal is stated to be up to 90% with a claimed 0.05 lb NO_X/mmBtu outlet condition achievable for the front-end of the ECO® process. Further sustained operational tests of the ECO® CDU are underway during the second and third quarters of 2005.

As this is a post-combustion multi-pollutant control technology, it is claimed that there is little sensitivity to the type boiler or burners that Powerspan's Electro-Catalytic Oxidation (ECO®) process can be potentially applied to in order to reduce NO_X emissions. The effectiveness of this ECO® process for NO_X control has been demonstrated on a slip-stream commercial demonstration unit (CDU) associated with pulverized fuel boilers firing midwestern or eastern bituminous coal.

Powerspan's published data from the commercial demonstration unit's performance of up to 90% when treating flue gas with an inlet NO_X concentration around 0.5 lb/mmBtu. This would result in a stack NO_X emission around 0.05 lb/mmBtu.

The ECO® process has not been demonstrated in a full-scale configuration on any unit, nor tested in a slipstream configuration on any boiler that fires western subbituminous coals or North Dakota lignite. It has also not been applied to emissions from a cyclone-fired boiler. According the EPA's Draft NSR Manual, "Technologies which have not been applied to (or permitted for) full scale operations need not be considered available: an applicant should be able to purchase or construct a process or control device that has already been demonstrated in practice".

There are a number of issues with firing North Dakota lignite that make the applicability of the ECO® process technically infeasible for MRY Station boilers. These issues include:

- Deposits and Pluggage: The flyash deposition characteristics of the North Dakota lignite are extremely severe. Anything that contributes to flyash deposition and pluggage within the barrier reactor is expected to have a detrimental impact on the multi-pollutant control performance of the ECO® process, and thus could have a serious impact on MRY Station operations. The lack of demonstrated operation on treating the emissions from a boiler firing coal with a high slagging index precludes the use of the ECO® process as technically feasible for BACT as applied to a boiler firing North Dakota lignite.
- Reliability and Availability: Milton R. Young Station's major planned outages for each unit are scheduled to occur once every three years. Any NO_X control technology selected as BACT will need to operate year-round, year in and year out, on a routine basis, while performing at high levels of pollutant reduction. The Powerspan ECO® system is a new technology and is not as highly developed as other more common NO_X and SO_2 control technologies such as SCR or SNCR plus wet or semi-dry flue gas desulfurization (FGD). It is expected to require a full-time, full-scale application with sustained continuous operation to confirm levels of currently demonstrated reliability and availability from the ECO® CDU are acceptable to meet the

expectation of infrequent major outages over long time periods while maintaining high levels of control.

There are additional factors that make the application of the ECO® process potentially more difficult than other established emission control technologies available for coal-fired powerplants:

- There is a lack of experience with the ECO® downstream ammonia scrubber's coproduct crystallization and granulization equipment design, operation, and maintenance, which was not included with the initial commercial demonstration unit. The coproduct stream that would normally feed into the crystallization and granulation processes was collected and transported offsite for this process step during CDU operation. Because crystallization and granulation of ammonium sulfate from an ammonia scrubber solution is not a new technological process, this was not considered a technical feasibility deficiency. For instance, the Dakota Gasification Company (DGC) in Beulah, ND currently operates an SO_2 scrubber utilizing ammonia as a reagent. Following the generation of ammonium sulfate, DGC crystallizes and granulates a fertilizer product on site. However, at MRY Station, considerable costs would be incurred for interim storage and shipment of the ECO® process scrubber's liquid bleedstream until sufficient experience has identified and eliminated potential failures and repairs for the crystallization and granulation equipment should it prove to be unreliable.

- Size of the barrier reactor: Powerspan recently indicated that they would scale the reactor for optimum cost and space arrangement based upon lessons learned from the CDU plant operation. The number of individual passages within a barrier reactor sized for either of MRY Station boilers' maximum flue gas flow and gas stream constituents is expected to require a cross-sectional area comparable to half of a large electrostatic precipitator. Although this has not been closely examined for all aspects of design, construction, operation and maintenance, the amount of physical space required to hold the barrier reactor and inlet and outlet ductwork is believed to not be available for potential retrofit to MRY Station units. Site space constraints are considered to be a barrier to technical feasibility for potential application of the ECO® process at Milton R. Young Station for Unit 1 and Unit 2's boilers.

- Additional station auxiliary power consumption: The barrier reactor, plus the ammonia scrubber and wet electrostatic precipitator additions by an ECO™ system, require an increase in station auxiliary power consumption. For NO_X control, this includes more horsepower required by the booster fan needed to compensate for the flue gas pressure drop created across the barrier reactor. It also includes the power consumed by the electrodes of the barrier reactor itself.

Because of the technical feasibility issues and lack of commercial availability and full-scale experience, especially on such high fouling coals, the ECO® system was considered technically infeasible as a BACT alternative for Milton R. Young Station for Unit 2's boiler.

A.1.4 "Layered" NOx Reduction Technologies

Many of the NO_X emission reduction technologies which involve furnace or convection pass areas for their introduction into the flue gas stream have been, or can potentially be, applied in combinations so as to result in an overall higher level of removal. Separated overfire air, various types of fuel reburn, and various forms of SNCR could potentially be combined in series to reduce NO_X emissions prior to boiler's flue gas exit. However, all the possible NO_X control technology combinations have not been installed on coal-fired powerplants, so actual feasibility of some combinations have not been demonstrated as viable, particularly in consideration of the special challenges posed by cyclone boilers firing lignite coal.

A.1.4.1 SOFA Combined With Other NO_X Reduction Technologies

Separated Overfire Air can be favorably combined with every other method in order to reduce the amount of reagent or reburn fuel required to achieve the resulting level of NO_X emission reduction. Some control technologies, especially conventional fuel reburn systems, require overfire air to complete the combustion of the staged fuel admitted to the upper furnace. Fuel lean gas reburn can be applied with or without SOFA, as this limited amount of staged fuel is introduced into an oxygen-rich atmosphere downstream of the cyclone burners and any overfire air injection points.

A.1.4.1.1 SOFA with SNCR

Selective non catalytic reduction technologies are post-combustion, in-furnace NO_X control alternatives that have been installed in numerous boilers of various designs, fuel types, with and without overfire air. It is usually advantageous to apply overfire air so that the amount of chemical reagent consumption can be minimized in order to achieve the targeted NO_X emission rate from the boiler outlet.

Tests at Conectiv's B.L England Station (Units 1 and 2) demonstrated that SNCR can decrease NO_X emissions as much as 31% at full load, from 0.55 to 0.38 lb/mmBtu, over and above the reduction possible from overfire air alone (approximately 60% drop, from 1.3 to 1.4 down to 0.55) in full operation. This is an overall NO_X emission reduction of 72% from pre-retrofit baseline[24].

SNCR can be applied alone or combined with either the basic or the advanced forms of separated overfire air (ASOFA) on MRY Station boilers. Air-staging the cyclones with the use of separated overfire air to further complement combustion NO_X reduction is an optional part of this technique. However, as previously explained in the discussion of SOFA alternatives, this will risk slag "freezing" in the barrels and lower furnace. Estimated NO_X emission rates for using SNCR techniques with North Dakota lignite considered published levels achieved by cyclone-fired units firing western subbituminous coal, and vendor estimates. SNCR with ASOFA is expected to reduce NO_X emissions approximately 32.6% below NO_X levels predicted for ASOFA operation, and potentially 58% overall from current baseline level for the MRY Station Unit 2 boiler with ammonia slip limited to approximately 5 ppmvd. This highest performing basic SNCR system is potentially able to achieve a NO_X emission rate of 0.330 lb/mmBtu, when combined with the advanced form of SOFA on MRY Station Units 2 boiler during operation at the pre-control baseline (near MCR load). These levels of NO_X reduction depend on the advanced form of separated overfire air technique to achieve the expected NO_X reduction percentages when applied to lignite-fired cyclone boilers.

Another form of SNCR is combined with separated overfire air. This is currently being marketed commercially as "Rotating Mixing" (Rotamix). In the United States' utilities industry, this has only been applied to pulverized coal-fired boilers. It is different than basic SNCR in that it includes a hot air booster fan and a small ambient air fan, and injects the ammonia (or urea) reagent into the high-pressure overfire air flow stream ahead of the ROFA nozzles' outlets. This mixture is imparted into the boiler in an offset fashion from opposite sides of the furnace at high velocities, with multi-port nozzles located at high elevations relative to the top burner row. This vendor (Mobotec USA) claims that Rotamix (rotating opposed fire air or ROFA + SNCR) helps to distribute the reagent across the furnace cross section, which maximizes in-furnace NOx reduction while minimizing negative impacts on carbon monoxide and flyash unburned carbon. Three tangentially-fired utility boilers burning eastern bituminous coal or Illinois bituminous coal were retrofitted with Rotamix, each achieving a NO_X reduction of approximately zero to 55 percent beyond the levels produced by ROFA alone, from pre-SNCR baselines of 0.22 to 0.28 lb/mmBtu down to 0.10 to 0.23 lb/mmBtu without low-NO_X burners[4,32,33,34].

While this variation of SNCR combined with separated overfire air could potentially be applicable to cyclone boilers, it has not been marketed to serve such applications. Since cyclone boilers do not require the addition of hot air booster fans for SOFA, and optimum injection locations for both SOFA and SNCR reagent may not coincide, Rotamix may not perform as well as, or significantly better than, a well-designed combination of conventional SOFA and SNCR. This technique is not distinct enough from basic SNCR from functional and air-staged cyclone NO_X reduction performance standpoints to warrant individual consideration for Milton R. Young Station boilers. Because of a lack of cyclone-fired boiler experience with ROFA and Rotamix, the latter was considered infeasible and thus was not included in the control effectiveness and cost-effectiveness sections of the main report.

A.1.4.1.2 SOFA with RRI

Rich Reagent Injection must be used in an oxygen-deprived atmosphere in order to effectively reduce nitrogen oxide emissions. This requires air-staged cyclones and separated overfire air operation.
The NO_X emission reduction reagent injection for RRI processes must be precisely located and carefully controlled to be effective. Operation outside of the required operating ranges can even result in increased NO_X emissions. Extensive computational fluid dynamic (CFD) simulations are needed to determine the optimum injection points. Boiler operating conditions will change with unit load and varying fuel characteristics. The RRI process control systems must be able to adjust for these changing conditions.

RRI has the potential to provide a moderate degree of NO_X reduction on coal-fired boilers. Data from B.L. England and Sioux plants show this technology can reduce NO_X emissions between zero and 39 percent beyond the amount attributable to overfire air system operation[23,24,25,26,27]. During initial demonstration testing of RRI at Ameren's Sioux Unit 1 boiler, a 500 MW unit firing a blend of PRB and midwestern bituminous coals (without SNCR), with SOFA in August 2001 at a lower furnace SR of approximately 0.99, NO_X emissions were reduced approximately 55% to 0.55 lb/mmBtu w/ SOFA only, with zero to 15% additional NO_X reduction from RRI (down to 0.47 lb/mmBtu) with zero ammonia slip[25]. Results of this initial RRI testing at Sioux plant were poor at cyclone stoichiometric ratios close to 0.99 because inconsistent, sporadic, and non-repeatable NO_X emissions reductions between zero and 15% were measured. Subsequent RRI testing at Sioux Unit 1 in March 2002 with SOFA at an average cyclone stoichiometric ratio around 0.95 showed NO_X emissions reduction of 29 percent (down to 0.27 lb/mmBtu) beyond those achieved with a modest amount of cyclone air-staging with SOFA (68% drop down to 0.38 lb/mmBtu from SOFA alone), for an 80% overall decrease from uncontrolled baseline; RRI CFD model predictions for these conditions were NO_X emissions reduction of 31% with FGR and 37% without FGR operation. Tested NO_X emissions with RRI+SOFA in 2002 were with a reagent normalized stoichiometric ratio (NSR) of 3 (lbs NH_3 per lb NO_X)[25].

Parametric testing at Sioux Unit 1 in May 2005 reduced NO_X emissions between 15-38% with RRI, down to 0.15 to 0.20 lb/mmBtu. Reagent NSR between 1.0 and 4.0 and low ammonia slip levels less than 2 ppm from an established baseline condition of 0.20 to 0.285 lb/mmBtu level achieved NO_X emissions as low as 0.12 lb/mmBtu with deep cyclone air-staging and SOFA operation firing an 80:20 PRB/Illinois coal blend at 480 MWg unit output[27].

The intent of the RRI process for NO_X reduction is that it must be used in conjunction with air-starved (substoichiometric staged-air) cyclone combustion resulting from the installation and operation of an OFA system, with or without SNCR. The cyclones' air/fuel stoichiometry must be carefully controlled to maintain fuel-rich conditions for the RRI process to be effective. The combustion gases in the vicinity of the RRI urea injection ports must be essentially devoid of free oxygen, in order to avoid oxidizing the nitrogen contained in the injected reagent, which will increase NO_X emissions. For lignite-fired cyclone boilers, the basic form of separated overfire air (without relocated lignite drying system vent ports) is incompatible with RRI. Reagent injection will be near the elevation of the existing lignite drying system vent ports in the lower front and rear walls of a lignite-fired cyclone boiler located immediately above the top rows of cyclones. These vent ports are located concurrently with the existing flue gas recirculation (FGR) ports on Unit 2's boiler. The oxygen introduced with the lignite drying system's vented moisture-laden airstreams will cause the urea to be oxidized, creating NO_X emissions.

The advanced form of SOFA relocates these lignite drying system vent ports from the lower to the middle furnace, enhancing the desired in-furnace nitrogen oxides reduction process. Therefore, in order for RRI to be even moderately effective in reducing NO_X emissions from a lignite-fired cyclone boiler, this technology must be combined with an advanced form of separated overfire air, whether installed with or without SNCR.

As mentioned in the feasibility discussion of applying separated overfire air to lignite-fired cyclone boilers, the degree to which each and every individual cyclone furnace can be successfully operated with less than theoretical (substoichiometric) combustion air directly impacts potential NO_X formation and further in-furnace emission reduction. Because the heat content of lignite from the Center mine is not consistent from hour to hour, there can be substantial deviations in air/fuel ratios for individual cyclones from the overall average.

In the case of MRY Station boilers, Minnkota has simultaneously sampled the unprepared lignite feed to several cyclones' lignite drying systems in order to determine the variability in the combustible and ash components of North Dakota lignite. This investigation found that fuel quality variations can result in individual samples' heating values to have a maximum differential of over 12% of the lignite samples' average.

TABLE A1-1 – Lignite Heating Values and Variations for Milton R. Young Station Unit 2

M.R. Young Station Individual Cyclone Lignite Samples		Differences Between Individual Cyclone Lignite Samples	
Higher Heating Values, Btu/lb	Percentage of Average HHV	HHV Differential, Btu/lb	Percentage of Average HHV
Minimum HHV: 5,852	88.9%	Minimum : 4	0.06%
Maximum HHV: 7,101	1.08%	Maximum : 797	12.1%
Average HHV: 6,584	100%	Average: 165	2.51%

When operating with air-staged conditions associated with separated overfire air, any individual cyclone with lignite heat input lower than average can allow significant amounts of oxygen to oxidize the urea reagent at high temperatures, thus increasing NOx emissions in that zone at that time. Cyclones with lignite heat inputs higher than average would produce lower stoichiometric air/fuel ratios and less NOx emissions. Less complete combustion in the deeply staged cyclones may release insufficient amounts of heat, thus raising the risk of solidifying the fuel ash so that it accumulates within the cyclone barrel. This could result in firing auxiliary fuel oil or taking the boiler out-of-service to remove the pluggage. Neither of these conditions is desirable because they result in increased emissions, lower performance, and higher operating costs.

The MRY Station Unit 2 boiler's cyclone air/fuel ratios vary in real-time based on significant changes in combustible content on an individual cyclone by cyclone basis. Adjustment of individual cyclone combustion air inputs to compensate for the variability in individual cyclone lignite heat input rates for Unit 2's boiler would be necessary to maintain consistent substoichiometric operation of every cyclone during air-staged combustion. This places great emphasis on achieving tight control over the air/fuel ratios on each cyclone during air-staged combustion operation in order for ASOFA to be successful in producing significant additional NOx emissions reduction on lignite-fired cyclone boilers.

There is no equipment available for coal-fired boilers that can measure the fuel heat input at the prepared feed injection point on such a variable fuel to allow the determination of reasonably accurate air/fuel ratios on individual cyclones in real time. Without being able to measure the cyclone air and heat inputs to allow for control of air/fuel proportions and emissions, the stoichiometric ratios of individual cyclones can not be established accurately to produce combustion products essentially devoid of free oxygen. This requirement is especially necessary when employing RRI to avoid increasing, rather than reducing, NO_X emissions on the Milton R. Young Station Unit 2 boiler.

Flue gas recirculation in MRY Station Unit 2 boiler's lower furnace could increase NO_X emissions by admitting oxygen-bearing flue gas in the vicinity of the injected urea if RRI were applied with basic or advanced forms of SOFA. To avoid this negative impact, FGR in the lower furnace would need to be discontinued. There is uncertainty whether modification or elimination of the use of FGR in the lower furnace of MRY Station's Unit 2 boiler could be successful in controlling lower furnace wall fireside ash deposition and gas temperatures.

Because of the significant insurmountable problems discussed above which would increase NO_X emission rates, RRI is considered technically infeasible for application on the Unit 2 cyclone boiler at the Milton R. Young Station.

A.1.4.1.3 SOFA with RRI and SNCR

When RRI is combined with separated overfire air and SNCR, it has demonstrated very high NO_X emissions reduction at Conectiv's B.L. England Unit 1 boiler during short-term testing firing eastern bituminous coal, on the order of 80% from an uncontrolled baseline around 1.2 lb/mmBtu[24]. In May 2005, testing RRI+SNCR+SOFA at Ameren's Sioux Unit 1 boiler firing a high PRB-blend coal demonstrated NO_X emissions as low as 0.12 lb/mmBtu. This was from an established baseline condition of 0.20 lb/mmBtu level achieved with deep cyclone air-staging and SOFA operation. These testing results when firing an 80%:20% PRB/Illinois coal blend at 480 MWg unit output with a reagent NSR of 4 and ammonia slip limited to less than 5 ppmvd, showed an overall 90% reduction with no apparent adverse short-term impacts of deeper air-staged combustion together with overfire air, RRI and SNCR applications[27].

Because of the significant insurmountable problems regarding RRI as mentioned above, RRI with SNCR and ASOFA is considered technically infeasible for application on the Unit 2 cyclone boiler at the Milton R. Young Station due to the variable heat content of the lignite fuel which allows the creation of oxygen-rich conditions in the boiler.

A.1.4.2 SNCR and Reburn

SNCR could potentially be installed downstream of separated overfire air and various types of fuel reburn, to reduce NO_X emissions prior to a boiler's flue gas exit. Several of these examples were already described[7,8,9,10,11,1213,14]. Conventional gas (CGR) or coal reburn systems, by and large, have not been combined with forms of SNCR, although at least one vendor (GE Energy) has promoted a combination of conventional gas reburn with SNCR and overfire air systems as "advanced" gas reburn. Only one example of permanent installation of SNCR with conventional gas reburn (and overfire air) on a tangentially-fired boiler was found in available technical literature[10] and vendor experience lists[14]. The vendor (GE Energy) that provided the advanced gas reburn system at 120 MW NRG Somerset Station claimed NO_X emissions were reduced by 44% from a baseline of 0.45 down to 0.25 lb/mmBtu with overfire air alone; an additional reduction of 20% resulting from conventional gas reburn with overfire air, down to 0.20 lb/mmBtu; and further decrease of 45% down to 0.11 lb/mmBtu using gas reburn with SNCR with an unstated amount of ammonia slip, for an overall reduction of 75% from uncontrolled baseline[14].

No examples of actual demonstration or permanent installation of SNCR with conventional gas or coal reburn (and overfire air) on cyclone-fired boilers were found in a search of published and proprietary technical literature. The lack of experience with these combinations on a cyclone-fired boiler, especially for lignite-firing, makes the application for MRY Station's boilers infeasible.

FLGR™ has been installed with SNCR for NO_X emission reduction on several pulverized coal boilers, as discussed in the following subsection. A potential advantage of FLGR™ over conventional coal or gas reburn techniques is that the former is generally compatible with, but does not require, the installation and operation of SOFA.

Rich Reagent Injection would appear to be less capable of being combined with fuel reburn, especially conventional fuel reburn alternatives with high amounts of reburn fuel injection. This is due to the expected need to idle (e.g. not fire) up to four of the twelve cyclones when operating the reburn system at full boiler load. In this case, the cooling air introduced into the idle cyclones, and any conveying air injected with pulverized reburn coal (or if natural gas is injected with recirculated flue gas), are expected to counteract the fuel-rich conditions of the air-and fuel-staged cyclones operating substoichiometrically. This will cause a portion of the amine reagent to be oxidized in the lower furnace, creating NO_X emissions instead of converting them to nitrogen and water. No example of actual demonstration or permanent installation of RRI with reburn (and overfire air) on cyclone-fired boilers was found in available technical literature or vendor experience lists. This combination is considered infeasible due to the location of injection and variable heat content of the lignite reburn fuel which allows the creation of oxygen-rich conditions in vicinity of RRI injectors in the lower furnace of Unit 2's boiler.

Hydrocarbon-enhanced SNCR (e.g. NO_XStar™) may potentially be combined with all types and forms of reburn previously discussed, since the location of the enhanced ammonia injection nozzles will be above (beyond) the elevation in the middle furnace where any reburn fuel should be reacted. No example of actual demonstration or permanent installation of HE-SNCR with reburn (and overfire air) on any coal-fired utility boilers, especially cyclone-fired units, was found in available technical literature or vendor experience lists. The advantage that HE-SNCR presents is the potential for greater-than-SNCR-levels of NOx reduction without significant amounts of gaseous hydrocarbon being required. Because of a lack of experience with HE SNCR applied to cyclone boilers, and none with significant amounts of fuel reburn, this combination has not been investigated further, and was not included in the control and cost-effectiveness analysis for NO_X controls.

A.1.4.2.1 Amine-Enhanced FLGR™ (AEFLGR™) or FLGR™ + SNCR

Fuel-lean gas reburn has been combined with SNCR as a hybrid form of amine reagent technologies on at least five pulverized coal-fired utility powerplants retrofit installations within the United States. This combination of technologies allows the boiler to be operated with FLGR™ alone, FLGR™ and SNCR simultaneously, or SNCR only (without SOFA) for the specific level of control desired or required.

No examples of actual demonstration or permanent installation of FLGR™ + SNCR (with or without overfire air) applied to a cyclone-fired boiler were found in available technical literature or vendor experience lists. The vendor (Fuel Tech) that provided the AEFLGR™ system at Mercer Station claimed NO_X emissions were reduced by 60% (from a baseline of 1.4 down to 0.56 lb/mmBtu) with 5 ppm ammonia slip without overfire air. A technical paper provides more details[18]. Another technical paper stated that FLGR™ alone only reduced NO_X emissions approximately 27% from the 1.4 lb/mmBtu baseline, down to 1.03 lb/mmBtu[35].

An AEFLGR™ system (with or without SOFA or ASOFA) may be potentially applied to a cyclone-fired boiler. The high capital and operating costs associated with applying fuel lean gas reburn is expected to make this economically unattractive, and the existing lignite pre-drying vent ports will likely limit the NO_X emission reduction potential of the FLGR™ component if installed without the advanced form of SOFA. The lack of experience with this combination on any cyclone-fired boiler, especially for lignite-firing, makes this combination infeasible for MRY Station Unit 2 boiler.

A.2.1 - U.S. Cyclone NOx Reduction Projects Summary

SELECTIVE NON-CATALYTIC REDUCTION/ RICH REAGENT INJECTION

Cyclone-Fired Boilers

Conectiv (formerly Atlantic Electric)
BL England Unit 1 Crushed Coal, single-wall cyclone-fired 1962 vintage
138 MW B&W boiler aqueous urea SNCR, 1995 startup eastern bituminous coal
Boiler has only 3 cyclone burners, arranged “1 over 2” style.
RJM implemented commercial Fuel Tech urea-based SNCR system installation in 1995 after short-term (3-month demonstration test) in 1993-1994. 31 % NOx reduction claimed, from 1.31 lb/mmBtu NOx baseline(1) for SNCR only; RJM claimed 35% reduction from 1.31 lb/mmBtu down to 0.85 lb/mmBtu (without overfire air) with urea-to-NOx NSR = 0.85 (RJM experience list).

Added eight temporary RRI ports (three nozzles on each lower sidewall, and two nozzles on the upper rear wall, and performed one month demonstration parametric testing of overfire air only (without SNCR or RRI), at 120 MW nominal boiler load and cyclone S.R. = 0.90 in 1999. REI claimed 55% NOx reduction from a 1.2 lb/mmBtu uncontrolled NOx baseline to 0.55 lb/mmBtu with OFA only, with stack CO emissions below 50 ppm. For Rich Reagent Injection; REI claimed 25-30% NOx reduction for RRI down to 0.38 lb/mmBtu from controlled baseline w/ OFA alone of 0.55 lb/mmBtu NOx and a RRI urea-to-NOx NSR = 2; also showed RRI+SNCR w/ OFA reduced NOx 55% to 0.25 lb/mmBtu (34% beyond RRI w/ OFA), for an overall 79% NOx reduction with a SNCR urea-to-NOx NSR = 1. Measured less than 1 ppm ammonia slip during RRI testing, < 5 ppm slip for RRI + SNCR. No significant increase in CO emissions during RRI testing(2).
Source: (1) ICAC White Paper; RJM experience list; (2) REI 2001 Technical Paper.

Conectiv (formerly Atlantic Electric)
BL England Unit 2 Crushed Coal, cyclone-fired, single-wall-fired 1964 vintage
160 MW B&W boiler SNCR, 1996 startup eastern bituminous coal
RJM implemented commercial Fuel Tech urea-based SNCR system in 1996, claimed 36% reduction from 1.36 lb/mmBtu down to 0.85 lb/mmBtu, urea-to-NOx NSR = 0.85 (without overfire air) (1).
An OFA system was added in 1998, resulting in NOx emissions of 0.33 lb/mmBtu, for an overall NOx reduction of 76%.
Source: RJM experience list. (Also listed in (1) ICAC White Paper).

AmerenUE (formerly Union Electric Co.)
Sioux Unit 1 Crushed Coal, opposed-wall cyclone-fired 1969 vintage
500 MW B&W boiler Rich Reagent Injection demonstration testing in 2001
Boiler has 10 cyclone burners, arranged “2 over 3” style, on opposite walls, and fires a blend of 85% to 50% western subbituminous (PRB) coal, with Illinois bituminous coal, petroleum coke, and tire-derived fuel.

Installed twenty temporary RRI ports (six nozzles on each lower sidewall, and four nozzles on each front and rear wall), and performed one month demonstration parametric testing of overfire air only and initial testing with RRI in August 2001, followed by additional testing in March 2002, and the second quarter of 2004. Added 8 RRI ports (1 in each sidewall, 4 in each front and rear wall) and 14 SNCR ports (5 on upper front wall, 9 on upper rear wall) to the furnace in early 2005, followed by three weeks of parametric testing and 3 days of continuous testing of RRI with SNCR and deeper-staged OFA.
Tested in August 2001 at lower furnace SR approx.=1.0, 0.55 lb/mmBtu w/ OFA only, only 15% NOx reduction w/ RRI, zero ammonia slip.

Tested in March 2002 at lower furnace SR approx.=0.95, from 0.38 lb/mmBtu baseline w/ OFA only, achieved 29% NOx reduction w/ RRI down to 0.27 lb/mmBtu, NSR=3, zero ammonia slip(3).
(assume blend of PRB and Illinois bituminous coal w/ tire-derived fuel and petroleum coke)(3).
Operation in the second quarter 2004 showed actual stack NOx averaged around of 0.30 lb/mmBtu with OFA only and lower furnace at a cyclone SR around 0.88 burning a 85% PRB, 15% Illinois #6 bituminous coal blend, presumably at 440 MW. This is a 75% NOx reduction from a 1.19 lb/mmBtu pre-control baseline. REI using CFD modeling predicted NOx down to 0.18 lb/mmBtu with RRI+OFA, and below 0.15 with RRI+SNCR under similar deep cyclone air-staging (1.19 to 0.28 lb/mmBtu is 76% reduction, 0.18 vs 0.28 is an additional 36% reduction w/ RRI, and 0.14 vs 0.28 is a 50% reduction w/ RRI+SNCR, for an overall reduction of 88%)(4).
Tested in May 2005 at 480 MWg with lower furnace SR approx. = 0.85-0.88, 76-83% reduction from 1.2 lb/mmBtu baseline down to as low as 0.20 lb/mmBtu w/ SOFA only firing 80% PRB, 20% Illinois #6 bituminous coal blend; additional 15-39% NOx reduction w/ RRI, to as low as 0.15 lb/mmBtu from 0.20-0.28 lb/mmBtu baseline w/ SOFA only at urea NSR varied between 1 and 4, with one ppm ammonia slip; achieved additional NOx reduction w/ RRI +SNCR down to 0.12 lb/mmBtu, NSR=4, ammonia slip10 ppm or less. RRI+SNCR w/ SOFA NOx reduction percentage varied from 15% to 50% below SOFA-only levels, with NSRs between 1 and 4.5. SNCR alone had 13% (NSR=1) to 32% (NSR=1) NOx reduction with ammonia slip around 1-2 ppm*.

REBURN – GAS, CONVENTIONAL

Cyclone-Fired Boilers

Constellation Energy (formerly Baltimore Gas & Electric)
C.P. Crane Station, Units 1 & 2 (MD)   Crushed Coal, cyclone-fired, eastern bituminous coal
2 x 200 MW B&W boilers   (four cyclones each)   1961, 1963 vintage
GE-EER Conventional Gas Reburn, 1999 startup
Added gas supply piping, metering, hangers, supports; reburn injectors and cooling air ductwork, OFA ductwork, injection nozzles and wall ports, field (assume eastern bituminous coal)
GE-EER claimed Gas Reburn with OFA lowered NOx between 60% and 65% from baselines of 1.50 lb/mmBtu to between 0.60 and 0.52 lb/mmBtu, at full load with reburn operation. No claims of percent reburn fuel or percent OFA included in GE-EER's experience list.
Another technical paper showed this installation of CGR operated with 25 percent reburn fuel(5).
Source: Sept. 2005 GE-EER experience list; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

City Water, Light & Power
Lakeside Unit 7   Crushed Coal, front-wall cyclone-fired, midwestern bituminous coal
300,000 lb/hr steam B&W boiler (approx. 33 MWe equivalent, two cyclones)   1961 vintage
Springfield, IL   DOE Clean Coal demonstration project (included sorbent injection)
GE-EER conventional gas reburn w/ OFA   1992 startup (CGR not currently operating)
Vendor claimed to lower NOx by 66% from 0.95 lb/mmBtu baseline to 0.32 lb/mmBtu. A GE-EER 2004 technical paper showed 25% reburn fuel yielded minimum NOx emissions(6).
A DOE NETL technical paper showed this demonstration of CGR from 5/93-10/94 (assume with OFA) with 23 percent reburn fuel reduced NOx 60% from 0.97 to 0.39 lb/mmBtu (5).
Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL 2004 Reburn Conference Technical paper.

Eastman Kodak Company
Kodak Park Boilers 41 & 42   Crushed Coal, front-wall cyclone-fired, 1964 & 1966 vintage

400,000 lb/hr steam B&W boilers (approx. 50 MWe equivalent, two 8-ft dia. cyclones)
Rochester, NY eastern bituminous coal
B&W conventional gas reburn w/ OFA December 1998, July 1998 startups (still operating)
Commercial installation of CGR, with (1) gas burner added to each sidewall + (2) large and (2) small OFA ports added to front wall above cyclones, utilizing higher reburn gas pressure (vs. Boiler #43) requires no flue gas recirculation; {Very small furnace w/ cyclone SR not <1.0}.
B&W claimed reburn with OFA lowered NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. B&W graph shows 10-12% percent reburn fuel to achieve 0.6 lb/mmBtu and 23-24% reburn gas input to reach 0.33 lb/mmBtu NOx (73% reduction) (7).
Another technical paper showed NOx lowered by 52% from 1.25 lb/mmBtu baseline to 0.60 lb/mmBtu with 18 percent reburn fuel(5).
Source: (7) B&W Technical Paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – GAS, CONVENTIONAL

Cyclone-Fired Boilers, continued

Eastman Kodak Company
Kodak Park Boiler 43 Crushed Coal, front-wall cyclone-fired 1968 vintage
600,000 lb/hr steam B&W boiler (approx. 60 MWe equivalent, two cyclones)
Rochester, NY eastern bituminous coal
B&W conventional gas reburn 1995 startup (still operating)
Commercial installation of CGR, with flue gas recirculation (FGR) for injection mass momentum w/ (1) FGR fan; (1) gas burner added to each sidewall + (2) OFA ports added front wall above cyclones. {Very small furnace/low residence time w/ cyclone SR not <1.0}
B&W claimed reburn with OFA & FGR lowered NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. B&W graph shows 18% percent reburn fuel to achieve 0.6 lb/mmBtu and 29% reburn gas input to reach 0.36 lb/mmBtu NOx (70% reduction) (7).
Another technical paper showed NOx lowered by 56% from 1.35 lb/mmBtu baseline to 0.60 lb/mmBtu with 18 percent reburn fuel(5).
Source: (7) B&W Technical Paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Tennessee Valley Authority (TVA)
Allen Station Unit 1 (TN) Crushed Coal, cyclone-fired (seven cyclones) 1959 vintage
300 MW B&W boiler PRB &western bituminous coal blend fired
GE-EER Conventional Gas Reburn, 1998 startup
Commercial installation added gas supply piping, metering, hangers, supports; reburn injectors and cooling air piping, OFA ductwork, injection nozzles and wall ports, field I&C devices.
Reburn with OFA claimed to lower NOx 65% from baseline 1.20 lb/mmBtu to 0.42 lb/mmBtu) at full load with reburn operation. No claims of percent reburn fuel included. (TVA also installed duplicate OFA systems on Allen Units 2 & 3 boilers).
Another technical paper showed NOx lowered by 65% from 0.86 lb/mmBtu baseline (to 0.30 lb/mmBtu) with 7 percent reburn fuel(5).
Source: Sept. 2005 GE-EER experience list; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – COAL, CONVENTIONAL

Cyclone-Fired Boilers

Alliant Energy (formerly Wisconsin Power & Light)
Nelson Dewey Station Unit 2 Crushed Coal, cyclone-fired, PRB coal 1962 vintage

110 MW B&W boiler 3-cyclones across front wall, 4 reburn burners +
4 OFA ports across rear wall, aligned vertically in columns.

US DOE Clean Coal Demonstration project of B&W's Conventional Coal Reburn, 1991 startup (since discontinued) added coal supply piping, reburn burners with flue gas recirculation, OFA ductwork + dual zone ports; coal feeder, pulverizer & PA fan, tested with PRB and bituminous coals. (western subbituminous coal)

B&W claimed reburn operation lowered NOx by 57% from baseline of 0.83 mmBtu to 0.38 lb/mmBtu at full load(7). Approx. 30% percent of total fuel input supplied as reburn fuel. Increased unit output by 10 MW, increased flyash unburned carbon by 4% (13-22% vs 9-18%), decreased furnace exit gas temperature (FEGT). OFA ports listed in B&W experience list.

B&W shows full load NOx w/o reburn was 0.75 lb/mmBtu, and 0.29-0.32 lb/mmBtu w/ PRB fuel during reburn operation (57% decrease). At 75% load, 0.64 vs 0.29-0.32 lb/mmBtu. At 55% load, 0.62 vs 0.29-0.31 lb/mmBtu without and with reburn activated(8).

Another technical paper showed NOx lowered by 52-55% from 0.82 lb/mmBtu baseline (to 0.39-0.34 lb/mmBtu) with 25-30 percent reburn fuel(5).

Source: (7) 2004 B&W Technical Paper; (5) DOE-NETL 2004 Reburn Conference Technical paper;
(8) B&W case history (from website, dated 1997).

REBURN – COAL, MICRONIZED, CONVENTIONAL

Cyclone-Fired Boilers

Eastman Kodak Company
Kodak Park #15 Boiler Crushed Coal, front-wall cyclone-fired, 1956 vintage
400,000 lb/hr steam B&W boiler (approx. 50 MWe equivalent, two cyclones)
Rochester, NY eastern bituminous coal
GE-EER micronized coal reburn1996 initial startup (operating since 1997)

Demonstration project performed with Dept. of Energy's US Clean Coal Technology Program. Project added flue gas recirculation for injection mass momentum, FGR fan and two micronized coal pulverizers; (6) reburn coal injectors added to rear wall + (1) reburn coal injector on each of the sidewalls, with (4) OFA ports added across front wall above cyclones(9). GE-EER designed and fabricated the coal injectors and OFA ports. {Extremely small furnace and low residence time}.

GE-EER claimed reburn + OFA w/ FGR reduced NOx by 50% from 1.20 lb/mmBtu baseline to 0.6 lb/mmBtu. No claims of percent reburn fuel included.

Another technical paper showed this demonstration of micronized coal reburn from 4/97-10/98 lowered NOx by 57% from 1.36 lb/mmBtu baseline (to 0.59 lb/mmBtu) with 17 percent reburn fuel(5).

Source: (9) DOE Topical Report Number 14 (May 1999); GE-EER experience list;(5) DOE-NETL 2004 Reburn Conference Technical paper.

REBURN – FUEL LEAN GAS REBURN

Cyclone-Fired Boilers

Midwest Generation (formerly Commonwealth Edison)
Joliet Station 9, Unit 6 Crushed Coal, opposed-wall cyclone-fired (nine cyclones)
340 MW B&W boiler 1959 vintage, 1997 startup (FLGR has since been decommissioned)

Energy Systems Associates demonstrated 25-30% NOx reduction using 5-10% of total heat input as reburn natural gas injected (without OFA)(5).

Another technical paper showed this demonstration in collaboration with Gas Research Institute of FLGR lowered NOx by 28-43% from 1.36 lb/mmBtu baseline (to 0.59 lb/mmBtu) with 7 percent reburn fuel(10).

Source: (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference);
(10) NGB Technologies Technical Paper.

REBURN – FUEL LEAN GAS REBURN w/ SNCR continued

Cyclone-Fired Boilers

Owensboro Municipal Utilities (KY) Crushed Coal, front-wall cyclone-fired
Elmer Smith Unit 1 (three cyclones) 1965 vintage
150 MW B&W boiler

CFD model study only predicted NOx reductions from 1.59 to 0.39 lb/mmBtu with OFA only (75% reduction, 0.90 SR); 25-30% NOx reduction using 6% of total heat input as reburn natural gas injected above OFA; 40-45% NOx reduction from SNCR with <5 ppm ammonia slip(11).
Source: (11) REI Technical paper.

Separated OVERFIRE AIR

Cyclone-Fired Boilers

Tennessee Valley Authority (TVA) Crushed Coal, cyclone-fired, 1959 vintage
Allen Station Units 2 & 3 (TN) (seven cyclones)
300 MW B&W boilers PRB &western bituminous coal blend
GE-EER Overfire air (duplicate of Allen 1), 1999 startup
GE-EER claimed to lower NOx with OFA alone up to 29% from baseline 1.20 lb/mmBtu to 0.85 lb/mmBtu on Units #2 and 3 at full load.
Source: Sept. 2005 GE-EER experience list.

AmerenUE (formerly Union Electric Co.)
Sioux Unit 1 Crushed Coal, opposed-wall cyclone-fired 1969 vintage
500 MW B&W boiler PRB/Illinois Coal blend
Boiler has 10 cyclone burners, arranged "2 over 3" style, on opposite walls, and fires a blend of 85% to 50% western subbituminous (PRB) coal, with Illinois bituminous coal, petroleum coke, and tire-derived fuel.
A ten-port OFA system (five ports on each front and rear wall) began operation in mid-2001, which reduced NOx emissions approx. 40-50% reduction from 1.1-1.3 (assume average of 1.19) down to 0.7 lb/mmBtu with moderate cyclone air-staging (cyclone SR from 1.19 to 1.0). (3) Subsequent testing and full load operation at deeper cyclone air-staging (SRs ≤ 0.90) has dropped NO$_X$ with SOFA alone to around 0.3 lb/mmBtu in 2004(4).
Source: (3) REI 2002 and 2003 Technical Papers; (4) REI 2004 Technical paper;* REI 2005 Technical paper

Coal burning cyclone-fired utility boilers in the United States that have been retrofitted with Separated Overfire Air CR technology are listed in Table A.2-1. A large majority of the cyclone-fired boilers listed burn western subbituminous coal (or PRB blended with midwestern bituminous coal).

TABLE A.2-1 – Cyclone-Fired Boiler Overfire Air Retrofit Installations(12)

Facility Name	Installation Date	Comments
Allen Station Units 1	Installed 1998*	OFA w/ CGR retrofit; has SCR
Allen Station Unit 2	Installed 1999*	(Similar to Unit 1, w/o CGR) have SCR
Allen Station Unit 3	Installed 1999*	(Similar to Unit 1, w/o CGR) have SCR
Asbury Unit 1	Installed 5/10/1999	Empire District, BART-eligible
Bailly Unit 7	Installed 2003(13)	SCR to be installed in 2006-7
Bailly Unit 8	Installed 5/31/2000	SCR retrofit 5/11/2004
Baldwin Unit 1	Installed 12/31/1999	SCR retrofit 4/28/2003
Baldwin Unit 2	Installed 5/8/2000	SCR retrofit 4/12/2002
Big Stone Unit 1	Installed 10/22/1997	part of conversion to PRB
BL England Unit 2	Installed 1998*	previous SNCR retrofit in 1996
CP Crane Unit 2	Installed 2/1/1999	OFA w/ CGR retrofit
Coffeen Unit 1	Installed 2/1/2001	SCR retrofit 4/21/2003
Coffeen Unit 2	Installed 2/9/2000	SCR retrofit 4/09/2002
Edgewater Unit 3	Installed 11/2001(13)	
Edgewater Unit 4	Installed 6/19/2001	
Joliet 9 Unit 6	Installed 2000(13)	
Kincaid Unit 1	Installed 4/28/2000	SCR retrofit 12/17/2002
Kincaid Unit 2	Installed 5/24/2000	SCR retrofit 6/07/2002
Allen S. King Unit 1	Installed 11/30/1999	
LaCygne Unit 1	Installed 2/28/2000	
Lake Road Unit 6	Installed 6/01/2002	
Michigan City Unit 12	Installed 4/1998(13)	SCR retrofit 5/01/2003
Nelson Dewey Unit 1	Installed 2002(13)	
Nelson Dewey Unit 2	Installed 2002(13)	
Paradise Unit 1	Installed 11/14/1998	SCR retrofit 5/01/2001
Paradise Unit 2	Installed 12/8/1999	SCR retrofit 5/01/2000
Paradise Unit 3	Installed 5/4/2000	SCR retrofit 3/10/2004
Powerton Unit 5-1	Installed 6/1/2003	
Powerton Unit 5-2	Installed 6/1/2003	
Powerton Unit 6-1	Installed 6/1/2002	
Powerton Unit 6-2	Installed 5/4/1999	
Schahfer Unit 14	Installed early 2000(13)	SCR retrofit 5/11/2004
Sibley Unit 2	Installed 5/24/2002	
Sibley Unit 3	Installed 5/4/1999	
Sioux Unit 1	Installed 4/30/2001	SNCR demo May 2005
Sioux Unit 2	Installed 4/30/1997	
State Line Unit 4	Installed 11/2001(13)	Similar to Joliet 9 Unit 6
Tanners Creek Unit 4	Installed 5/12/2002	
Thomas Hill Unit 1	Installed June 2004(13)	
Thomas Hill Unit 2	Installed November 2000(13)	

Note: This table does not include every installed U.S. coal-fired cyclone boiler OFA retrofit project.

* Vendor experience list (GE Energy for Allen Station Units 1-3; RJM for BL England Unit 2)
(13) Burns & McDonnell internal database.

Coal burning cyclone-fired utility boilers in the United States that have been retrofitted with SCR technology are listed in Table A.2-2. This list includes at least eighteen cyclone-fired boilers burning western subbituminous coal (or PRB blended with midwestern bituminous coal). The highest emission reductions listed in Table A.2-2 for SCR systems are for clean reactor catalyst and ideal operating conditions.

TABLE A.2-2 – Cyclone-Fired Boiler High-Dust SCR Installations

Facility[1]	**Unit Size[2],MW**	**Tested Control Efficiency[3]**	**Tested Outlet NO_X Emission Rate (lb/mmBtu)[3]**	**2003 Ozone Season Average NO_X Emission Rate[4] (lb/mmBtu)**

[1] – original design fuel for all listed cyclone boilers was bituminous coal
[2] – Generator nameplate rating, March 2002 Energy Information Administration report DOE/EIA-0095(2000). Actual unit MW output rating may be higher or lower than nameplate.
[3] – Burns & McDonnell internal database.
[4] – as reported to US EPA, available from their website at http://cfpub.epa.gov/gdm/index.cfm
[5] – includes application of separated overfire air for combustion NO_X control
[6] – current fuel believed to be a blend of subbituminous and bituminous coals
[7] – NAD = no published data from SCR emission testing found on these units.
[8] – original air preheaters were tubular-type; changed to rotary-type during SCR retrofit
[9] – Design NO_X removal efficiency is higher, approx. 90%.
[10] – current fuel believed to be subbituminous coal

For Merrimack Unit 1's SCR, inlet (i.e. uncontrolled) NO_X was 1.34 lb/mmBtu, for a blend of high sulfur bituminous and medium or low sulfur bituminous coals, and requires year-round SCR operation for compliance. The catalyst was designed for 88.9% NO_X removal efficiency and 5 ppm ammonia slip. SCR commercial service date July 20, 1999. [(14) Babcock Borsig Power 2000 technical paper on SCRs].

For Merrimack Unit 2's SCR, inlet (i.e. uncontrolled) NO_X was 2.66 lb/mmBtu, for a blend of high sulfur bituminous and medium or low sulfur bituminous coals, and requires year-round SCR operation for compliance. Initial testing demonstrated 70% removal(15), which exceeded the 65% requirement to achieve a 0.92 lb/mmBtu permit limit. The catalyst was designed for 85-95% NO_X removal efficiency and 5 ppm ammonia slip(16).

Dynegy Midwest Gen/Havana Unit 6[10]	(2000)	0.46 /0.20 / 0.102[9]	488
PSEG Power LLC / Mercer Unit 1[11]	(2005)	- / (0.63) / N/A	320
PSEG Power LLC / Mercer Unit 2[11]	(2004)	- / (0.76) / N/A	320

[1] – Burns & McDonnell internal database.

[2] – Current fuel is eastern or midwestern bituminous coal, except Havana

[3] – US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005, except where noted. Dates in () are believed to be accurate but have not been confirmed.

[4] – The three values are "Pre-control average", "2004 annual average", and "2003 ozone season average" NO_X emission rates, as reported to US EPA. Pre-control and year 2004 annual average data as shown in US EPA Docket OAR-2002-0076-0446 Technical Support Document for BART NOx Limits for Electric Generating Units Excel Spreadsheet 6/15/2005, posted on their website: http://docket.epa.gov/edkpub/do/EDKStaffItemDetailView?objectId=090007d48084562b. Values shown in parentheses are year 2003 annual average where 2004 data is not available. Year 2003 and 2003 ozone season data is available from the EPA's website at http://cfpub.epa.gov/gdm/index.cfm, includes application of separated overfire air for combustion NO_X control where applicable.

[5] – Generator nameplate rating, March 2002 Energy Information Administration report DOE/EIA-0095(2000). Actual unit MW output rating may be higher or lower than nameplate.

[6] – This boiler has low-NOx burners for combustion controls.

[7] – Carolina Power & Light plants listed here have two boilers per unit, total nameplate for Mayo is 736 MW, Roxboro is 745 MW; emission numbers are the average of both boilers.

[8] – This boiler has low-NOx burners and overfire air for combustion controls.

[9] – This is preliminary data reported to the US EPA for 2004 ozone season average emission rate.

[10] – This boiler's current fuel is believed to be subbituminous coal.

[11] – Mercer boilers listed have low-dust SCR with flue gas reheat. Unit size is approximate, not nameplate.

N/A = complete 2004 ozone season data is not available, and 2003 ozone season data is not representative of the post-SCR installation emission rate.

SELECTIVE NON-CATALYTIC REDUCTION

Pulverized coal-fired boilers

American Electric Power (AEP) Pulverized Coal, cell-burner, opposed wall-fired B&W boiler
Cardinal Unit 1 1967 vintage; Low NO_x burners installed in October 1998
600 MW (nominal) Brilliant, Ohio
Fuel Tech urea-based SNCR installed in October 1998.
Fuel Tech, DOE, EPRI-member utilities SNCR demonstration project. Tested in March-April 1999, claimed 65% reduction with LNBs + SNCR w/ 5 ppm NH_3 slip, (from pre-LNB retrofit baseline of 1.20 lb/mmBtu*) down to 0.52 lb/mmBtu at 620 MW (100% MCR). SNCR reduced NO_X 31% below LNBs alone (0.75 lb/mmBtu baseline), at 620 MWg (100% MCR), 34% reduction at 75% MCR (450 MWg), and 42% reduction at minimum load (340 MWg, 55% MCR) ≤ 5% ammonia slip(17), burning eastern bituminous coal. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005; (1)ICAC White Paper, (17) 2000 Fuel Tech technical paper, *Riley Power (Babcock Power Inc.) experience list 8/16/04.

Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 SNCR startup
Fuel Tech commercial SNCR installation claimed 25% NOx reduction from low-NO_X burner w/o OFA baseline of 0.58 lb/mmBtu (down to 0.44 lb/mmBtu on SNCR alone). Urea-to-NOx NSR not stated. (Also see FLGR + SNCR installation summaries for pulverized coal boilers).
Source: Fuel Tech experience list dated 1/28/2005.

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 5 1956 vintage; eastern bituminous coal
154 MW CE boiler SNCR startup in 2002
Mobotec USA “Rotamix” ammonia-based SNCR system injects aqueous ammonia liquid into a high velocity boosted separated overfire air (ROFA) system at the boiler.
CP&L technical paper claimed to lower NO_X from 0.28 lb/mmBtu baseline by 43% to 0.16 lb/mmBtu in 2002 with 5 ppm NH_3 slip following the installation of ROFA in 2000.
Overall reduction 73% from full-load pre-ROFA baseline 0.60 lb/mmBtu to 0.16 lb/mmBtu(18).
Mobotec claimed further NO_X reduction was possible by injecting urea in place of ammonia, achieving 0.13 lb/mmBtu instead of 0.18 lb/mmBtu, which would be 54% decrease from 0.28 lb/mmBtu with ROFA alone, or 78% overall decrease(19). Ammonia-to-NOx NSR not stated.
Source: (18) CP&L 2002 Technical paper; (19) Mobotec 2003 technical paper.

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 6 twin-furnace (eight corner), 1958 vintage; eastern bituminous coal
175 MW CE boiler SNCR startup in 2001
Mobotec USA “Rotamix” ammonia-based SNCR system, injects aqueous ammonia liquid into a high velocity boosted separated overfire air (“ROFA”) system at the boiler.
CP&L technical paper claimed to lower NO_X from 0.23 lb/mmBtu baseline by 22% to 0.18 lb/mmBtu with 5 ppm NH_3 slip following the installation of ROFA+SNCR in 2001(18). Presentation slide graph shows no reduction for Rotamix beyond ROFA alone at full load NO_X emission rate of 0.23 lb/mmBtu. Ammonia-to-NOx NSR not stated.
Overall reduction 67% from full-load pre-ROFA baseline 0.54 lb/mmBtu to 0.18 lb/mmBtu.
Mobotec claimed further NO_X reduction was possible by injecting urea in place of ammonia, achieving 0.10 lb/mmBtu instead of 0.18 lb/mmBtu, which would be 56% decrease from 0.23 lb/mmBtu with ROFA alone, or 81% overall decrease(19). Urea-to-NOx NSR not stated.
Source: (18) CP&L 2002 Technical paper; (19) Mobotec 2003 technical paper.

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Cinergy (formerly Cincinnati G&E) Pulverized Coal, Tangentially-fired,
Miami Fort Unit 6 (Ohio) 1960 vintage; startup prior to 2000
163 MW CE boiler
Fuel Tech urea-based SNCR system, claimed to lower NOx by 35% from 0.55 lb/mmBtu baseline(1).(assume eastern bituminous coal). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, (1) ICAC White Paper.

Conectiv (formerly Delmarva Power & Light)
Edgemoor Unit 3 Pulverized Coal, Tangentially-fired, 1954 vintage
84 MW CE boiler mid-March 1996 startup; (assume eastern bituminous coal)
Hamon Research-Cottrell supplied a urea-based SNCR system. HRC claimed 35% NOx reduction with less than 10 ppm ammonia slip. Urea-to-NOx NSR not stated.
Another source shows a 30% reduction from 0.54 lb/mmBtu baseline(1).
Source: Hamon experience list (not listed by Fuel Tech); (1) ICAC White Paper.

Conectiv (formerly Delmarva Power & Light) Pulverized Coal
Indian River Units 3 & 4 (Millsboro, DE) Unit 3 is front wall-fired, 1974 vintage
178MW and 440 MW Unit 4 is turbo-fired opposed-wall, 1980 vintage
B&W, DB Riley boilers Spring 2000 startup (eastern bituminous coal)
Hamon Research-Cottrell supplied a urea-based SNCR system (not listed by Fuel Tech) on both units. HRC claimed 35% NO_X reduction with less than 5 ppm ammonia slip. Urea-to-NOx NSR not stated.
An REI 1999 technical paper shows a pre-SNCR baseline of 0.37 and 0.44 lb/mmBtu, respectively. (20)
Another source listed these units as having a pre-control NO_X baseline of 0.97 and 0.57 lb/mmBtu, and 2004 post-SNCR startup average of 0.32 and 0.33 lb/mmBtu, respectively. (12)
Source: Hamon experience list (not listed by Fuel Tech); (20) REI 1999 technical paper;

Dominion Generation (Virginia E&P Co.) Pulverized Coal, Tangentially-fired
Clover Station, Units 1 & 2 (VA) ABB/CE boilers, 1995, 1996 vintage
2 x 465 MW (eastern bituminous coal)
Urea-based SNCR (Fuel Tech system) 1995, 1996 startup (initial commercial)
Fuel Tech claimed NOx reduced by 25% from 0.32 lb/mmBtu baseline (to 0.24 lb/mmBtu).
Source: Fuel Tech experience list dated 1/28/2005. Urea-to-NOx NSR not stated.

Dynegy Midwest Generation (formerly Illinois Power) Pulverized Coal, Tangentially-fired
Vermillion Station, Unit 1 1955 vintage
82 MW CE boiler, bituminous Illinois coal
Mobotec USA "Rotamix" urea-based SNCR system with rotating opposed fired air (ROFA).
Mobotec 2004 technical paper claimed to lower NO_X by 55% from 0.22 lb/mmBtu baseline to 0.10 lb/mmBtu in April 2004 with urea-based Rotamix SNCR and < 5 ppm CO. NH_3 slip not mentioned. Overall reduction 83% from full-load pre-ROFA baseline 0.58 lb/mmBtu to 0.10 lb/mmBtu (21). Urea-to-NOx NSR not stated.
Source: (21) Mobotec 2004 technical paper.

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Eastern Utilities Associates, Pulverized Coal, Tangentially-fired
Montaup Electric Company 1959 vintage
Somerset Unit 8 (Massachusetts) Summer 1995 startup
112 MW CE boiler (eastern bituminous coal)
Hamon Research-Cottrell supplied a urea-based SNCR (Fuel Tech system), claimed to lower NOx below 0.38 lb/mmBtu (Mass. RACT). Urea-to-NOx NSR not stated.
Another source listed 28-60% NOx reduction from a 0.49-0.89 lb/mmBtu baseline(1).
Source: Hamon experience list, Fuel Tech experience list dated 1/28/2005, (1)ICAC White Paper.

First Energy Pulverized Coal, Tangentially-fired,
Eastlake Unit 3 (Ohio) 1954 vintage
130 MW CE boiler (w/ division wall) (eastern bituminous coal)
Urea-based SNCR (Fuel Tech system) SNCR startup prior to 2000
Fuel Tech claimed to lower NOx from 20-32.5% from 0.34-0.40 lb/mmBtu baseline(1). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, (1) ICAC White Paper.

First Energy Pulverized Coal, wall-fired,
Sammis Unit 2 (Ohio) 1960 vintage
180 MW Foster Wheeler boiler SNCR startup Fall 1999
Urea-based SNCR (Fuel Tech system) (eastern bituminous coal)
Fuel Tech claimed to lower NOx from 25-30% from 0.45 lb/mmBtu baseline (1). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, (1) ICAC White Paper.

First Energy Pulverized Coal, wall-fired,
Sammis Units 6 & 7 (Ohio) 1969 & 1971 vintage
680 MW B&W Universal Pressure boilers (eastern bituminous coal)
Urea-based SNCR (Fuel Tech system) SNCR startup after 1999
Fuel Tech claimed to lower NOx from 25% from 0.38 lb/mmBtu baseline. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005.

New England Power Company (NEPCO)
Salem Harbor Station Pulverized Coal, front wall-fired,
Units 1, 2 & 3 1952, 1952, 1958 vintage (eastern bit. coal)
84 MWe x 2, & 156 MWe B&W boilers SNCR startup prior to 2000
Urea-based SNCR (Fuel Tech system)
Fuel Tech claimed 66% (50-75%) NOx reduction from baseline of 1.0 ± 0.1 (range 0.85-1.12) lb/mmBtu, (which would lower NOx to around 0.34±0.07 lb/mmBtu). Urea-to-NOx NSR not stated. {These NOx reduction percentages may include impact of low-NOx burners}.
Source: Fuel Tech experience list dated 1/28/2005, (1)ICAC White Paper.
(Also see LNB installation summaries for pulverized coal boilers).

Northeast Utilities (formerly Public Service of New Hampshire)
Schiller Units 4, 5, & 6 Pulverized Coal/#6 Fuel oil, front-wall-fired
50 MWe x 3Foster Wheeler boilers 1952, 1955, 1957 vintage
Urea-based SNCR (Fuel Tech system) Colombian bituminous coal
August 1999 startup
RJM implemented Fuel Tech urea-based commercial SNCR installation on all three boilers.

RJM claimed 50% reduction from 0.50 lb/mmBtu pre-SNCR baseline to 0.25 lb/mmBtu for SNCR coal-firing operation; NO_X baseline 0.82 lb/mmBtu prior to RJM's LNB modifications installed in 1994, 1992, & 1994 (39% reduction); Urea-to-NOx NSR not stated.
Fuel Tech claimed 30% NO_X reduction for SNCR from baseline of 153 ppm firing #6 fuel oil on Units 4 & 6 only.
Source: RJM experience list, Fuel Tech experience list dated 1/28/2005.

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Owensboro Municipal Utilities (KY) Pulverized Coal, Tangentially-fired,
Elmer Smith Unit 2 1974 vintage
300 MW CE boiler eastern bituminous coal
Hamon Research-Cottrell supplied an ammonia-based SNCR system but stated no claims for NOx reduction; (this project is not listed in ICAC White Paper(1)). Ammonia-to-NOx NSR not stated.
Source: Hamon experience list.

PECO Energy (formerly Philadelphia Electric Company)
Cromby Unit 1 Pulverized Coal, front wall-fired divided furnace
160 MWe B&W boiler 1954 vintage eastern bituminous coal
RJM installed Fuel Tech urea-based SNCR with low NO_X burner modifications & OFA in 1999, June 1999 startup.
RJM claimed 29% SNCR NO_X reduction from baseline of 0.35 lb/mmBtu, down to 0.25 lb/mmBtu with urea NSR = 0.8; RJM provided burner modifications of B&W XCL low-NOx burners installed in 1994 + OFA; this reduced NO_X from 0.50 to 0.35 lb/mmBtu (30% reduction) without SNCR. Urea-to-NOx NSR not stated.
Source: RJM experience list; (1)ICAC White Paper.

Exelon (formerly PECO Energy/ Pennsylvania Electric Company)
Eddystone Units 1 & 2 Pulverized Coal Tangentially-fired, 1954 vintage
318, 333 MW each CE boilers 1999 SNCR startup, eastern bituminous coal
Fuel Tech claimed 30% NOx reduction from baseline of 0.26 lb/mmBtu.

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Hudson Station, Unit 2 Pulverized Coal, opposed-wall-fired, 1968 vintage
660 MWe Foster Wheeler boiler eastern bituminous coal March 1999 startup
Fuel Tech urea-based commercial SNCR installation claimed 25% (initial) NOx reduction for SNCR alone from baseline of 0.65 lb/mmBtu (down to 0.49 lb/mmBtu). Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, also listed in (1)ICAC White Paper. (Also see FLGR+SNCR installation summaries for pulverized coal boilers).

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]

Mercer Station	(2) twin-furnace boilers, 320 MWe each, DB Riley turbo-fired	
Unit 1 and Unit 2	front wall PC, wet-bottom (slagging ash) eastern bituminous coal	
Furnace #11 & #12	1960 vintage	April 1999 startup
Furnace #21 & 22	1961 vintage	May 1999 startup

Fuel Tech urea-based commercial SNCR installation claimed 30-35% NOx reduction from baseline of 2.0 lb/mmBtu on SNCR alone, down to 1.4 lb/mmBtu. Urea-to-NOx NSR not stated.

Source: Fuel Tech experience list dated 1/28/2005; also listed in (1)ICAC White Paper. (Also see FLGR+SNCR installation summaries for pulverized coal boilers)

SELECTIVE NON-CATALYTIC REDUCTION continued

Pulverized coal-fired boilers

Reliant Energy (formerly GPU Genco)   Pulverized Coal
(formerly Sithe, formerly Penelec)   Tangentially-fired
Seward # 15 (PA)   mid-1990's SNCR startup
Units 4 & 5   eastern bituminous coal
62 & 156 MW CE boilers   1950 & 1957 vintage
Urea-based SNCR (Fuel Tech system), later installed an in-duct SCR to reduce NH_3 slip.
Fuel Tech claimed to lower NOx 35% for SNCR only (55% for combined SNCR/SCR from 0.78 lb/mmBtu baseline). Boilers have since been demolished and replaced with CFBs. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005, (1)ICAC White Paper.

Rochester Gas & Electric   Pulverized Coal, Tangentially-fired
Russell Station, Units 1-4 (NY) 1948, 1950, 1953, 1957 vintage
1 x 50 MW, 2 x 65 MW, 1 x 85 MW CE boilers   eastern bituminous coal
Urea-based SNCR (Fuel Tech system)   SNCR startup prior to 2000
Vendor claimed to lower NOx by 15-27.5% from 0.28 – 0.42 lb/mmBtu baselines. Urea-to-NOx NSR not stated.
Source: Fuel Tech experience list dated 1/28/2005.

HYDROCARBON-ENHANCED AMMONIA SNCR (NOxStar™)

Pulverized coal-fired boilers

Tennessee Valley Authority (TVA)   Pulverized Coal twin-furnace, tangentially-fired,
Kingston Power Station (TN)   1955 vintage   eastern bituminous coal
Unit 9, 200 MWe CE boiler   NOxStar™ startup January 2002
Demonstration of NOxStar™ hydrocarbon-enhanced ammonia-based SNCR installation.
Mitsui Babcock claimed 68% NOx reduction from baseline of 0.55 lb/mmBtu down to 0.17 lb/mmBtu with boosted OFA and NOxStar™ with < 5 ppm ammonia slip; NOxStar™ alone reduced NOx by 53%(22); boosted OFA only reduced NOx from 0.55 to 0.45 lb/mmBtu (18% reduction). Ammonia-to-NOx NSR not stated.
TVA's website reported that "an earlier version of NOxStar was installed at Kingston Fossil Plant Unit 9 in 2002 with mixed results. NOx reductions were achieved, but the boiler was damaged" (http://www.tva.gov/environment/repotrs/envreports/aer/2003/env_compliance.htm)
Source: (22) Mitsui Babcock Technical paper, October 2003.

Tennessee Valley Authority (TVA)   Pulverized Coal, wall-fired
Colbert Station (AL)   1955 vintage
Unit 4, 192 MWe twin-furnace B&W boiler w/ FGR eastern bituminous coal
First commercial installation of NOxStar™ hydrocarbon-enhanced ammonia-based SNCR technology.
Mitsui Babcock showed 80% NOx reduction from baseline of 0.50 to 0.10 lb/mmBtu; using < 0.1% of total boiler heat input for propane input and 1% of total steam flow generated in the boiler for lance cooling(23); 2004 SNCR system startup. Ammonia-to-NOx NSR not stated.

REBURN – GAS, CONVENTIONAL

Pulverized coal-fired boilers

Allegheny Power (formerly West Pennsylvania Power)
Hatfield's Ferry Station
Units 2 & 3, 600 MW (nominal) each (B&W boilers)

Pulverized Coal, opposed wall-fired
cell-burner, 1969 & 1972 vintage
eastern bituminous coal

GE-EER Gas Reburn; 1999 startup (Unit 2) & 2003 (Unit 3)
GE-EER Low NOx burners, boosted OFA, gas reburn system.
GE-EER claimed to lower NOx up to 67% from baseline of 0.60 lb/mmBtu to 0.20 lb/mmBtu at full load with reburn operation on Unit 2, 68% from 0.62 lb/mmBtu to 0.20 lb/mmBtu on Unit 3. No claims of percent reburn fuel included.
GE-EER technical paper shows approx. 35% NOx reduction at 600 MW load with LNB + OFA w/o reburn fuel, and an additional 50% reduction to 0.20 lb/mmBtu with reburn fuel(24).
B&W added 20 OFA ports in 1994 per B&W's experience list. No NOx reduction claims. Source: Sept. 2005 GE-EER experience list; (24) GE-EER 2004 Technical paper. Unit 2 and Unit 3 listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – GAS, CONVENTIONAL continued

Pulverized coal-fired boilers)

Conectiv (formerly Delmarva Power & Light)
Edgemoor Unit 4
160 MW CE boiler

Pulverized Coal, Tangentially-fired
1966 vintage, eastern bituminous coal
1999 startup

GE-EER Gas Reburn project added gas supply piping, metering, hangers, supports, reburn injectors and cooling air piping; OFA ductwork, injection nozzles and wall ports, field instrumentation. No FGR or OFA booster fans.
Vendor claimed to lower NOx up to 48% from baseline of 0.32 lb/mmBtu to 0.16 lb/mmBtu) at full load with reburn operation. No claims of percent reburn fuel included.
GE-EER technical paper shows approx. 32% NOx reduction for gas reburn with 4-mill operation at 160 MW load from 0.31 lb/mmBtu LNB + OFA baseline w/o reburn fuel (down to 0.21 lb/mmBtu), and 48% NOx reduction for gas reburn with 3-mill operation, to 0.16 lb/mmBtu (24).
Source: Sept. 2005 GE-EER experience list; (24) GE-EER 2004 Technical paper. Listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference)

Dynegy (formerly Illinois Power)
Hennepin Unit 1
71 MW CE boiler

Pulverized Coal, Tangentially-fired
1966 vintage
eastern bituminous coal

GE-EER Gas Reburn, 1990 startup (not currently operating); GE-EER Orimulsion Reburn, 1997.
DOE Clean Coal demonstration project (included sorbent injection).
Vendor claimed gas reburn w/ OFA lowered NOx up to 67% from baseline of 0.75 lb/mmBtu to 0.25 lb/mmBtu) at full load; 65% reduction from baseline of 0.75 lb/mmBtu down to 0.26 lb/mmBtu with subsequent Orimulsion reburn operation.
GE-EER 2004 technical paper shows 18% gas reburn fuel yielded minimum NOx emissions(6).
Another technical paper showed this 80 MW US DOE Clean Coal demonstration project in January 1991-January 1993 lowered NOx by 67% from 0.75 lb/mmBtu baseline (to 0.25 lb/mmBtu) with 18 percent reburn fuel(5).
Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL 2004 Reburn Conference technical paper, and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference). (Also see Conventional Oil reburn installation summaries for pulverized coal boilers).

REBURN – GAS, CONVENTIONAL continued

Pulverized coal-fired boilers)

AES (formerly New York State Gas & Electric (NYSEG)

Greenidge #6 (NY)	Pulverized Coal, Tangentially-fired,	1953 vintage
100 MW CE boiler	GE-EER Conventional Gas Reburn, 1996 startup	

Vendor claimed to lower NOx 55% from 0.63 lb/mmBtu baseline to 0.28 lb/mmBtu at full load with reburn operation burning eastern bituminous coal. Gas Research Institute predicted would achieve 76% (down to 0.15 lb/mmBtu) w/ advanced gas reburn.
GE-EER 2004 technical paper shows 23% reburn fuel yielded minimum NOx emissions around 0.23 lb/mmBtu(6).
EPA's "Scorecard on Reburning 6/1/2004" shows a 109 MW t-fired boiler (listed as Greenidge Unit 4) lowered NOx by 50% from 0.50 lb/mmBtu baseline (to 0.25 lb/mmBtu) with 10 percent reburn fuel (no longer operating) (5).
Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Potomac Electric Power (formerly West Pennsylvania Power)

Chalk Point Station	Pulverized Coal	opposed wall-fired B&W boilers
Units 1 & 2	1964, 1965 vintage	eastern bituminous coal
360 MW (nominal)	GE-EER Gas Reburn, 2000 startup	

Vendor claimed to lower NOx up to 43% and 45% from 0.60 lb/mmBtu baseline to 0.34 and 0.33 lb/mmBtu) at full load with reburn operation, respectively. No claims of percent reburn fuel included.
Source: 2002 GE-EER experience list. Listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Xcel Energy (formerly Public Service Company of Colorado)

Cherokee Unit 3	Pulverized coal, wall-fired, 1962 vintage
175 MW B&W boiler	western bituminous coal
DOE Clean Coal demonstration project	November 1992-January 1995

Gas reburn demonstration performed with Dept. of Energy and Gas Research Institute 1992-1995. Existing boiler with 16 burners was retrofitted with low NO_X burners and GE-EER gas reburn OFA, FGR, and reburn injectors. Added OFA booster fan, 800 hp flue gas recirculation fan for injection mass momentum, for increased gas injection mass momentum (which was subsequently removed). The CGR installation portion has since been decommissioned.
Vendor claimed to lower NOx up to 64% from baseline of 0.73 lb/mmBtu to 0.26 lb/mmBtu) at full load with reburn operation.
GE-EER 2004 technical paper shows 15-20% reburn fuel yielded minimum NOx emissions(6).
A 2004 DOE-NETL technical paper showed this project achieved 0.46 lb/mmBtu NO_X emissions with low NO_X burners alone (37% reduction), further reduced NO_X by 44% with 12.5 percent reburn fuel(5).
A 2001 DOE-NETL technical paper claimed a NOx reduction of 65% at an average reburn gas heat input of 18% of total boiler fuel input, with and without FGR. Demonstrated 70% NOx reduction at higher reburn input rates. Referred to technology as GR-LNB. FGR was added for gas injection momentum but was subsequently removed to reduce fuel input. (25)
Source: Sept. 2005 GE-EER experience list; (6) GE-EER 2004 Technical paper; (5) DOE-NETL 2004 Reburn Conference technical paper and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference); (25) DOE-NETL 2001 Technical paper; also in (9) DOE 1999 Topical Report Number 14.

REBURN – OIL, CONVENTIONAL

Pulverized coal-fired boilers

Dynegy (formerly Illinois Power) Pulverized Coal, Tangentially-fired
Hennepin Unit 1 1966 vintage, eastern bituminous coal
71 MW CE boiler 1997 startup

GE-EER Orimulsion Reburn system w/ OFA, claimed orimulsion reburn lowered NOx up to 65% from baseline of 0.75 lb/mmBtu to 0.26 lb/mmBtu at full load with Orimulsion reburn operation (installed after gas reburn was demonstrated in early 1990's). No claims for percent reburn fuel included.

GE-EER 2004 technical paper shows 60% reduction with subsequent Orimulsion reburn (6).

Source: GE-EER experience list; (6) GE-EER 2004 Technical paper. Orimulsion not mentioned in (5) DOE-NETL 2004 Reburn Conference technical paper or DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference). (Also see Conventional Gas Reburn installation summaries for pulverized coal boilers).

New Brunswick Power
Coleson Cove, Bunker C/Orimulsion–fired, opposed-wall
St. John, New Brunswick, Canada
3x 350 MW B&W Boilers

Sixteen new low-NO_X oil/Orimulsion burners, eight reburn burners, nine SOFA ports, two combustion air booster fans, reburn and OFA wall penetration openings, OFA windboxes, ductwork, dampers, and accessories were added(7).

Another technical paper showed this reburn system lowered NOx by 78% from 1.0 lb/mmBtu baseline to 0.22 lb/mmBtu at 25 percent reburn fuel input(5).

Source: (7) B&W 2004 Technical Paper;(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Georgia Power Pulverized Coal, Tangentially-fired
Scherer Unit 1 1982 vintage
887 MW CE boiler 2000 oil reburn startup

GE-EER Oil Reburn system, claimed to lower NOx from baseline of 0.36 lb/mmBtu.

GE-EER 2004 Technical paper shows reduction up to 48% (to 0.19 lb/mmBtu) at 800 MW load with oil reburn operation. No claims of percent reburn fuel included(24).

Source: Sept. 2005 GE-EER experience list shows this as a coal reburn project with eastern bituminous coal, reducing NO_X emissions 33% from 0.36 to 0.24 lb/mmBtu;
(24) GE-EER 2004 Technical paper. Not listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – COAL, MICRONIZED, CONVENTIONAL

Pulverized coal-fired boilers

AES (formerly New York State Electric and Gas Milliken Station Unit 1)
Cayuga tangentially-fired, pulverized coal, 1956 vintage
148 MWe, CE boiler eastern bituminous coal
GE-EER micronized coal reburn system 1996 startup (still operating)

US DOE Clean Coal demonstration project from March 1997-April 1999 lowered NOx with this reburn system by 29% from 0.35 lb/mmBtu baseline to 0.25 lb/mmBtu at 14 percent reburn fuel input(5). Not listed in GE-EER's experience list nor in their 2004 technical paper.

Source: (5) DOE-NETL 2004 Reburn Conference technical paper and DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – COAL, MICRONIZED, CONVENTIONAL continued

Pulverized coal-fired boilers

E. ON US Holdings (formerly Louisville Gas and Electric)
R.D. Green Station Units 1 & 2 (KY)   wall-fired, pulverized coal, vintage unknown
293 MWe, 2 boilers   eastern bituminous coal
GE-EER coal reburn system   Startup dates: 2003 & 2002, respectively
Vendor claimed to lower NOx up to 57% from baseline of 0.45 lb/mmBtu to 0.20 lb/mmBtu at full load with reburn operation.
Reburn system listed on EPA's "Scorecard on Reburning 6/1/2004" shows NOx lowered by 44% from baseline of 0.45 lb/mmBtu down to 0.25 lb/mmBtu (with unknown reburn fuel input(5)).
Another technical paper showed baseline NOx with existing low-NOx burners was 0.45 lb/mmBtu, and reduced NOx emission 40% to 0.27 lb/mmBtu with OFA, and further reduced NOx emissions 22% down to 0.21 lb/mmBtu with the coal reburn system in operation[26].
Source: (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference);
(24) GE Energy 2004 Technical paper, and (26) March 2004 Modern Power Systems issue.

Cheng Loong (not in United States)
Unit #1, 250 MWe   wall-fired, bituminous pulverized coal, vintage & mfr unknown
GE-EER coal reburn system   2000 Startup (still operating)
Source: GE-EER experience list
Vendor claimed to lower NOx 44% from baseline 0.45 lb/mmBtu to 0.25 lb/mmBtu) at full load with OFA alone; further reduced NOx 28% to 0.18 lb/mmBtu, for 60% overall reduction. Recent (2004) data shows NOx down to 0.14 lb/mmBtu (69% overall) with up to 30 percent reburn fuel(24).
Source: (24) GE Energy 2004 Technical paper; GE-EER experience list. Listed in (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – GAS, CONVENTIONAL w SNCR

Pulverized coal-fired boilers)

NRG Somerset   Pulverized Coal, Tangentially-fired,   vintage
Unit 6 Boiler 8 (NY)   GE-EER Conventional Gas Reburn,
120 MW CE boiler   Fuel Tech SNCR, 2003 startup
Reburn vendor claimed to lower NOx 55% from 0.45 lb/mmBtu baseline to 0.20 lb/mmBtu at full load with reburn operation burning Venezuelan coal. The SNCR system further reduced NOx emissions 45% down to 0.11 lb/mmBtu, for an overall reduction of 77%.(26).

REBURN – FUEL LEAN GAS REBURN (FLGR)

Pulverized coal-fired boilers

Duke Power Company   tangentially-fired, pulverized coal
Riverbend Unit 7   eastern bituminous coal   1954 vintage
140 MWe, CE boiler   1998 FLGR startup, gas reburn decommissioned since then
Previously installed ABB/CE's Low NOx Concentric Firing System (LNCFS-1) with Close-Coupled Overfire Air (CCOFA); (pre-mod NOx + combustion mods date not known).
Commercial FLGR installation claimed 34% NOx reduction from full-load baseline of 0.42 lb/mmBtu down to 0.29 lb/mmBtu w/ the combustion modifications and FLGR gas reburn fuel at 7% of total boiler heat input. CO emissions were above 1000 ppm corrected to 3% O_2.(27)
Vendor claimed to lower NOx 57% from 0.47 lb/mmBtu baseline to 0.20 lb/mmBtu) at full load with separated OFA alone; further reduced NOx 45% to 0.11 lb/mmBtu with low-NOx burners, OFA, gas reburn, and SNCR, for 77% overall reduction; no claims for amount of reburn fuel(24).

EPA's "Scorecard on Reburning 6/1/2004" showed this reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input(5).
Source: (27) ESA, GRI, NGB 1998 Technical paper; (24) GE Energy 2004 Technical paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

REBURN – FUEL LEAN GAS REBURN (FLGR) continued
Pulverized coal-fired boilers
Wisconsin Electric Power Company (WEPCO)
Pleasant Prairie Unit 1 DB Riley, turbo-fired PC, Powder River Basin coal
620 MWg 1980 vintage 1999 startup
Fuel Tech listed FLGR installation and claimed 20% NOx reduction from baseline of 0.45 lb/mmBtu (to 0.36 lb/mmBtu). No claims of percent reburn fuel input included.
Source: Fuel Tech experience list dated 1/28/2005. (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference). (Also see FLGR + SNCR installation summaries for pulverized coal boilers).

REBURN – FUEL LEAN GAS REBURN w/ SNCR (Amine-Enhanced FLGR)
Pulverized coal-fired boilers
Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 startup
Commercial urea-based Fuel Tech SNCR +FLGR installation claimed 50% NOx reduction from baseline of 0.58 lb/mmBtu (426 ppm) down to 0.29 lb./mmBtu w/ 5 ppm ammonia slip(1). Low NO_X burners were previously retrofitted in 1997 without separated overfire air(28). This is 33 % lower than 0.44 lb/mmBtu baseline for SNCR alone. (Also see SNCR installation summaries for pulverized coal boilers). Urea-to-NOx NSR not stated.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(5).
Another technical paper showed 52% NOx reduction down to 0.28 lb/mmBtu at all loads, from 99 MWg to 207 MWg (48% to 100% MCR) with an average NH_3 slip of 3 ppm. FLGR alone achieved 23% NOx reduction with 6% reburn fuel and < 400 ppm CO at full load. (28)
Source: Fuel Tech experience list, (1)ICAC White Paper; (5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference); (28) CP&L and Fuel Tech 2001 Technical paper.
(Also see SNCR installation summaries for pulverized coal boilers).

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Hudson Station, Unit 2 Pulverized Coal, opposed-wall-fired, 1968 vintage
660 MWe Foster Wheeler boiler eastern bituminous coal March 1999 startup
Commercial SNCR + FLGR urea-based Fuel Tech installation claimed 40% NOx reduction from baseline of 0.65 lb/mmBtu (down to 0.39 lb/mmBtu) w/ 10 ppm ammonia slip(1). This is 20 % lower than 0.49 lb/mmBtu baseline for SNCR alone. Urea-to-NOx NSR not stated.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(5).
Source: Fuel Tech experience list, (1)ICAC White Paper;(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).
(Also see SNCR installation summaries for pulverized coal boilers).

REBURN – FUEL LEAN GAS REBURN w/ SNCR (Amine-Enhanced FLGR) continued

Pulverized coal-fired boilers

Public Service Enterprise Group (PSEG) Power LLC [formerly Public Service Electric & Gas of New Jersey (PSE&G)]
Mercer Station (2) twin-furnace boilers, 320 MWe each, DB Riley turbo-fired
Unit 1 and Unit 2 front wall PC, wet-bottom (slagging ash) eastern bituminous coal
Furnace #11 & #12 1960 vintage May 1999 startup
Furnace #21 & 22 1961 vintage May 1999 startup
Commercial urea-based Fuel Tech SNCR + FLGR installation claimed 60% NOx reduction from baseline of 1.4 lb/mmBtu (down to 0.56 lb/mmBtu) w/ 5 ppm ammonia slip (1). This is 72 % lower than 2.0 lb/mmBtu baseline without control. Initial demonstration of AEFLGR coinjected amine-enhanced natural gas into Furnace 22 in 1998. Subsequently installed AEFLGR on both units to reduce NOx starting in May 1999 using (2) levels of AEFLGR retractable gas injectors and (2) levels of SNCR injectors(29).
Urea-to-NOx NSR not stated, goal was NSR < 1.25.
{Note both units have since been retrofitted with low-dust tail-end SCRs in 2004; SNCR systems are still capable and operated as needed, mostly for flyash conditioning to aid ESP performance}
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 1999, but not currently operating(5).
Source: Fuel Tech experience list, (1)ICAC White Paper; (29) PSE&G, FT and ESA 2000 Technical paper;(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

Wisconsin Electric Power Company (WEPCO)
Pleasant Prairie Unit 1 DB Riley, turbo-fired PC, Powder River Basin coal
620 MWg 1980 vintage 1999 startup
Fuel Tech urea-based SNCR +FLGR demonstration installation claimed 56% NOx reduction from baseline of 0.45 lb/mmBtu to 0.20 lb/mmBtu w/ 5 ppm ammonia slip(1). This is 44 % lower than 0.36 lb/mmBtu baseline for FLGR alone.
EPA's "Scorecard on Reburning 6/1/2004" showed this SNCR-enhanced reburn system lowered NOx by 25-30% with 5-10 percent reburn fuel input in 2000, but not currently operating(5).

(5) DOE-NETL Scorecard on Reburning 6/1/2004 (from 2004 Reburn Conference).

LOW NO_x BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR

Pulverized coal-fired boilers

AEP Cardinal Unit 1 Pulverized Coal cell-burner, opposed wall-fired B&W boiler
600 MW (nominal) 1967 vintage; Low NO_x burners installed in October 1998
Produced 0.75 lb/mmBtu NOx post-LNB install baseline at full load.
LNBs reduced NO_X 57% from 1.20 down to 0.52*, produce NO_X at approx. 0.57 lb/mmBtu at min. load w/o SNCR (range 0.51 to 0.65) and produce 0.75 lb/mmBtu NO_X at approx. 585 MW (top of load range tested, NO_X range 0.73 to 0.86 lb/mmBtu) (17).
(50) original B&W circular burners were recently replaced on Cardinal Units 2 & 3 by Buckeye Power with DB Riley (now Babcock Power) CCV type low NOx burners.
Source: *Riley Power (Babcock Power Inc.) 8/16/04 experience list; (17) 2000 Fuel Tech technical paper.
(Also see SNCR installation summaries for pulverized coal boilers).

Carolina Power & Light (Progress Energy)
Asheville Unit 1 Pulverized Coal, front wall fired
200 MWe DB Riley boiler 1964 vintage, eastern bituminous coal, June 2000 startup
Low NO_X burners were previously retrofitted in 1997 without separated overfire air(22). NOx reduction was 46% from pre-LNB installation baseline of 1.08 lb/mmBtu (12) down to 0.58 lb./mmBtu (28).

(Also see SNCR, and FLGR with SNCR installation summaries for pulverized coal boilers).

LOW NO_x BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued
<u>Pulverized coal-fired boilers</u>

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 5 1956 vintage; eastern bituminous coal
154 MW CE boiler ROFA startup in 2000
Mobotec USA's Rotating Opposed Fire Air (ROFA) is a high velocity boosted separated overfire air system claimed to lower NO_X without retrofitting low-NOx burners. This was the first U.S. installation of Mobotec USA's "Rotating Opposed Fire Air" (ROFA) on a utility boiler, which utilizes a booster fan.
CP&L technical paper claimed to lower NO_X 53% from full-load pre-ROFA baseline 0.60 lb/mmBtu to 0.28 lb/mmBtu with ROFA alone following the installation of ROFA in 2000(18).
Source: (18) CP&L 2002 Technical paper. (Also see SNCR installation summaries for pulverized coal boilers).

Carolina Power & Light (Progress Energy) Pulverized Coal, Tangentially-fired
Cape Fear Unit 6 twin-furnace (eight corner), 1958 vintage; eastern bituminous coal
175 MW CE boiler ROFA startup in 2001
This unit's "ROFA" system was installed as part of a "Rotamix" SNCR + ROFA system.
CP&L technical paper shows ROFA alone reduced NOx 57% from full-load pre-ROFA baseline 0.54 lb/mmBtu to a NO_X emission rate of 0.23 lb/mmBtu. (18)
Source: (18) CP&L 2002 Technical paper. (Also see SNCR installation summaries for pulverized coal boilers).

Conectiv (formerly Delmarva Power & Light)
Indian River Units 3 & 4 (Millsboro, DE) Unit 3 is front wall-fired, 1974 vintage
178MW and 440 MW Unit 4 is turbo-fired opposed-wall, 1980 vintage
B&W, DB Riley boilers eastern bituminous coal
REI performed CFD modeling on both units for potential SNCR application.
Unit 3 has Riley Low NOx burners (16), (8) front wall and (8) rear wall OFA ports, (8) wall boundary air ports, (66) side wall OFA slots, claimed baseline NOx around 0.37 lb/mmBtu w/o SNCR (20).
Unit 4 has (24) front and rear wall down-fired burners, (28) front and rear wall SOFA ports, claimed NOx around 0.44 lb/mmBtu w/o SNCR (20) {furnace has "Mae West" belt}.
Riley provided 16 CCV low-NOx burners for Unit 3 in 1994, and claimed to reduce NOx emissions by 67% from pre-LNB baseline of 1.05 lb/mmBtu down to 0.34 lb/mmBtu.
Source: (20)REI 1999 Technical Paper; Riley Power (Babcock Power Inc.) 8/16/04 experience list. (Also see SNCR installation summaries for pulverized coal boilers).

Dayton Power & Light Pulverized Coal, Tangentially-fired
Killen Station, Unit 2 1955 vintage
632 MW CE boiler, bituminous Illinois coal
GE-EER provided low-NOx burners in 1999. Vendor claimed full load NO_X was reduced by 23% from a 0.57 lb/mmBtu baseline down to 0.44 lb/mmBtu.
Source: GE-EER Experience list 2/1/02. (Also see low-dust SCR installation list for pulverized coal boilers)

LOW NO_x BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued

Pulverized coal-fired boilers

Dynegy Midwest Generation (formerly Illinois Power) Pulverized Coal, wall-fired
Havana Station, Unit 6 1978 vintage
460 MW B&W boiler, bituminous Illinois coal
GE-EER provided modifications to the original B&W dual-register burners, and an OFA system in 2000. Vendor claimed full load NO_X was unchanged from 0.38 lb/mmBtu baseline.
Source: GE-EER Experience list 2/1/02. (Also see low-dust SCR installation list for pulverized coal boilers)

Dynegy Midwest Generation (formerly Illinois Power) Pulverized Coal, Tangentially-fired
Vermillion Station, Unit 1 1955 vintage
82 MW CE boiler, bituminous Illinois coal
This rotating opposed fire air (Mobotec USA ROFA) system was installed in July 2002, as part of a “Rotamix” SNCR + ROFA system, without low-NOx burners.
Mobotec 2004 technical paper claimed to lower full load NO_X by 62% from 0.58 lb/mmBtu baseline to 0.22 lb/mmBtu in July 2002 (without LNB or SNCR). (21)
Source: (21) Mobotec 2004 technical paper. (Also see SNCR installation summaries for pulverized coal boilers).

Georgia Power Pulverized coal, opposed wall-fired,
Harlee Branch Unit 1 250 MW B&W boiler, 1965 vintage 2003 startup
Harlee Branch Unit 2 359 MW Riley boiler, 1967 vintage 1998 startup
B&W provided 24 DRB-4Z low NOx burners for Unit 1 B&W boiler, 24 DRB-XCL low NOx burners for Unit 2 Riley boiler (believe southeast coast lignite is primary fuel).
Source: B&W’s experience list. No NOx reduction claims.

Kansas City Power & Light Pulverized coal, opposed wall-fired, 600 MW B&W boiler
Hawthorn Unit 5 30 burners, 2001 vintage, (Powder River Basin coal)
B&W provided 30 DRB-4Z low NOx burners and 11 OFA ports with the new boiler.
Source: B&W’s experience list. No NOx reduction claims.

New England Power Company (NEPCO)
Salem Harbor Station Pulverized Coal, front wall-fired,
Units 1, 2 & 3 1952, 1952, 1958 vintage (eastern bit. coal)
84 MWe x 2, & 156 MWe B&W boilers LNBs startup in 1995, 1995, and 1993
Riley claimed Unit 1 LNBs reduced NOx emissions by 57% from baseline of 1.10 lb/mmBtu down to 0.42 lb/mmBtu; Unit 2’s LNBs achieved 42% NOx reduction from a baseline of 0.95 lb/mmBtu down to 0.55 lb/mmBtu; Unit 3’s LNBs achieved 60% NOx reduction from a baseline of 1.05 lb/mmBtu down to 0.42 lb/mmBtu.
Source: Riley Power (Babcock Power Inc.) 8/16/04 experience list.
(Also see SNCR installation summaries for pulverized coal boilers).

Northeast Utilities (formerly Public Service of New Hampshire)
Shiller Station Pulverized Coal/#6 Fuel oil, front-wall-fired
Units 4, 5, & 6 1952, 1955, 1957 vintage
50 MWe x 3 Foster Wheeler boilers
RJM provided (6) Low NO_x burner modifications per boiler in 1994, 1992, & 1994 respectively;
LNBs reduced NOx 43% from 0.85 to 0.48, 50% from 1.0 to 0.50, and 51% from 0.82 to 0.40 lb/mmBtu.
Source: RJM experience list

LOW NO_x BURNERS (Replacement or modifications) w/ and w/o OVERFIRE AIR continued

Pulverized coal-fired boilers

Potomac Electric Power (formerly West Pennsylvania Power)

Chalk Point Station	Pulverized Coal	opposed wall-fired
Units 1 & 2	1964, 1965 vintage	eastern bituminous coal
360 MW (nominal)	B&W boilers	

DB Riley (now Babcock Power) CCV type low NOx burners retrofitted in 1993 and 1994, respectively. Vendor claimed to lower NOx up to 52% and 50% from 1.35 and 1.40 lb/mmBtu baselines (to 0.65 and 0.70 lb/mmBtu, assumed at full load).
Source: Riley Power (Babcock Power Inc.) 8/16/04 experience list. (Also see Conventional Gas Reburn installation summaries for pulverized coal boilers).

Xcel Energy (formerly Public Service Company of Colorado)

Cherokee Unit 3	Pulverized coal, wall-fired, B&W boiler, 16 burners, 1962 vintage
175 MW	October 1992 baseline testing started (western bituminous coal)

Installed (16) Foster Wheeler Controlled Flow/Split Flame low NO_x replacement burners as part of a DOE Clean Coal Technology gas reburn demonstration performed with Gas Research Institute 1992-1995.
Uncontrolled NOx w/ original B&W flare-type burners was 0.73 lb/mmBtu. Replacement LNBs (assuming OFA included) reduced NO_X 37% to 0.46 lb/mmBtu(25).
Source: (25) DOE NETL 2001 Technical paper.

ASH IMPACTS ON SCR CATALYST PERFORMANCE

EXECUTIVE SUMMARY

The ash deposition behavior of the lignites from North Dakota is the most complex and severe of any coals in the world, and installation of catalysts for NO_x reduction is going to be plagued with problems. The Center lignite fired at the Milton R. Young (MRY) Power Station is highly variable in abundance of various types of ash/slag-forming components. Ash-forming components consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with oxygen functional in the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. The alkali and alkaline-earth elements combine with minerals during combustion, resulting in low-melting-point phases that cause a wide range of fireside deposition problems. In addition, the alkali and alkaline-earth elements also form very small particles that are carried into the backpasses of the combustion system and react with flue gas to form sulfates that can cause deposition, blinding, and plugging problems in selective catalytic reduction (SCR) systems. This report analyzes these problems, and concludes that SCR is not a feasible option to control NOx emissions at MRY Power Station because of the high sodium levels present in the coal.

Following is a list of the key problems that are associated with Center lignite which have not been overcome and, in our opinion, make the installation of SCR at the MRY plant technically infeasible for NO_x control.

➢ Blinding of Catalyst Pores by High Sodium Compounds

  X High levels of alkali and alkaline-earth elements present in the coal fired at the MRY plant produce small particles that react to form sulfates that blind the catalyst pores. The high levels of sodium in the coals combined with calcium will produce low-melting-point eutectic sulfate compounds that will form and melt inside the pores of the catalyst.
  - Alkali and alkaline earth sulfates are enhanced by cyclone fired system. The cyclone firing results in partitioning of the ash between bottom slag and the body of the boiler. The sulfate forming materials are more concentrated in the ash as a a result of cyclone firing.

  - Sulfate formation is enhanced by the presence of an SCR catalyst; this accelerates the sulfation reactions, causing blinding of the catalyst.

  - The sulfate reactions are more severe at MRY because of the high temperature where an SCR would be installed. The higher temperature increases the rate of formation of sulfates and rate of pore plugging.

  - The testing conducted by the Germans found catalyst deactivation and blinding occurs when firing coals with lignite or brown coals that have ashes that are rich in alkali and alkaline-earth elements. .

- The findings by the Germans were confirmed by recent SCR catalyst slipstream testing that showed significant evidence of sodium and calcium-rich sulfate formation that fill and plug the catalyst at both lignite- and subbituminous-coal-fired power plants. The results of this recent testing showed that the presence of sodium significantly enhanced the formation of bonding of particles and more rapid sulfation, filling of pores, and rapid increase in pressure drop across the catalyst.

- Deposit carryover, or "popcorn ash," plugging the top of the SCR catalyst is a significant problem because of the extremely high deposition rates of the Center coal. When firing Center coal, deposits form on various parts of the boiler requiring continuous sootblowing. The sootblowing of upstream heat-exchange equipment will cause deposit fragments to be carried back to the SCR catalyst, resulting in plugging. In addition, during sootblowing of the SCR catalyst, the entrainment of deposit fragments along with the sootblowing media will result in significant erosion of the catalyst surfaces.

- Recent testing with subbituminous and lignitic coals indicated a significantly higher level of pore filling and plugging in the catalyst exposed to lignite ash as compare to subbituminous coal ash. The catalyst pores as well as the catalyst surface in the lignite tests were completely coated with a sodium calcium sulfate material, while only pore filling was found in the subbituminous coal testing. The pressure drop across the catalyst exhibited for lignite was 4 to 5 times greater than that found for a catalyst exposed to subbituminous coal ash. The plugging occurred over a 1000 hour test period.

➢ Cold Side SCR Installation

- High-sodium lignite coal from the Center Mine Hagel A and B seam coal produces significant levels of homogeneously condensed sodium sulfate that pass through the ESP and wet scrubber.

- These small particles have been shown to pass through a wet scrubber and will accumulate on surfaces of tail-end SCR systems. The accumulated materials require sootblowing to remove the particulate and will result in increased opacity.

- Liquid pyrosulfate materials at temperatures as low as 535°F from sodium sulfate materials occurs in coal-fired power systems and is well documented. Pyrosulfates will form and cause blinding of tail-end SCR devices. In addition, SCR systems are known to catalyze the formation of SO_3 from SO_2. The presence of SO_3 significantly enhances the formation of the pyrosulfates.

ASH IMPACTS ON SCR CATALYST PERFORMANCE

INTRODUCTION

Ash produced during combustion of coal in conventional power systems is a major problem that results in decreased efficiency, unscheduled outages, equipment failures, and increased cleaning. The many ways in which the detrimental effects of ash manifest themselves in a boiler system include fireside ash deposition on heat-transfer surfaces, corrosion and erosion of boiler parts, poor slag flow, and production of fine particulates that are difficult to collect. Decades of research have been conducted to develop a better understanding of the chemical and physical processes of ash formation and deposition in combustion systems. Overviews of ash-related issues and compilations of work by many investigators can be found by referring to the work of Mehta and Benson (1), Schobert (2), Baxter and DeSollar (3), Couch (4), Williamson and Wigley (5), Benson and others (6), Benson (7), Bryers and Vorres (8), Raask (9, 10), and Benson (11). This work has led to a detailed understanding of ash formation and behavior in combustion systems as well as the development of predictive methods (12, 13).

The chemical composition and physical characteristics of ash-forming or inorganic components (mineral and organically associated elements) of the fuel(s) fired have an influence on the following processes in the combustion systems:

- Firing conditions such as cyclone, pulverized coal, and low-NO_x burners
- Transformations of coal inorganic components to ash particulate and vapor-phase species
- Boiler design characteristics, including number of burners, radiant section area, tube bank spacing, access for cleaning, and number of sootblowers
- Ash transport to heat-transfer surfaces in utility boilers
- Erosion wear and sticking
- Ash deposit growth and impact on heat transfer
- Ash blinding and plugging of selective catalytic reduction (SCR) catalysts
- Ash deposit removability

The ash deposition in North Dakota lignite-fired power plants is a major problem that impacts all fireside surfaces of the power plant. The ash problems are due to the variable and complex nature of inorganic components associated with lignite coals (2). Upon combustion, the inorganic components undergo chemical and physical transformations that produce intermediate inorganic species in the form of inorganic gases, liquids, and solids. During the gas-cooling processes in the boiler, the gas-phase species condense and the liquid-phase materials solidify. The abundance of these gas-phase and liquid materials entrained in the bulk gas flow is highly dependent upon coal composition and system operating conditions. The inorganic materials are transported to heat-transfer and catalyst surfaces by diffusion, electrophoresis, thermophoresis,

and inertial impaction. The particle sticking and accumulation rates are dependent upon the quantity of ash and the abundance and viscosity of the liquid-phase components. In high-temperature regions of the boiler, high-temperature sodium–calcium–aluminosilicate liquid phases act as the sticky material, causing deposit initiation, growth, and development of deposit strength. As the temperature of the flue gases decreases, the condensation and reaction of flame-volatilized species play a more significant role in the formation of deposits from lignite coals. The formation of sodium and/or calcium magnesium sulfates dominates the deposit accumulation mechanisms at lower temperatures. The aluminosilicate phases are dominant above about 1800°F. Below about 1800°F, the sulfate phases become stable, with an optimum temperature of formation of about 1400°F, and can form at temperatures as low as 300°F.

The most significant problems that prohibit the successful operation of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates and phosphates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency (14–16).

INORGANIC COMPOSITION OF LOW-RANK COALS

Inorganic elements in coal occur as discrete minerals, organically associated cations, and cations dissolved in pore water. The fraction of inorganic components that are organically associated varies with coal rank. Lower-ranked subbituminous and lignitic coals have high levels of oxygen, which act as bonding sites for cations such as sodium, magnesium, calcium, potassium, strontium, and barium (other minor and trace elements may also be present in this form). In higher-ranked coals, bituminous and anthracite, inorganic components consist mainly of minerals. Mineral grains are usually the most abundant inorganic component in coal. The major mineral groups found in coals include silicates, aluminosilicates, carbonates, sulfides, sulfates, phosphates, and some oxides.

The behavior of ash produced during coal combustion is related to the abundance, size, and association of mineral grains in the coal. In addition, the association of the mineral grain with the coal matrix influences the temperature and gaseous environment the mineral is exposed to during combustion. A mineral associated with the organic part of a coal particle is said to be included. A mineral that is not associated with organic material is referred to as excluded. The behavior of the organically associated elements, those elements that are atomically dispersed in the coal matrix, must also be measured as to their abundance in the coal. The organically associated elements will react and interact with the other ash-forming constituents during combustion.

The Center lignite is highly variable in abundance of various types of ash/slag-forming constituents. Ash-forming components in the Center lignite are of two types. The first form may constitute up to 50% of the ash and is derived from inorganic elements (sodium, magnesium, calcium, and potassium) associated with oxygen functional in the organic matrix of the coal. The second type consists of mineral grains (sand, clay, limestone, and pyrite). The minerals are discrete particles of ash-forming species and the sources of silicon, aluminum, iron, titanium, and minor amounts of the calcium and potassium. The Center lignite fired at the Milton R. Young (MRY) plant has been examined extensively because of its problem with ash behavior. Analyses

of as-fired and drill core samples have been conducted. The mean and the range of selected components are shown in Figure 1. The results indicate that both the abundance of ash and the abundance of major oxides in the ash vary significantly. In addition, the abundance of alkali and alkaline-earth elements (Na and Ca) varied dramatically. Variations in Si were found to be the most significant. High levels of Ca and/or Na were found for lower-ash coals as compared to high levels of Al and Si associated with higher-ash coals (17, 18).

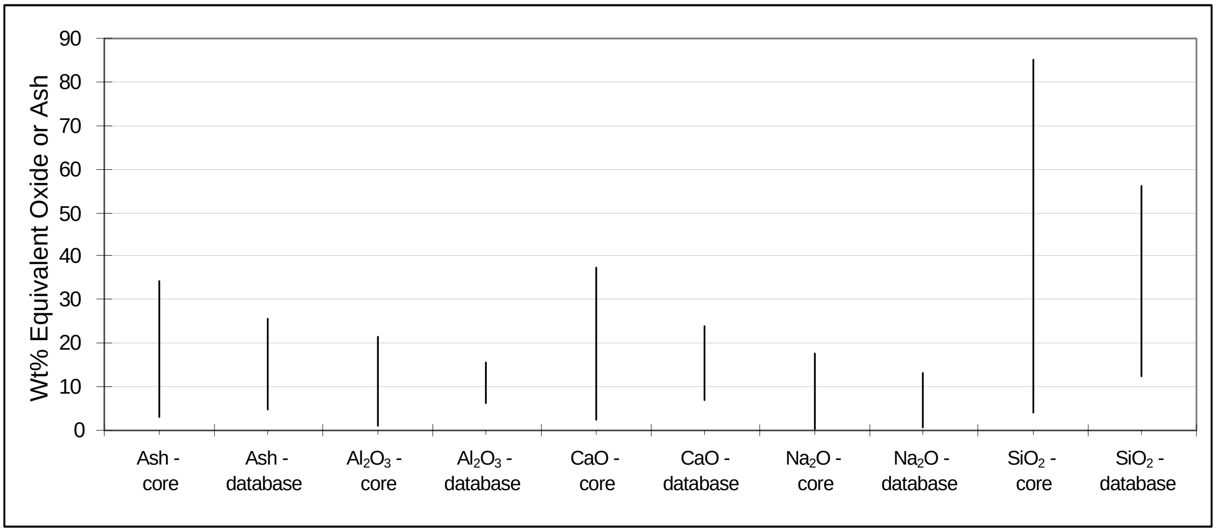

Figure 1. Variability of ash and selected constituents in core analysis database provided by BNI Coal, Ltd. and Minnkota as fired coal analysis database.

The variability of the ash-forming components has been examined for the approximately 5000 samples characterized to date. Wide variations in ash contents and the major ash-forming constituents are observed. During the mining processes, the inorganic components are mixed, and some of the extreme characteristics are diluted (17).

INORGANIC TRANSFORMATIONS AND ASH FORMATION

The inorganic coal components undergo complex chemical and physical transformations during combustion to produce intermediate ash species. The inorganic species consist of vapors, liquids, and solids. The partitioning of the inorganic components during combustion to form ash intermediates depends upon the association and chemical characteristics of the inorganic components, the physical characteristics of the coal particles, the physical characteristics of the coal minerals, and the combustion conditions.

The physical transformation of inorganic constituents depends on the inorganic composition of the coal and combustion conditions. The inorganic components can consist of organically associated cations, mineral grains that are included in coal particles, and excluded mineral grains. There is a wide range of combinations of mineral–mineral, mineral–coal,

mineral–cation–coal, and mineral–mineral–cation–coal associations in coal. These associations are unique to each coal sample.

The physical transformations involved in fly ash formation include 1) coalescence of individual mineral grains within a char particle, 2) shedding of the ash particles from the surface of the chars, 3) incomplete coalescence due to disintegration of the char, 4) convective transport of ash from the char surface during devolatilization, 5) fragmentation of the inorganic mineral particles, 6) formation of cenospheres, and 7) vaporization and subsequent condensation of the inorganic components upon gas cooling. As a result of these interactions, the ash has a bimodal size distribution. The submicron component is largely a result of the condensation of flame-volatilized inorganic components. The mass mean diameter of the larger particles is approximately 12 to 15 μm, depending upon the coal and combustion conditions. The larger-size particles have been called the residual ash by some investigators (19) because these ash particles resemble, to a limited degree, the original minerals in the coal. Processes such as ash mineral coalescence, partial coalescence, ash shedding, and char fragmentation during char combustion and mineral fragmentation, all play an important role in the size and composition of the final fly ash. Loehden and others (20) and Zygarlicke and others (21) indicate that three potential modes for fly ash generation can be used to describe fly ash particle-size and composition evolution. The first, "fine limit," assumes that each mineral grain forms a fly ash particle and that the organically associated elements form fly ash particles of less than 2 μm. The second, "total coalescence," assumes one fly ash particle forms per coal particle. The third, "partial coalescence," suggests that the fly ash composition and particle size evolve because of partial coalescence.

The transformations of excluded minerals are dependent upon the physical characteristics of the mineral. Excluded minerals such as quartz (SiO_2) can be carried through the combustion system with its angular structure still intact. Excluded clay minerals can fragment during dehydration, melt, and form cenospheres. The behavior of excluded pyrite depends upon its morphology. Some of the pyrite may be present as framboids. Framboidal pyrite may fragment more easily than massive pyrite particles. In addition, the decomposition of pyrite is very exothermic, and it transforms to pyrrhotite and oxidizes to FeO, Fe_3O_4, and Fe_2O_3 during combustion.

ASH DEPOSITION ON HEAT-TRANSFER AND OTHER SURFACES EXPOSED TO ASH AND FLUE GAS

The characteristics of a deposit depend upon the chemical and physical characteristics of the intermediate ash species, geometry of the system (gas flow patterns), gas temperature, gas composition, and gas velocity. Figure 2 illustrates the ash deposition phenomena in utility boilers. Ash particle accumulations occur via transport of particles to the fireside surfaces (heat transfer, ceramic materials, support materials, SCR catalysts, baghouse materials, and ESP wires and plates) and sticking of the particles. The transport mechanisms important for ash deposition include small-particle mechanisms for particles less than 10 μm that involve thermophoresis, electrophoresis, and vapor-phase and small-particle diffusion; and large-particle mechanisms for particles greater than 10 μm that involve inertial impaction. The ability of larger particles to stick depends upon the quantity and viscosity of the liquid phase on the particle surface.

Thermophoresis is a phenomenon that involves the transport of very small particles as a result of a thermal gradient from hot gases to cooler surfaces. Electrophoresis is the transport of particles because of a difference in charge. Vapor-phase and small-particle diffusion occurs in the boundary layer next to the surface and results in transport of ash to the surface. Inertial impaction is a larger-particle phenomenon where the particles are of a sufficient size and density to leave airflow patterns around the tube and impinge upon the surface of a tube or deposit. Deposits that form in high-temperature regions of the boiler, such as the radiant section, are called slag deposits. Deposits that form in lower-temperature regions of the boiler, such as in the convective pass on steam tubes and lower-temperature surfaces such as SCR catalysts, are called fouling deposits. Slag deposits are usually associated with a high level of liquid-phase components and are exposed to radiation from the flame. This is a description that many researchers use to aid in classification of deposits since some engineers call any type of deposit "slag". Slag deposits are typically dominated by silicate liquid phases, but may also contain moderate to high levels of reduced iron phases such as FeO and FeS. The liquid characteristics of the silicates are highly dependent upon the quantities of Na, Mg, Ca, K, and Fe ash on the silicates. In addition, the initiating layers of slag deposits may consist of very fine particulate and can produce a reflective ash layer. This phenomenon is especially evident when high organically associated calcium subbituminous coal is fired. These coals produce small CaO particles that usually form the initiating layers.

Fouling deposits form in the lower-temperature regions of the boilers and, in most cases, do not contain the high levels of liquid phases that are usually associated with slagging-type deposits. Fouling deposits contain lower levels of liquid phases as compared to slag deposits. The fouling deposit liquid phases usually consist mainly of sulfates that bind the particles together. Fouling deposits typically form as a result of the reaction of gas-phase sulfur oxide species with particles rich in alkali and alkaline-earth elements.

ASH-RELATED EXPERIENCES AT MRY FACILITY

The MRY is a minemouth electrical generating plant located near Center, North Dakota. The station consists of two units: Unit 1, rated at 276 MWg, began production in 1970; Unit 2, rated at 506 MWg, began production in 1977. Both Units 1 and 2 are equipped with B&W cyclone-fired boilers; the Unit 1 boiler has seven cyclones, and the Unit 2 boiler has twelve cyclones. Annual station gross generation is approximately 5.5 million MWh.

BNI Coal Ltd. is the sole coal supplier for the MRY Station. Coal is mined from the nearby Center mine, which consists of three distinct seams varying from 2½–9 feet thick. Coal is strip-mined using two draglines and is loaded with front-end loaders and delivered to the plant with bottom-dump haul trucks. Annual coal production is 4.3 million tons per year.

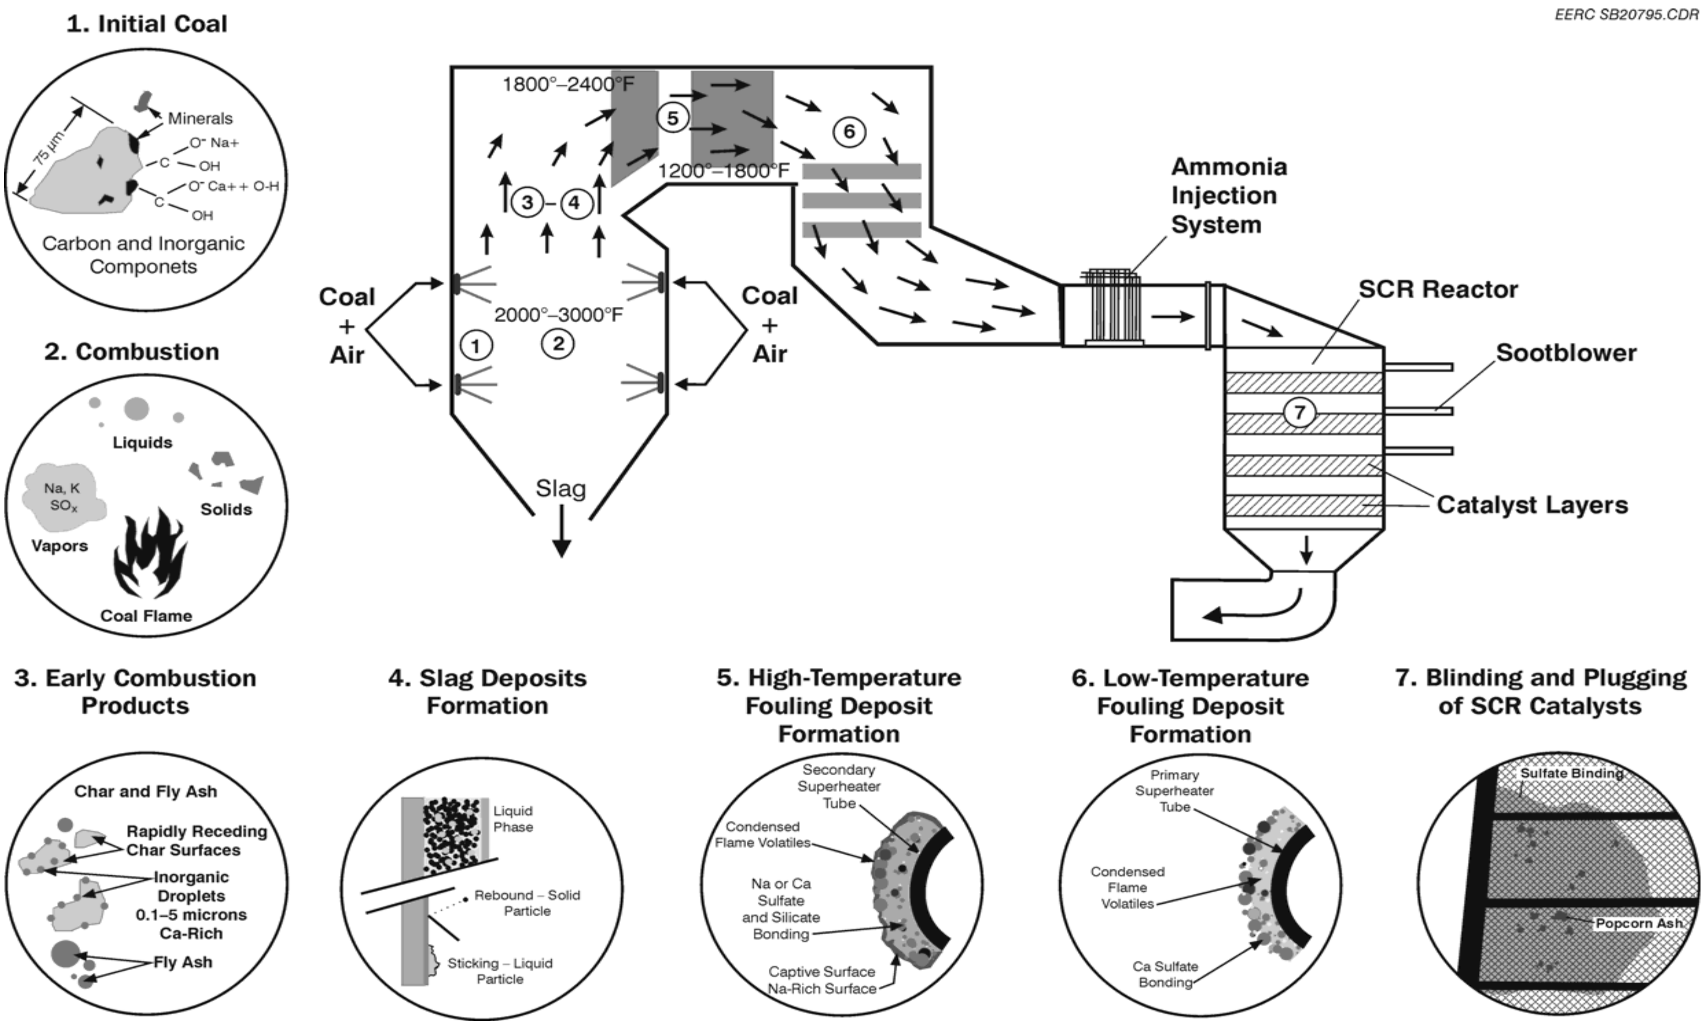

Figure 2. Overall processes of ash deposition typical of a lignite- or subbituminous-fired boiler.

History of Furnace Slagging/Fouling

Prior to 1991, besides annual maintenance outages, load reductions and forced outages due to furnace slagging/fouling were the largest cause of production loss. In 1985, operating guidelines were established that reduced furnace slagging/fouling, including deslagging outages scheduled every six months.

In 1991, a 3-month boiler cleaning cycle was proposed and initiated. The goal of this program was to increase annual generation by running the units at higher sustained loads and scheduling boiler-cleaning outages at 3-month intervals. However, furnace slagging/fouling continued to have a significant impact on plant operations. Success was measured in the number of production days between boiler-cleaning outages.

During the mid-1990s, a major outage every third year was scheduled for each unit. In addition, Unit 1 cleaning outages were scheduled for 80–90-day runs (four cleaning outages per year), and Unit 2 cleaning outages were scheduled for 65–75-day runs (five cleaning outages per year). The problem was that furnace and convection-pass surfaces gradually become coated with ash deposits, which, over time, sootblowers cannot remove. Some of the contributors to the ash deposits were as follows:

- Organically associated sodium is a primary contributor to deposition problems. Sodium is vaporized in the cyclones and condenses on other ash particles, causing them to become sticky and deposit at the furnace exit. The problem is associated with sulfate formation and occurs in the convective pass, including the economizer. Samples show that sodium in the ash varies from 0.6%–13.0%.

- Organically associated calcium is another component that causes deposition problems. Unlike sodium, calcium does not produce a vapor-phase component. Calcium does react with silicate (derived from clays) to cause low-melting-point phases that produce wall deposits and deposits in the high-temperature regions of the convective pass. Calcium also produces very small particles that will be transported to heat-transfer surfaces, resulting in the formation of thin, light-colored layers called reflective ash. These small particles of ash are carried through to the back passes where they are sulfated and can combine with sodium to cause the formation of strongly bonded sulfate-based deposits. Samples show that calcium in the ash varies from 6.8%–24.0%.

- Clay minerals and quartz – Center lignite can contain high levels of illite, which has a 1:3 Al:Si ratio and high levels of potassium, both of which cause wall slagging and high-temperature fouling. Quartz and other clays can significantly contribute to the mass of the deposits. Samples show that ash content varies from 5.0%–25.5%.

Advanced Boiler Performance Indices

Advanced indices are used to relate the coal characteristics as determined by computer-controlled scanning electron microscopy (CCSEM) and chemical fractionation to ash behavior in a coal-fired utility boiler (12). Fuel performance is estimated in terms of slag flow behavior,

abrasion and erosion wear, wall slagging, high-temperature silicate-based convective pass fouling, and low-temperature sulfate-based convective pass fouling. The following indices are used to assess the effects of ash behavior on utility boiler performance:

- Convective-Pass Fouling Indices

  Sulfation Index: Indicates the propensity of deposit to form in the convective pass of the utility boiler in the temperature range from 1000°–1750°F. This index is based on the availability of alkali (Na and K) and alkaline-earth (Ca and Mg) elements to react with SO_2 and SO_3 to form sulfates. The sulfates are the primary materials that cause particle-to-particle bonding in high-calcium coals. The sulfates are thermodynamically stable at temperatures below about 1650°F. Index values range from 1 (low) to 10 (severe).

  Silicate Index: Indicates the propensity of deposits to form from 1600°–2400°F. This index is related to the formation of deposits in which the silicate material is the primary component that bonds the deposits together. The information used to derive the index includes the size of the minerals such as quartz and clay minerals, availability of alkali and alkaline-earth elements, and viscosity of the silicate liquid phase. Index values range from 1 (low) to 200 (severe).

- Waterwall Slagging

  Slagging Index: Indicates the propensity of a deposit to form on the radiant walls from 2000°–3000°F. The basis of the slagging index is the size of the minerals (especially the illite, quartz, and pyrite), association of the calcium (calcite can contribute to slagging), and viscosity of the silicate-based liquid phase. Index values range from 1 (low) to 20 (severe).

- Wear Indices

  Abrasion Index: This index indicates the potential for wear of fuel preparation and handling equipment. The wear is related to the hardness of minerals in the coal. The primary minerals of concern include quartz and pyrite. The index values range from 0.1 (low) to 10 (severe).

  Erosion Index: This index indicates the potential for wear of boiler parts due to the impaction of fly ash particles. The erosion index is dependent upon the size of the ash/mineral particle, size of the particle, and velocity of the particle. The index values range from 0.1 (low) to 1.0 (severe).

- Cyclone Slagging Index: This index provides information on the slag flow behavior in cyclones. The factors that are included in this index include the partitioning of the ash in the cyclone based on size and association of the ash-forming components in the coal. The partitioning of the ash between the slag and entrained ash can significantly influence the flow behavior of the slag. Standard partitioning criteria have been developed to provide the composition of the slag. The composition is used to estimate the viscosity of the slag as a function of temperature. The index values have several ranges as follows: 1 (low viscosity), 1.5–2.5 (optimum viscosity), >3.0 (slag freezing).

- Strength Development Index: The strength index is based on the ability of the deposited material to develop strength. Strength development is primarily dependent upon the abundance and viscosity of the liquid-phase components in the deposits. Index values less than 0.25 indicate that the material will produce weak deposits; index values of 0.25–0.34 indicate weak-to-moderate-strength deposits; index values of 0.34–0.41 indicate high-strength deposits; and index values >0.41 indicate flowing slag.

Indices were calculated for a range of coals from the Center mine, and the propensity for ash deposition in various portions of the boiler indicates wide variations, as shown in Table 1. The BNI numbers indicate the location in the seams where the coal originated: Kinneman Creek seam (KC), Hagel A (HA), and Hagel (HB). Each seam has a different distribution of minerals and organically associated elements that can have a significant impact on the formation of deposits in the system. Comparison of Center lignite to subbituminous and bituminous coals from other regions of the United States, shown in Table 2, indicates significant differences in the potential to form deposits in the boilers. In all cases, the lignite (not the worst coal from Center mine) from the Center mine has a high propensity to produce deposits as compared to the other coals.

Another indication of the variability of lignites can be illustrated based on the calculation of the temperature where the slag flow would occur. This is defined as the T250 temperature, where the slag viscosity is 250 poise. Frequency distributions of the T250 values for all the data for coals analyzed are illustrated in Figure 3. Calculations of T250 values for 1212 samples obtained from the Center mine database (17) were made using empirical relations derived from CCSEM and chemical fractionation data and knowledge of how ash partitions in the cyclone. Figure 3 shows a bimodal distribution in the T250 based on the Urbain equation calculations. The primary mode was at a value of 2000°F. The secondary mode was at about 2700°F. The results indicate that many of the coals have a sufficiently low T250 for good slag flow. However, coals with T250 at 2700°F are not suitable for maintaining good slag flow.

Figures 4 through 6 illustrate the variations in T250 for the various seams of coals characterized. The HA and HB seam coals appear to have large numbers of samples, with T250 values at or near 2000°F. The KC seam coal, as illustrated in Figure 6, has extremely high T250 values. Based on these data, the KC coals are not favored relative to the slag flow behavior of the ash.

Frequency distributions of cyclone slagging index values indicated significant variations in slagging potentials of coals mined from the three seams, KC, HA, and HB. This information proved particularly useful in planning the mining and firing of coal from the KC seam.

During a July 1999 test burn, the composition of the cores was used to examine and illustrate the variability of the delivered coal quality based on base-to-acid ratio calculated from the ash composition. Figure 7 shows the variation in the base-to-acid-ratio and the seam where the coal was loaded. The base-to-acid ratios were calculated from core data that corresponded to the location in the seam where the coal was mined. There is a significant variation in the base-to-acid ratio for the coals. The coals that have the highest base-to-acid ratio are typically from the HA seam. HB seam coals generally have an intermediate base-to-acid ratio. KC or top-seam coal has the lowest base-to-acid ratio. Lower base-to-acid-ratio coals typically produce slag with high viscosities.

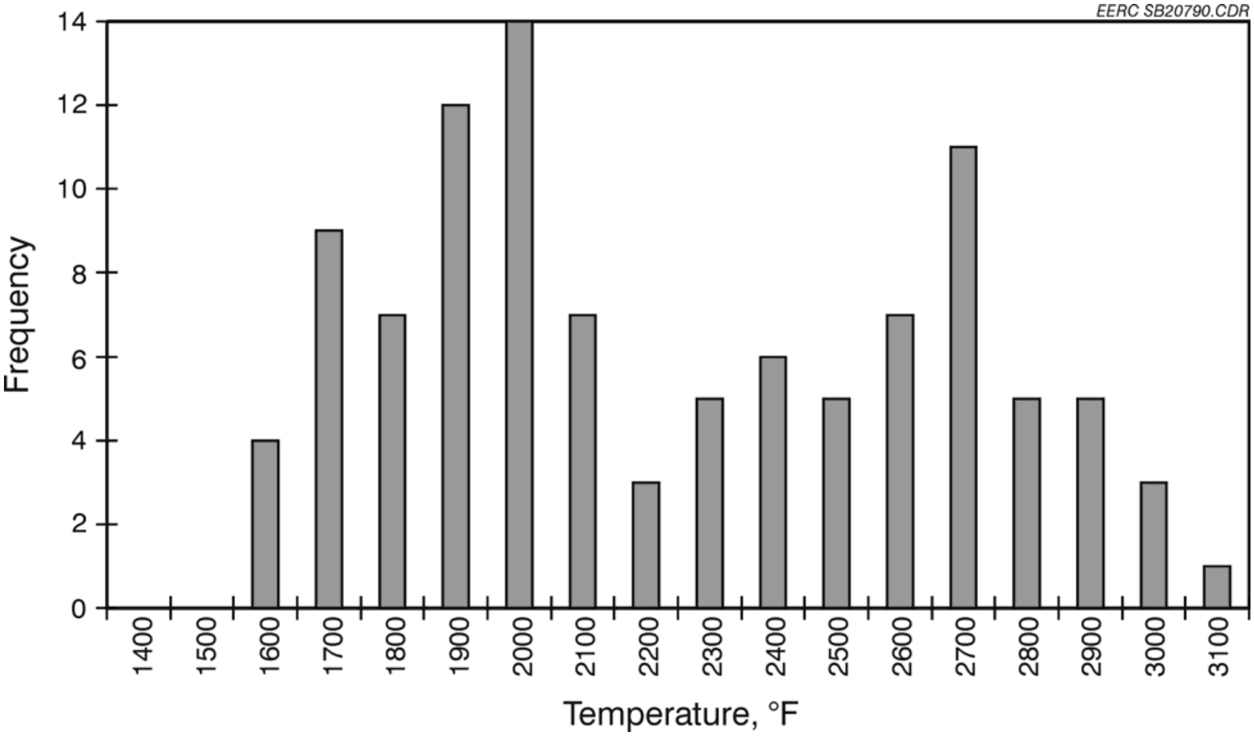

Figure 3. T_{250} frequency distribution for all Coal Quality Management System (CQMS) data, °F.

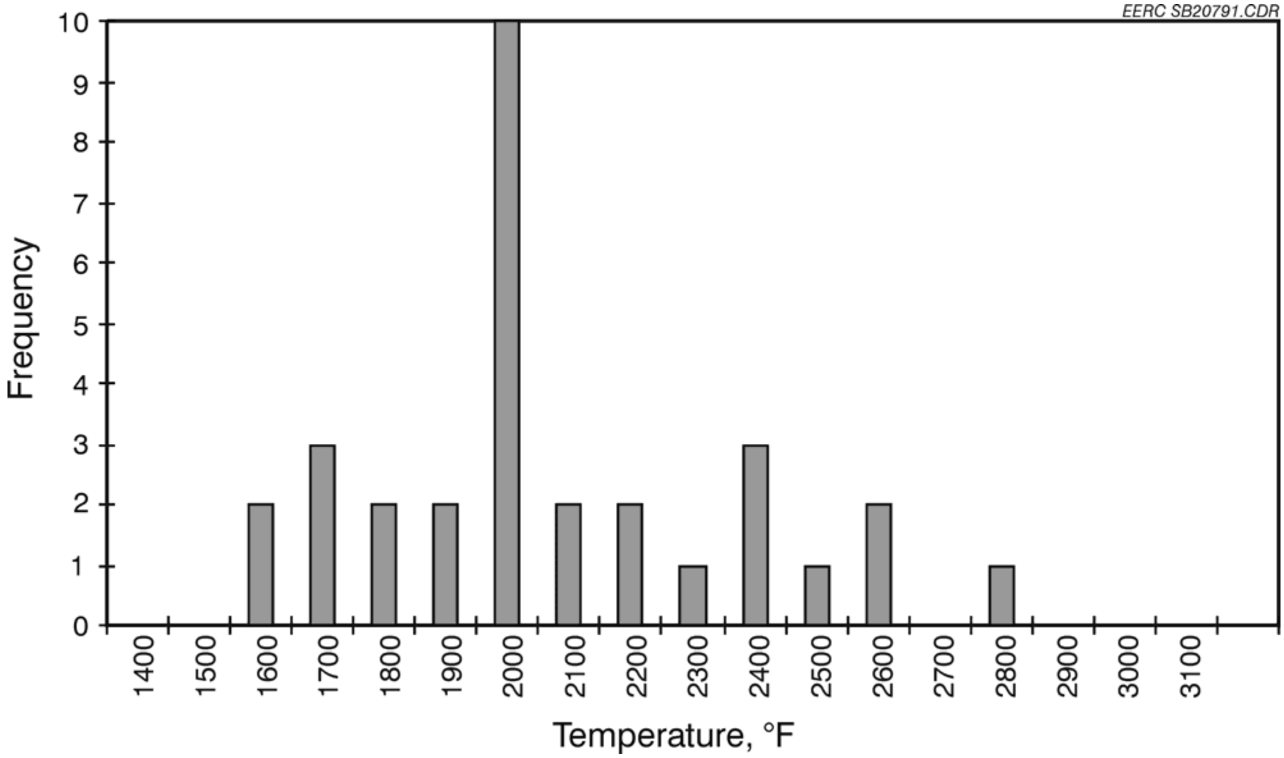

Figure 4. T_{250} distribution for HA seam coal.

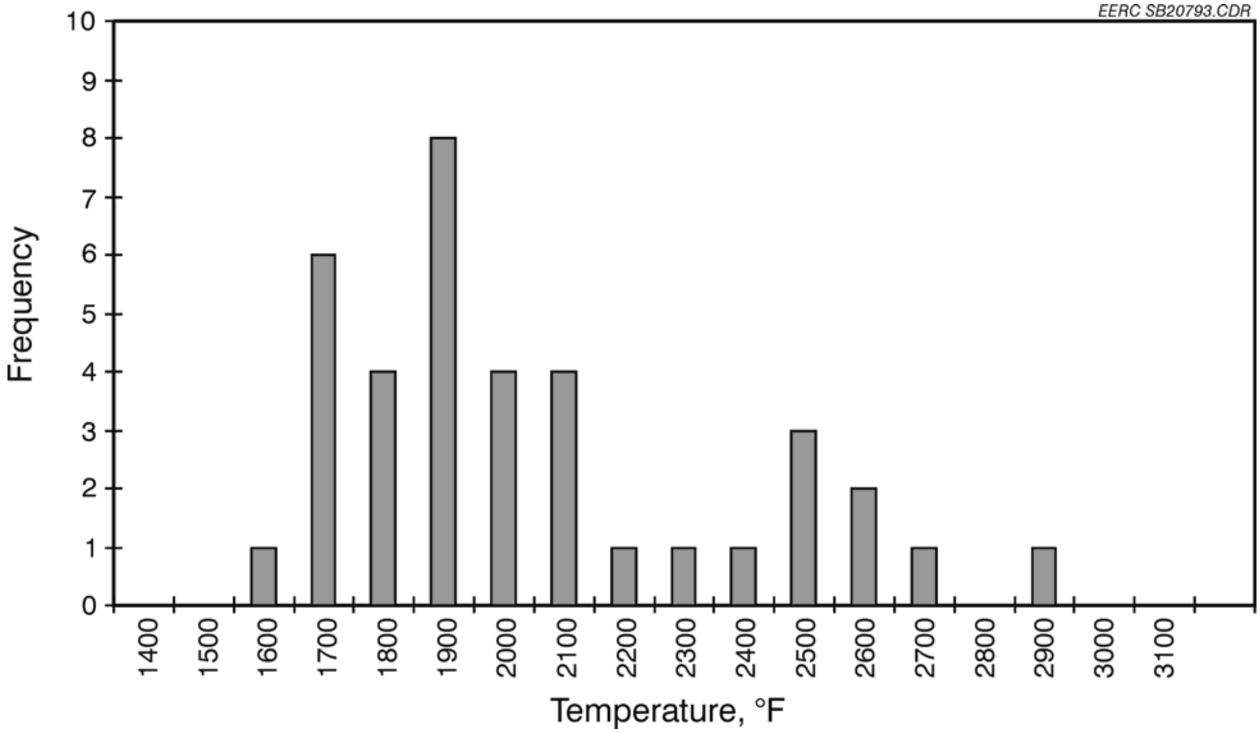

Figure 5. T_{250} distribution for HB seam coal.

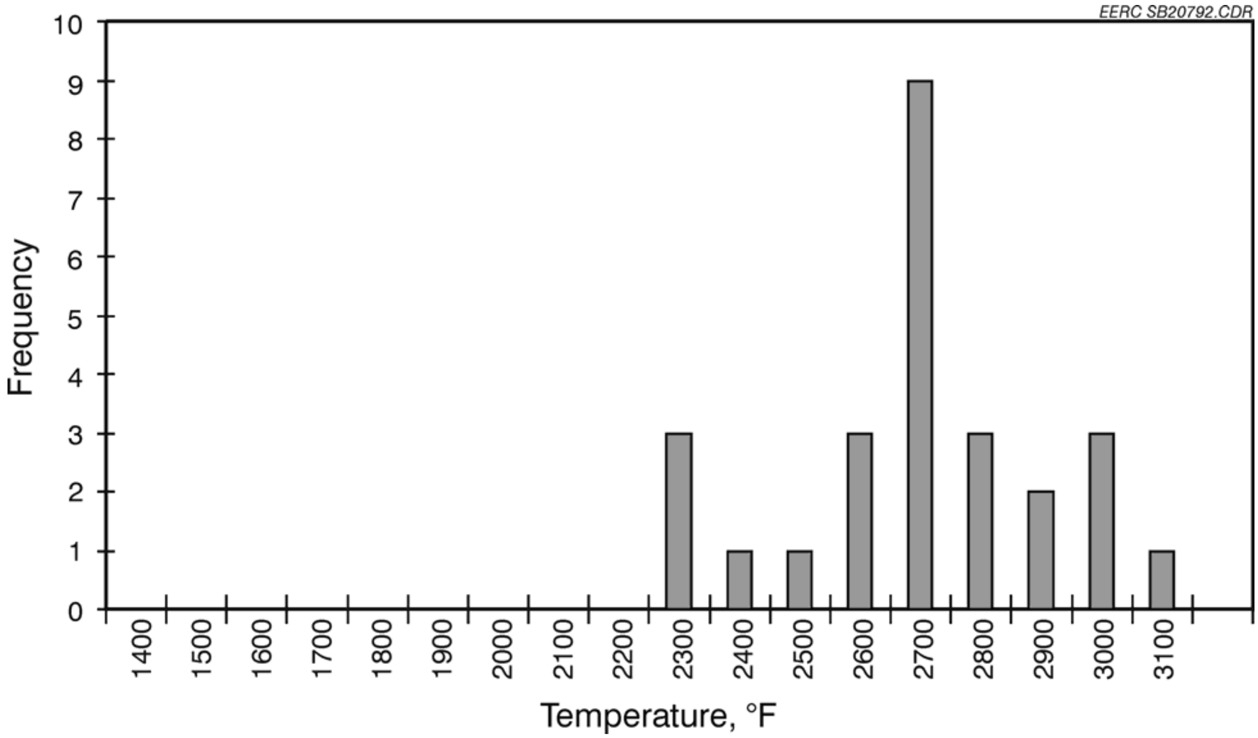

Figure 6. T_{250} distribution for KC seam coal.

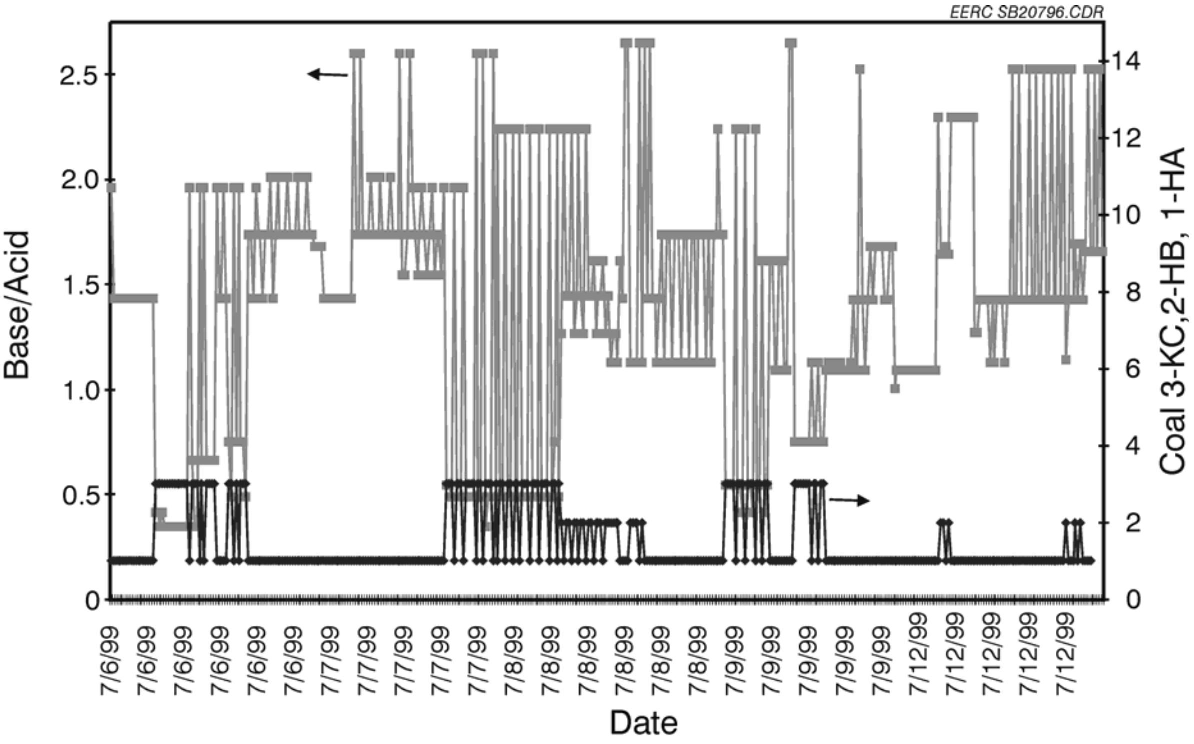

Figure 7. Variations in the delivered coal quality during a test burn period.

Figure 7 shows the sequence of deliveries beginning on July 6 and ending on July 12, 2004. During this period, the majority of the coal delivered was from the HA seam, followed by KC, and HB. Most of the deliveries alternated between KC and HA. Figure 6 shows several instances where significant quantities of KC coal were delivered, on July 6 through July 9. The quantity of KC coal delivered will have the potential to increase the viscosity of the slag and result in poor slag flow from the cyclones.

ASH-RELATED IMPACTS ON SCR CATALYST PERFORMANCE

Ash-related impacts on SCR catalyst performance will depend upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design (14–16, 22). The problems currently being experienced on SCR catalysts include the following:

- Formation of sulfate- and phosphate-based blinding materials on the surface of catalysts.
- Carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing on top of the SCR catalysts.

Licata and others (14) conducted tests on a South African and German Ruhr coal and found that the German Ruhr coal significantly increased the pressure drop across the catalyst because of the accumulation of ash. They found that the German coal produced a highly adhesive ash consisting of alkali (K and Na) sulfates. In addition, they reported that the alkali elements are in a water-soluble form and highly mobile and will migrate throughout the catalyst material, reducing active sites. The water-soluble form is typical of organically associated alkali elements in coals. The German Ruhr Valley coal has about 9.5% ash and 0.9 % S on an as-received basis, and the ash consists mainly of Si (38.9%), Al (23.2%), Fe (11.6%), and Ca (9.7%), with lower levels of K (1.85%) and Na (0.85%) (15). Cichanosicz and Muzio (16) summarized the experience in Japan and Germany and indicated that the alkali elements (K and Na) reduced the acidity of the catalyst sites for total alkali content (K+Na+Ca+Mg) of 8%–15% of the ash in European power plants. They also found that alkaline-earth elements such as calcium react with SO_3 on the catalyst, resulting in plugging of pores and a decrease in the ability of NH_3 to bond to catalyst sites. The levels of calcium in the coals that caused blinding ranged from 3%–5% of the ash.

The mechanisms for this type of low-temperature deposition have been examined and modeled in detail at the Energy & Environmental Research Center (EERC) in work termed Project Sodium and Project Calcium in the early 1990s; however, the focus of those projects was specific to primary superheater and economizer regions of boilers and not SCR systems (22, 23). Deposit buildup of this type can effectively blind or mask the catalyst, diminishing its reactivity for converting NO_2 to N_2 and water and potentially creating increased ammonia slip (14). Arsenic and phosphates, which are not uncommon in low-rank coals, may also play a role in catalyst degeneration. Arsenic is a known catalyst poison (14) in applications such as catalytic oxidation for pollution control. Phosphates can occur in low-temperature ash deposits to create blinding effects, and they also occur with arsenic and can cause catalyst poisoning (23).

Lignite and subbituminous coals produce ash that plugs and blinds catalysts (25–28). The problems currently experienced with SCR catalysts include the formation of sulfate- and phosphate-based blinding materials on the surface of catalysts and the carrying of deposit fragments, or popcorn ash, from other parts of the boiler and depositing them on top of the SCR catalysts (14). The most significant problem that limits the successful application of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates, phosphates, and possibly carbonates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency (14–16, 27–28). The degree of the ash-related impacts on SCR catalyst performance depends upon the composition of the coal, the type of firing systems, flue gas temperature, and catalyst design (15–16, 24, 27–28).

In studies (7) the impacts of temperature and the presence of catalyst on the ability of ash to sulfate were examined. The tests were conducted using a thermogravimetric analyzer (TGA). TGA testing was conducted using a <5-µm-size fraction of ash produced from Powder River Basin (PRB) coals and lignites and exposing them to vapor-phase sulfur dioxide with and without catalyst at several temperatures. The aim of the testing was to determine the potential of the formation of sulfates to cause particle-to-particle bonding that leads to the formation of deposits in the temperature range where SCR catalysts are used. The TGA testing is focused on determining the reactivity of the <5-µm ash produced from selected PRB and blends to sulfur dioxide and gas-phase phosphorus species as a function of temperature. Testing was conducted to determine the weight gain with flue gas containing ammonia. The impact temperature on the weight gain due to the formation of sulfates for a PRB blend is shown in Figure 8. The rates of sulfation were found to increase with increased temperature. The results show an increase in the weight gains when ammonia and phosphorus were added. Ground catalyst was mixed with PRB and placed in the TGA. Increases in weight gain were observed when catalyst was added as compared to baseline cases for 100% PRB, as shown in Figures 8 and 9, respectively. The presence of catalyst enhances the formation of sulfates.

Full-Scale Slipstream Testing

More recently (8), the behavior of ash and mercury in flue gas produced from the combustion of lignite and subbituminous coals from the United States of America in selective catalytic reduction (SCR) systems for nitrogen oxide removal has been examined. Typically, these coals contain ash-forming components that consist of inorganic elements (sodium, magnesium, calcium, and potassium) associated with the organic matrix and mineral grains (quartz, clays, carbonates, sulfates, and sulfides). Upon combustion, these coals produce ash that has an abundance of alkali and alkaline-earth-rich oxide particles (<5 µm) that are carried into the backpasses of the combustion system and react with flue gas to form sulfates and possibly carbonates. The forms of mercury in the flue gas produced from the lignite and subbituminous coals are dominated by the elemental form. Slipstream testing was conducted at two subbituminous-fired power plants and one lignite-fired power plant to determine the impacts of ash on SCR plugging, blinding, and mercury oxidation.

The SCR slipstream system consists of two primary components: the control room and the SCR reactor. The reactor section consists of a catalyst section, an ammonia injection system, and sampling ports for NO_x at the inlet and exit of the catalyst section. The control room houses a computer system that logs data and controls the gas flow rates, temperatures, pressure drop across the catalyst, and sootblowing cycles. The computer is programmed to maintain constant temperature of the catalyst, gas flow rates, sootblowing cycles, and ammonia injection. The computer is equipped with a modem that allows for downloading of data and modification of the operation of the reactor from a remote computer located at the EERC.

Flue gas is isokinetically extracted from the convective pass of the boiler upstream of the air heater. The temperature is typically about 790°F. The flue gases pass through a 4-inch pipe equipped with sampling, thermocouple, and pressure ports. Ammonia is injected into the piping upstream of the reactor section. The reactor consists of a steel housing that is approximately 8.5 inches square and 8 feet long. The reactor section has three components, including a flow straightener, a pulse section or sootblower, and a catalyst test section. A metal honeycomb is used as a flow straightener upstream of the catalyst section and is about 6 inches long. A purge section was installed ahead of the catalyst test section to remove accumulated dust and deposits. The catalyst test section is located downstream of the purge section. The entire catalyst section is insulated and equipped with strip heaters for temperature control. The catalyst test section is 3.28 ft (1 m) in length and houses three catalyst sections. Thermocouple and pressure taps are located in the purge sections for measurements before and after each section.

The induced-draft fan is used to extract approximately 400 acfm (200 scfm) of flue gas from the convective pass of the utility boiler to achieve an approach velocity of 5.2 m/s (17.0 ft/s). The gas velocity is similar to that found in full-scale applications. The total gas flow through the reactor represents a thermal load of approximately 300 kW.

The range of operating conditions for the reactor is listed below:

- Gas temperature: ~700°–800°F
- Gas flow rate: 400–500 acfm
- Approach velocity range: 5.0–5.5 m/sec
- Ammonia injection rate: 0.5:1 with NO_x level
- Tempering air for fan: ~ 50–200 scfm
- Catalyst dP: 0.5–1.0 inches water column
- Fan sized for up to 30 inches water column

The catalyst installed at the Baldwin and Coyote Stations was the Haldor Topsoe catalyst. Topsoe's DNX-series of catalysts comprises SCR DENOX catalysts tailored to suit a comprehensive range of process requirements. DNX-series catalysts are based on a corrugated, fiber-reinforced titanium dioxide (TiO_2) carrier impregnated with the active components vanadium pentoxide (V_2O_5) and tungsten trioxide (WO_3). The catalyst is shaped to a monolithic structure with a large number of parallel channels. The unique catalyst design provides a highly porous structure with a large surface area and an ensuing large number of active sites. The pitch of the catalyst was approximately 6 mm.

The catalyst installed at the Columbia Station was a Babcock Hitachi plate-type catalyst. This catalyst is a TiO_2-based plate catalyst, developed and manufactured by Hitachi. The pitch of the catalyst was approximately 10 mm.

The coals produced ash that had significant accumulations of ash on the catalyst on both macroscopic and microscopic levels. On a macroscopic level, there were significant observable accumulations that plugged the entrance as well as the exit of the catalyst sections. On a microscopic level, the ash materials filled pores in the catalyst and, in many cases, completely masked the pores within 4 months of operation.

The deposits on the surfaces and within the pores of the catalyst consisted of mainly alkali and alkaline-earth element-rich phases that have been sulfated. The results of this testing found that the <5-µm ash rich in alkali and alkaline-earth elements is captured on the surface and within the catalyst pores. These materials react with SO_2/SO_3 in the flue gas, resulting in the formation of a continuous phase that blinds the catalyst. The ability of elemental mercury to be oxidized across the SCR catalyst was investigated at a North Dakota lignite-fired plant. These results showed no oxidation of mercury across the SCR catalyst.

The reactor was installed at the Baldwin Station and operated for a 6-month time period on the Haldor Topsoe catalyst. The information obtained from testing included pressure drop, sootblowing cycles, and reactor temperatures. Figure 10 show the pressure drop across the catalyst test periods from 0 to 2 months. During the first two months of operation, the pressure was about 0.5 inches of water; at the end of two months, the pressure drop was about 0.8 inches of water, indicating plugging had occurred. The air was pulsed a minimum of every 8 hours in an attempt to maintain cleanliness. The reactor was monitored on a daily basis, and adjustments in pulsing cycles were made in order to minimize deposit accumulation. However, for the first two months, the pressure drop steadily increased. There are several periods where the unit was taken off-line; during those times, the temperature of the catalyst was maintained. At 2-month intervals, a section of catalyst was removed and replaced with a new one.

For Months 2 through 4, the pressure drop was highly variable initially but was about 0.8 inches of water. From Months 4 through 6, the pressure drop was maintained between 0.6 and 0.8 inches of water. This is due to the installation of a fresh catalyst section and leaving two thirds of the catalysts in place that were partially plugged. The gas velocity in the single section of new, clean catalyst was high because of channeling, and the result of the high gas flow was less deposition and accumulation. Gas velocity has a significant impact on the potential for deposits to form. However, at high gas velocity, low NO_x conversion is likely.

The reactor was installed at the Columbia Station and operated for a 6-month period of time with the Babcock Hitachi catalyst. The information obtained from the testing included pressure drop information, sootblowing cycles, and reactor temperature. Figure 11 shows the test periods from 0 to 2 months. The pressure drop across the SCR upon installation was about 0.4 inches of water and increased to an average of about 0.5 inches of water, but ranged from less than 0.4 to greater than 0.8 inches of water. The pressure drop for Months 2 to 4 increased from about 0.5 to 0.7 inches of water because of accumulation of ash. After cleaning the reactor and replacing one catalyst section, the pressure drop was about 0.3 but increased to over

0.6 inches of water up to about 4100 hours. There was an outage at the plant, and aggressive pulsing of the reactor was conducted; the pressure drop was brought back down to 0.3 but rapidly increased to over 0.5 inches of water within 500 hours.

The same reactor that was installed at the Baldwin Station was moved and installed at the Coyote Station. In addition, the same Haldor Topsoe catalyst type was used in the reactor. The reactor was operated for a 6-month period of time. Figure 12 shows the test periods from 0 to 2 months. As this paper is being prepared, the reactor is still operating on-site. The pressure drop across the catalyst upon installation was about 0.4 inches of water. After only 750 hours, the pressure drop was 1.5 inches of water, indicating significant plugging and blinding. Very aggressive air pulsing was conducted, with little success in removing the deposits. The pressure drop for the catalyst was over two times greater than the pressure drop observed for the Baldwin Station utilizing the same reactor and same catalyst. At about 1700 hours, the reactor was cleaned, and a section of catalyst was removed for characterization. The pressure drop after cleaning was about 0.8 to 1.0 inches of water. The pressure drop did not increase as rapidly because of the higher velocities through the clean section of the catalyst.

The tops of the catalysts were photographed during inspection and sampling of the catalyst sections. Figure 13 shows the ash materials that accumulated on the catalyst inlet after 2 months of operation. The most significant accumulation was noted for the Coyote Station, followed by Columbia and Baldwin. The Coyote Station had some larger pieces of ash deposit material on the surface as well as plugging of the catalyst passages. The Baldwin Station showed some obvious deposition along the walls of the reactor and some accumulation on the inlet sections. The Columbia Station showed more significant accumulation and plugging than the Baldwin Station.

After 4 months, the tops of the catalysts were photographed during inspection and sampling of the catalyst sections, as shown in Figure 14. The most significant accumulation was noted for the Coyote Station and some accumulation for the Baldwin Station.

SCR Ash Deposit Characterization

The characteristics of the ash materials that collected on the catalyst surfaces and pores were characterized by SEM and x-ray microanalysis and, in selected cases, XRD was used to determine the crystalline phases present. The catalysts were sampled after 2, 4, and 6 months. The sections were sampled, and approximately 2.5-cm squares were mounted for SEM analysis on double-stick tape and in epoxy resin. The double-stick tape samples allowed for characterization of the external morphology of the particles and catalyst surface. The samples mounted in resin were cross-sectioned and polished, which allowed for more detailed and quantitative analysis of the bonding materials and materials that accumulated in the pores of the catalyst. Detailed information on all the samples can be found elsewhere (add FPT reference). Examples of two deposit and catalyst analysis are presented here.

The 6-month sample from the Baldwin Station showed extensive sulfation of the alkaline-earth elements present in the deposits. Figures 15a and 15b show regions of the catalyst where all the pores were blocked and a minimal amount of deposit on the surface of the catalyst. Figure

15c shows a higher-magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of calcium- and sulfur-rich material, likely in the form of calcium sulfate. The chemical compositions of selected points that indicate the presence of high levels of calcium and sulfur are listed in Table 3. There is much more extensive bonding of the materials with the sulfate matrix as compared to the 2-month sample. In addition, there are some regions of high levels of calcium, aluminum, and sulfur present. The calcium aluminum materials are likely derived from the calcium aluminum phosphate minerals found in the coal fired at this plant.

The 4-month sample from the Coyote Station showed particles adhering to the surface and filling pores in the catalyst. Figure 16 shows the 4-month sample from the Coyote Station. The catalyst showed particles adhering to the surface and completely filling and masking the pores in the catalyst. The external morphology of the catalyst surface shows the masking of the catalyst surface. Chemical compositions of selected points are shown in Table 4. The 4-month sample shows more sulfation than the two months of exposure samples. Figures 16b and 16c shows a higher-magnification view of the deposit that is filling the catalyst pore. The deposit consists of particles of fly ash bonded together by a matrix of sodium-, calcium-, and sulfur-rich material, likely in the form of calcium sulfate. Significant sodium was found in the deposits, as shown in Table 4. The sample shows significant evidence of sulfation after 4 months of exposure and was much more pronounced than the samples for the Baldwin and Columbia Stations that are fired on PRB coals. The presence of sodium enhances the bonding and sulfation of the particles to form a strongly bonded matrix (22).

SCR Deposit Formation Mechanisms

The mechanism for the formation of deposits that blind SCR catalysts involves the transport of very small particles rich in alkali and alkaline-earth elements, the surface of the catalyst, and reactions with SO_2/SO_3 to form sulfates. The formation of SO_3 from SO_2 is catalyzed by the SCR; this, in turn, increases the reaction rate of SO_3 to form sulfates. In some cases, the alkali and alkaline-earth elements will also react with CO_2 to form carbonates. XRD analysis identified $CaSO_4$ as a major phase and $Ca_3Mg(SiO_4)_2$ and $CaCO_3$ as minor phases.

Lignite and subbituminous coals contain high levels of organically associated alkali and alkaline-earth elements including sodium, magnesium, calcium, and potassium, in addition to mineral phases. The primary minerals present in these coals include quartz, clay minerals, carbonates, sulfates, sulfides, and phosphorus-containing minerals (6).

During combustion, the inorganic components in the coal are partitioned into various size fractions based on the type of inorganic component, their association in the coal, and combustion system design and operating conditions. Significant research has been conducted on ash formation mechanisms and relationships to impacts on power plant performance (1–6, 9–13, 19–21, 29). During combustion, the inorganic components associated with western subbituminous and lignite coal typically are distributed into various size fractions of ash. The smaller size fractions of ash are dominated by partially sulfated alkali and alkaline-earth elements. These ash particles are largely derived from the organically associated cations in the coal. The larger size fraction has higher levels of aluminum and silicon derived from the mineral fraction of the ash-forming component of the coal. Entrained ash was extracted from the Columbia Station at the point of the inlet to the SCR reactor and was aerodynamically classified and analyzed. The composition of the size fractions was compared to the chemical composition of the ash deposited on and in the catalyst, as shown in Figure 17. The comparison shows that the composition of the particle captured in the SCR catalyst is very similar to the <5-µm size fraction. The deposited material shows significantly more sulfation than the entrained-ash size fraction, indicating that the sulfation process occurs after the particles are deposited in the catalyst.

The mechanism of SCR catalyst blinding when firing lignite or subbituminous coals is shown in Figure 18 (30). The requirements for the formation of deposits that blind SCR catalyst include firing a coal that produces significant levels of <5-µm-sized particles. The particles are transported into the pores of the catalyst and subsequently react with SO_3 to form sulfates. The sulfate forms a matrix that bonds other ash particles. The SCR catalyzes the formation of SO_3 and thereby increases the rate of sulfation (24, 25). The sulfation of CaO increases the molar volume, resulting in the filling of the pore. For coals that have high sodium contents, formation of low-melting-point phases such as pyrosulfates is possible (31). Pyrosulfate materials can melt at temperatures as low as 535°F in coal-fired power systems.

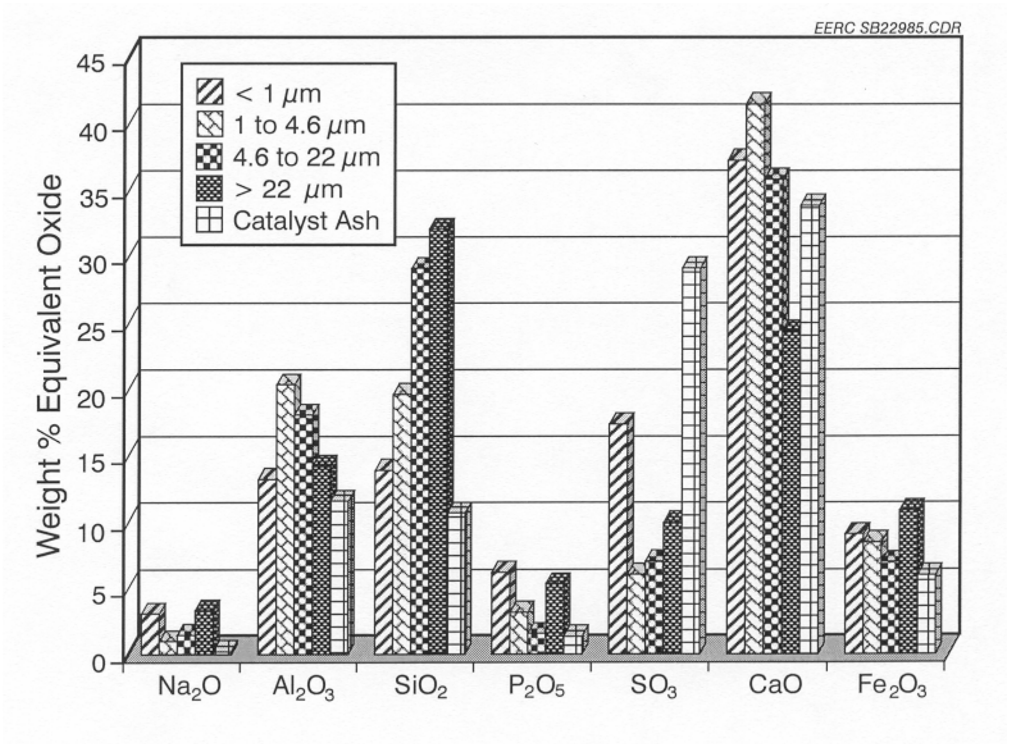

Figure 17. Comparison of entrained ash and deposited ash on catalyst for Columbia Station.

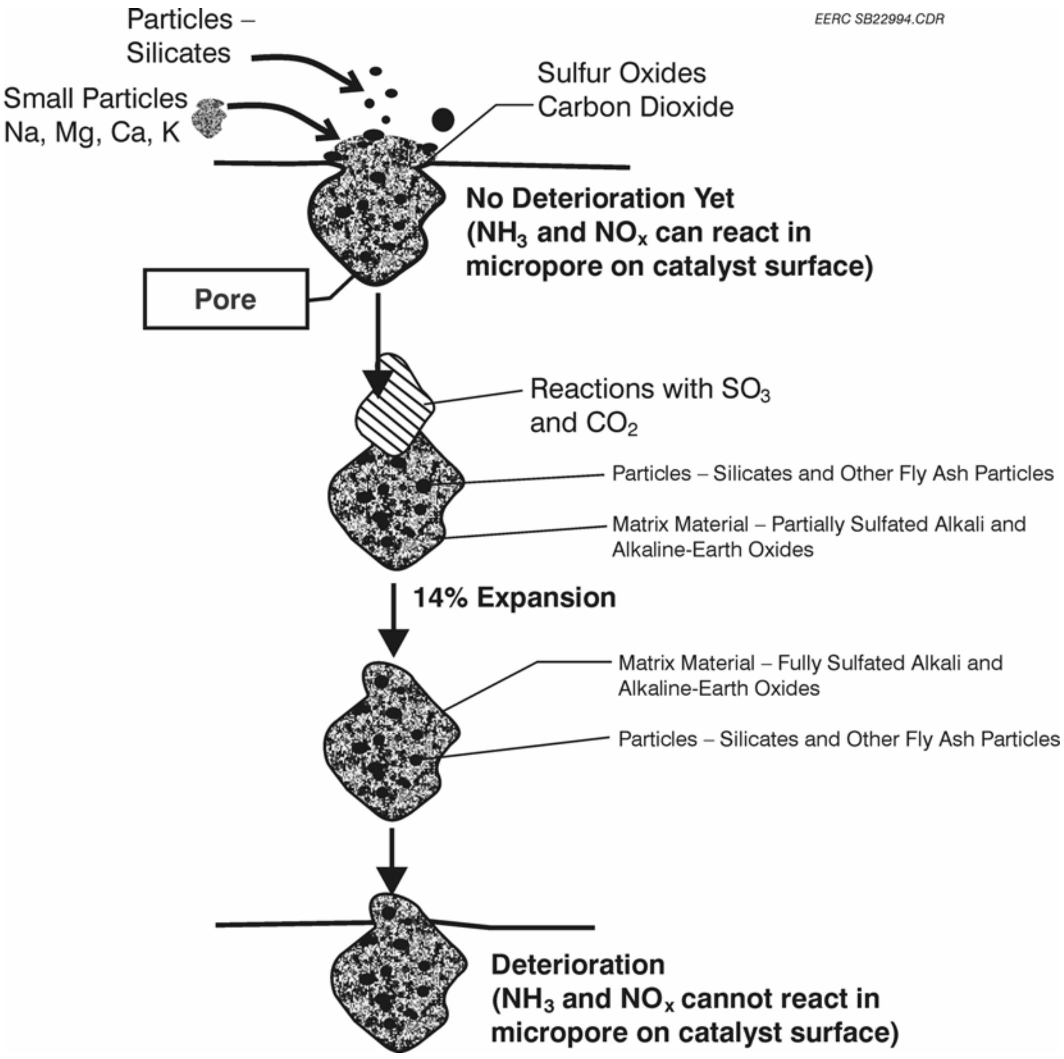

Figure 18. Mechanism of SCR catalyst blinding via the formation of sulfates and carbonates (modified after Pritchard and others [30]).

Low-Temperature Pyrosulfates

The presence of sodium sulfate in the flue gas exiting a scrubber will cause problems to low-dust and tail-end devices such as selective catalytic reduction (SCR) systems for NO_x reduction. There are two problems associated with the fine particulate rich in sodium sulfate on downstream devices. These include accumulation of fine particles on the SCR that, when sootblown, will cause opacity problems, and that the fine particles on the SCR will form pyrosulfates such as $(K_{1.5}Na_{0.5})S_2O_7$ that have melting points as low as 535°F (31) that will blind the catalyst. The presence of these compounds in low-temperature corrosion deposits is well known (32). In addition, the presence of SO_3 enhances the formation of the low-melting-point pyrosulfates (31). The sodium sulfate materials will cause opacity and SCR catalyst blinding problems that limit the feasibility of the low-dust or tail-end SCR technology for use with high-sodium lignite coals.

The sodium sulfate materials will be transported to the catalyst surfaces by diffusion, electrophoresis, and, possibly, inertial impaction. The particles are held in place by weak electrostatic and van der Waals forces. Once accumulation takes place, the sodium sulfate particles will react with flue gas components, resulting in the formation of pyrosulfates. The formation of pyrosulfates involves the following processes (31):

1. Formation of sulfates such as Na_2SO_4 and K_2SO_4

2. Conversion of SO_2 to SO_3 in the bulk gas phase – catalytically active surface such as an SCR catalyst – $SO_2 + \frac{1}{2} O_2 \rightarrow SO_3$

3. Pyrosulfate formation – $Na_2SO_4 + SO_3 \rightarrow Na_2S_2O_7$

The melting points of selected pyrosulfate phases are shown in Table 5.

Table 5. Melting Points of Selected Pyrosulfate Compounds

Compound	Temperature, °C	Temperature, °F
$K_3Fe(SO_4)_3$	618	1144
$K_3Al(SO_4)_3$	654	1209
$KFe(SO_4)_2$	694	1281
$Na_3Fe(SO_4)_3$	624	1155
$Na_3Al(SO_4)_3$	646	1195
$NaFe(SO_4)_2$	690	1274
$Na_2S_2O_7$	401	754
$K_2S_2O_7$	300	572
$(K_{1.5}Na_{0.5})S_2O_7$	279	535

Melting points for pyrosulfates between 535° and 770°F have been reported in the literature. Much of the past work has focused on the formation of these phases on tube surfaces. These species contribute to the corrosion of heat-transfer surfaces in coal-fired power plants. The exact melting point depends on the relative amounts of sodium and/or potassium.

There is significant evidence for the formation of sodium-rich fine particulate in full-scale power plants when firing high-sodium-containing coals. For example, Minnesota Power's Boswell Energy Station found that when it fired high-sodium, lower-ash subbituminous coal, it experienced increases in opacity. Hurley and Katrinak (33) conducted a field-testing project on Unit No. 4, a pulverized coal-fired boiler equipped with an electrostatic precipitator and a wet scrubber, to better understand the reasons for the opacity problems. During the field testing, sampling of the coals, flue gases, and scrubber materials was conducted. The particulate in flue gases downstream of the scrubber was aerodynamically classified using an impactor and multicyclone. The sized fractions were analyzed to determine the composition of the submicron-sized fraction.

The results of the study indicated that the particulate collected downstream of the scrubber was coal-related and caused by the high sodium content of one of the coals. Vapor-phase sodium condenses in the convective pass to form fine sodium sulfate particles or other Na species that later react with ash particles. Pure Na_2SO_4 particles are too small to be removed by scrubbing.

CONCLUSION: SCR IS NOT FEASIBLE FOR NO_X REDUCTION AT MILTON R. YOUNG

The ash deposition behavior of the lignites from North Dakota is the most complex and severe of any coals in the world, and installation of catalysts for NO_x reduction is going to be impossible because of the formation of sodium calcium sulfates in the pores of the catalyst. Following is a list of the key roadblocks associated with lignites which have not been overcome and, in our opinion, make the installation of SCR catalyst at the MRY plant technically infeasible for NO_x control.

- High alkali and alkaline-earth elements present in the coal fired at the MRY plant form sulfates that blind the catalyst.
    - Cyclone-firing partitions the ash during combustion. As a result the level of sodium and calcium in the fly ash is enhanced and will increase the SCR catalyst blinding.
    - Sulfate reactions increase with increasing temperature, and the suggested temperature of installation at the MRY facility is higher than typical installations; therefore, sulfation problems are enhanced.
    - Sulfate formation is also enhanced by the presence of an SCR catalyst; this accelerates the sulfation reactions, causing blinding of the catalyst.
    - The high levels of sodium in the coals combined with calcium produces low-melting-point eutectic compounds that will melt on the surface.
    - Sulfates form on the surfaces of catalysts firing PRB coals. Lignites will be several orders of magnitude worse because of the higher levels of sodium.

- The ash components to impact SCR performance in Japan and Europe (14–16) include alkali and alkaline-earth elements that result in sulfate formation. The total calcium content and the sum of the calcium, magnesium, potassium, and sodium provide an indication of the problems that occur. For the coals fired at the MRY power plant, the CaO content ranges from 6.8%–19.99%, and the sum of the alkali and alkaline-earth elements range from 9.33%–29.87% of the ash. The levels of calcium in Center lignite are 2 to 4 times higher than the problematic coals in Japan and Europe.

- The finding or work conducted in Germany and Japan were confirmed by recent SCR catalyst slipstream testing that showed significant evidence of sodium and calcium-rich sulfate formation that fill and plug the catalyst at both lignite (North Dakota)- and subbituminous-coal-fired power plants. The results of this recent testing showed that the presence of sodium significantly enhanced the formation of bonding of particles and more rapid sulfation, filling of pores, and rapid increase in pressure drop across the catalyst.

- Deposit carryover, or popcorn ash, plugging the top of the SCR catalyst with deposit fragments, is a significant problem because of the extremely high deposition potential of the coal. The formation of deposits in various parts of the boiler requires continuous sootblowing. The deposit fragments are likely going to be carried with the bulk gas flow to the SCR catalyst, resulting in plugging.

- The variability of the lignite is a problem of unique concern at MRY. The deposition potential of the coal is always changing rapidly, resulting in rapid growth and formation of deposits in various sections of the boiler. Aggressive sootblowing of all fireside surfaces is already required to maintain full-load operation. The sootblowing of upstream heat exchange equipment will cause deposit fragments to be carried back to the SCR catalyst, and during sootblowing of the SCR catalyst, the entrainment of deposit fragments along with the sootblowing media will result in significant erosion of the catalyst surfaces.

The ash-related impacts of the lignites from North Dakota are the most complex and severe of any coals in the world, and installation of tail-end SCR systems for NO_x reduction will not be possible. The key problems associated with lignites that have not been overcome and, in our opinion, make the installation of tail-end SCR systems at the MRY plant technically infeasible for NO_x control at MRY's Units 1 and 2 are listed below:

X High-sodium lignite coal from the Center Mine Hagel A and B seam coal produces extreme levels of homogeneously condensed sodium sulfate that pass through the wet scrubber. In addition, the cyclone-firing system captures much of the ash as slag, resulting in a decrease in ash that is available for providing condensation sites for vapor-phase sodium compounds upon gas cooling. This results in an increased homogeneous condensation of sodium sulfate.

X These small particles pass through a wet scrubber and will accumulate on surfaces of tail-end SCR systems. The accumulated materials cannot feasibly be resolved through conventional sootblowing and cleaning technologies to remove the particulate.

X Recent testing with subbituminous and lignitic coals indicated a significantly higher level of pore filling and plugging in the catalyst exposed to lignite ash as compare to subbituminous coal ash. The catalyst pores as well as the catalyst surface in the lignite tests were completely coated with a sodium calcium sulfate material, while only pore filling was found in the subbituminous coal testing. The pressure drop across the catalyst exhibited for lignite was 4 to 5 times greater than that found for a catalyst exposed to subbituminous coal ash. The plugging occurred over a 1000 hour test period.

The formation of liquid pyrosulfate materials at temperatures as low as 535°F from sodium sulfate materials occurs in coal-fired power systems and is well documented. Pyrosulfates will form and cause blinding of tail-end SCR devices. In addition, SCR systems catalyze the formation of SO_3 from SO_2. The presence of SO_3 significantly enhances the formation of the pyrosulfates at MRY to an extreme level that cannot be dealt with effectively using cleaning technologies that exist today.

APPENDIX C

COST METHODOLOGY

CAPITAL COST ESTIMATE DETAILS FOR NO_X CONTROLS

O&M COST ESTIMATE DETAILS FOR NO_X CONTROLS

C.1 METHODOLOGY FOR ESTIMATED COSTS

The summary economic evaluations of each alternative are presented in the cost impact sections of the main report. Capital and O&M cost estimates for each alternative are presented individually. The Levelized Total Annual Cost (LTAC) for all the alternatives for control of a single pollutant (i.e. NO_X) from a single unit is then presented together with Unit Control Costs. The Levelized Total Annual Cost (LTAC) represents the levelized annual cost of procurement, construction and operation over a 20 year design life, again in current (2006) dollars. As a minimum, the design life for any alternative was taken to be that recommended by "The EPA Air Pollution Control Cost Manual", Sixth Edition, January 2002, EPA/452/B-02-001[i].

The LTAC is also used to calculate the average annual and incremental cost effectiveness of each alternative. The LTAC represents an annual payment in current day dollars sufficient to finance the project over its entire life.

In determining the LTAC a Capital Recovery Factor and an O&M Levelization Factor were calculated from the project economic conditions and then applied separately to the estimated capital and O&M costs. The equation used is shown below.

$$LACC / NPV = \left(\frac{i(1+i)^n}{(1+i)^n - 1} \right) = CRF$$

Where,
LACC = Levelized Annual Capital Cost
NPV = Net Present Value of the capital investments required.
i = discount rate
n = design life in years
CRF = Capital Recovery Factor

Therefore:

LACC = CRF x NPV

For the economic conditions described in Table C.1-1 the Capital Recovery Factor was calculated to be 0.08718.

In determining the levelized annual O&M cost the estimated annual O&M cost, the inflation rate, the discount rate, and the equipment life are taken into account. The O&M Levelization Factor (OMLF) was calculated as follows.

$$LAOMC / A_1 = \left(\frac{1+i_d}{1+i_i} - 1 \right) \left(\frac{i_d (1+i_d)^n}{(1+i_d)^n - 1} \right) = OMLF$$

Where,
A = Levelized Annual O&M Cost (LAOMC)
A_1 = Total annual O&M cost in current dollars
i_d = discount rate
i_i = inflation rate
n = design life in years

Therefore:

$$LAOMC = OMLF \times A_1$$

For the economic conditions described in Table C.1-1 the Operating and Maintenance Levelization Factor was calculated to be 1.24873.

The Levelized Total Annual Cost, or LTAC is the sum of the levelized capital cost and the levelized O&M cost. Therefore:

$$LTAC = LACC + LAOMC = (CRF \times P) + (OMLF \times A_1) = 0.08718 \times P + 1.24873 \times A_1$$

The differences between alternatives are also presented graphically in the form of a plot of the annual emissions reduction (tpy) versus the LTAC for each alternative. This form of plot graphically depicts the cost effectiveness or Unit Control Cost (in $/ton of pollutant reduction) of each alternative relative to all of the others. The cost effectiveness is also referred to as the Unit Control Cost and defined as the LTAC divided by the annual emissions reduction (ton/yr). The area on the plot indicated by the various data points represents the cost effectiveness envelope for the alternatives under consideration. A smooth line is drawn on this plot connecting the rightmost points (those with the lowest cost for a given level of emissions reduction). This line is referred to as the Dominant Control Curve (DCC). The DCC defines the right hand boundary of the envelope encompassing all of the alternatives considered. The DCC is used as a screening tool between considered alternatives. Those alternatives whose plotted position is above and/or to the left of the DCC are not as cost effective as those forming the line and thus can be eliminated from further analysis if desired.

In order to compare various pollutant control alternatives, the Unit Control Cost and the incremental Unit Control Cost of each alternative were also calculated and tabulated for comparison purposes. The Unit

Control Cost compares control technologies on a basis of dollars expended per ton of pollutant reduced ($/ton). This relationship is graphically depicted in the DCC chart.

To more accurately compare between alternatives with different costs and control efficiencies, the incremental cost effectiveness is also determined for those alternatives on the DCC. The incremental cost effectiveness is defined as the LTAC of a given control option minus the LTAC of an alternative, divided by the difference between the annual emissions reduction (tpy) of the given control option and the alternative being evaluated. The combination of these two economic analyses can be used as an argument for the elimination of control technologies with significantly greater marginal control costs than the given case. The equation used for the incremental cost effectiveness is shown below.

$$ICF = \frac{(LTAC_1 - LTAC_2)}{(AE_1 - AE_2)}$$

Where,

ICF = Incremental cost effectiveness ($/incremental ton removed)
$LTAC_1$ = Levelized Total Annual Cost of control alternative No. 1 ($/yr)
$LTAC_2$ = Levelized Total Annual Cost of control alternative No. 2 ($/yr)
AE_1 = Control option No. 1 Annual Emissions Reduction (ton/yr)
AE_2 = Control option No. 2 Annual Emissions Reduction (ton/yr)
(The higher cost, more effective control option is subscript 1 in this equation.)

The economic analyses presented in this report not only include the estimated capital and O&M costs for each alternative, but also the LTAC for economic comparison of the various alternatives. In addition, the Unit Control Cost or cost effectiveness is presented for each alternative. Finally, a comparison between alternatives, in the form of the marginal cost effectiveness, is presented in both numerical and graphical form. Thus a comprehensive comparison of the economic impacts of each alternative, as well as the differences in economic impact between alternatives is clearly presented.

Table C.1-1 – Economic Factors(1),(2)

Total Possible Operating Hours per Year	8,760
Amortization Life, Years	20
Cost of Money	6%
Property Taxes, Insurance, %	NA
Conversion Tax (in lieu of property tax)	NA
Amortization Rate for APC Capital Costs	6%
Interest During Construction (IDC)	6%
Discount Rate (used to calculate NPV)	6%
Construction Cost Escalation	3%
Non-Fuel O&M Escalation	2.5%
Fuel (coal and natural gas) Escalation	2.5%
Auxiliary Electric Power Cost, $/MW-hr	$35.00
Urea Cost, ($/ton delivered, 50% aqueous solution)	$380.00
Natural Gas ($/mmBtu)	$7.98

(1) - All financial percentages and unit auxiliary electric power cost were provided by MPC.
(2) - All costs are in 2006 dollars unless noted otherwise.

C.2 NOx CONTROLS - CAPITAL COST ESTIMATES

The capital costs to implement the various NO_X control technologies were largely estimated from unit output capital cost factors ($/kW) published in technical papers discussing those control technologies. In the cases of SNCR and FLGR, preliminary vendor budgetary cost information was obtained and used in place of, or to adjust, the published unit output cost factors. These cost estimates were considered to be study grade, which is + or – 30% accuracy, or better.

The limitations of these capital cost estimates developed from unit capital cost factors multiplied by unit output are:

- Scope basis uncertainty – inability to precisely determine what scope of supply, including such things as balance-of-plant (BOP) systems and equipment improvements were required, assumed, or accounted for when developing the unit cost factors. Some alternatives may have higher indirect or BOP capital costs than others. Similarly, the inclusion of general facilities, preproduction and inventory costs, and other indirect costs is not known. It is likely that the utility owner’s final total expenditure for the implementation of the alternatives, especially options that are most capital cost-intensive, will be greater than the calculated cost estimates.
- Location-specific influences – most NO_X control techniques have been applied primarily to eastern bituminous coal-fired plants located near large metropolitan areas, not in largely rural, upper midwestern United States locales. The amount of space available is dependent on the existing powerplant equipment and building layout and property plot area, versus what is expected to be required for implementing various control technologies. Transportation and local/regional labor costs are also variables.
- Size influences – some technologies’ capital costs are more sensitive to “economies of scale” than others.
- Capacity margins – some technologies’ may require higher capacity margins to allow sustained operation at high throughput rates over extended periods of time.
- Reliability concerns – some technologies’ have been refined to a higher degree, and others may require more component redundancy than others in order to avoid performance reductions and potential outages for failures and repairs or replacements.
- Inflationary influences – the significant increases in 2004-2005 for raw material costs, especially steel and alloys for fabrication of structural and mechanical components, has occurred after many of these technologies were installed in projects upon which the referenced unit capital cost factors were based.

- Market conditions – as demand increases for emission controls, some alternatives become more cost-competitive, while others do not. This can be influenced by the relative supply and demand for the technology and number of suppliers who can furnish it. The demand for some alternatives can also be strongly influenced by the stringency of the local, state, and national regulatory requirements. Schedule for implementation and availability of local/regional labor for installation contractors are also market-driven factors.

The estimated NO_X control costs are in addition to capital costs to provide normal replacements of the existing Milton R. Young Station's major power generating equipment.

C.2.1 Separated Overfire Air Capital Cost Estimates

Installation of separated overfire air systems typically includes windbox and/or secondary combustion air supply duct modifications, boiler waterwall tube openings, airflow distribution devices (dampers/registers), airflow controls and measurement instrumentation, and related structural and electrical tie-ins to the existing plant facilities. A basic separated overfire air retrofit system installed on a lignite-fired cyclone boiler includes ports across the front and rear walls of the upper furnace. The unit capital cost factor is expected to be above the high end of the typical published cost range of \$5-10/kW[ii] (\$11.5/kW or \$5.500,000[3] for MRYS Unit 2), due to the large ducts, relatively tall furnace (compared to typical bituminous coal-fired cyclone boilers), and the need to avoid existing obstructions within the boiler house.

An advanced form of SOFA unique to North Dakota lignite-fired boilers will include relocation of the existing lignite drying system vent port openings from the lower primary furnace to the upper furnace, to be placed at the same elevation as the new SOFA ports. This requires extension of the existing cyclones' lignite drying systems' vent piping to supply the new boiler furnace ports. This retrofit will also close-off the existing FGR ports in the lower front and rear furnace walls of Unit 2, currently coinciding with the existing pre-dry vent ports. These FGR ports may be blocked, or relocated to the lower portion of the upper (secondary) furnace, across the front and rear walls. This is expected to cost in the area of +\$9.5/kW or \$4,500,000 for Unit 2's additional capital cost over and above the basic SOFA system. Overall, the advanced version of separated overfire air technology is estimated to have an installed capital cost of approximately \$10.0 Million (\$21.0/kW) for MRYS Unit 2.

C.2.2 Reburn Capital Cost Estimates

C.2.2.1 Coal Reburn Capital Cost Estimates

There is one alternative that includes a new coal reburn system. Capital cost estimates for coal reburn systems are highly dependent on the requirements for reburn fuel preparation and feeding to the boiler. For the purposes of this analysis, the application of a pulverized coal reburn system assumed the need to make extensive additions to the existing fuel preparation equipment in the existing plant facilities and feeding to new furnace injectors. At least two new fine-grind pulverizers, or MPS-89 standard pulverizers followed by dynamic classifiers are expected to supply the amount of finely ground reburn coal for this method.

Addition of new electrical loads for the pulverized coal preparation equipment to the existing plant facilities will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power will be available for powering the new pulverizers/micro-mills and related new coal reburn equipment, but this has not been confirmed.

The existing crusher bays do not have floor space available to allow the new milling equipment for reburn fuel preparation to be located adjacent to the existing coal crushers. This will require a separate building or addition to the existing powerhouse to be built to provide sufficient space to enclose the new milling and coal silo/handling equipment. Separate modified pulverized coal-style burners or coal injectors will be installed through new openings in the upper furnace front and rear waterwalls at or above the elevation of the existing lignite drying system vent ports, along with new overfire air ports located at a higher elevation, above the reburn fuel injectors. This would have the capacity to supply approximately up to thirty percent of the total full load fuel heat input to the boiler through the coal reburn injectors. This coal reburn system design was not expected to change the existing cyclone silo/feeder arrangement, such that all cyclones would remain operational. To achieve maximum NO_X emission control, only the advanced form of SOFA for pulverized coal reburn was included. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BACT analysis.

The installed capital cost of pulverized coal reburn for the cyclone boilers at Milton R. Young Station used in this cost effectiveness analysis was estimated based upon a Clean Air Markets Division [CAMD] of the US EPA dollar per kilowatt unit capital cost factor for cyclones. The installed capital cost estimate of $40.65 Million for MRYS Unit 2’s pulverized coal reburn alternative used in this cost effectiveness analysis was estimated based upon applying a 3.5% assumed inflation cost adjustment to the CAMD unit capital cost factor for cyclones of $82.33/kW (x 1.035 = $85.2/kW) included in a WRAP (Western Regional Air Partnership) draft report[iv] published on their website, dated April 26, 2005. The cost to relocate the lignite drying system vent ports and FGR ports was added to the inflation-adjusted CAMD number ($85.2 + $9.5/kW = $94.7/kW), since coal reburn is expected to include separated overfire air but not the extra costs for the special improvements identified for air-staged lignite-firing in cyclone boilers. This increased the installed capital cost by $4.M for MRY Station Unit 2's coal reburn system to a total of $45,154,000. This does not include the additional particulate matter collection capacity considered necessary to limit the expected negative impact on opacity from this option.

To control particulate matter (PM) emissions that would be expected to increase from installation and operation of pulverized or micronized coal reburn, additional PM collection capacity will be required. A hybrid form of PM collection that supplements the existing electrostatic precipitator's performance, referred to as COHPAC (COmpact Hybrid PArticulate Collector). This was estimated in 2002 dollars at $30,200,000 for MRYS Unit 2's COHPAC[3]. Adjusted by an escalation factor of 1.2623, the installed capital cost of the COHPAC addition was estimated to be $36,013,000 for MRYS Unit 2 in 2006 dollars. When the COHPAC addition was combined with the Lignite Reburn and ASOFA alternatives, the resulting total estimated capital costs were $81,167,000 for MRYS Unit 2 ($94.7 + $75.5 = $170.2/kW).

C.2.2.1 Gas Reburn Capital Cost Estimates

Conventional gas reburn options assume that seventeen percent of the total fuel heat input to the boiler is through the new gas reburn injectors to be located in the lower secondary furnace above the top rows of cyclones. Eight to twelve gas reburn injectors would be expected to be required in this case. Seven percent of the total fuel heat input to the boiler through the gas reburn injectors is assumed to be supplied for the fuel lean gas reburn alternatives. Four to eight gas reburn injectors could be assumed in FLGR™ cases. Gas reburn options assume that a new high-pressure gas pipeline would be brought from near Bismarck, ND approximately twenty six miles. The pipeline diameter is proportional to the amount of fuel required for the specific alternative, ranging from 24 inches for conventional gas reburn to 12 inches for fuel lean gas reburn cases. A station gas main, with new gas trains, consisting of valves, metering, and safety shutoff valves for the front and rear boiler for the gas injectors' supply, would be furnished and installed.

The capital costs for conventional gas reburn alternatives were estimated considering unit capital costs published in published technical literature. One vendor that has supplied numerous domestic utility boiler gas reburn systems (GE Energy, formerly GE-EER) published $10/kW for gas reburn in a 2001 technical paper[v]. Another source published a 2005 technical paper[vi] that provided a unit capital cost range for gas reburn of $15/kW to $30/kW. Neither source included a detailed scope description nor cost breakdown for engineering, equipment, materials, and labor to install a gas reburn system.

Site-specific needs and challenges identified for applying conventional gas reburn to Milton R. Young Station, and lack of detailed gas reburn project scope and equipment descriptions available in published technical literature leads to a much greater degree of uncertainty with regards to an accurate capital cost estimate for this alternative. For the purposes of this study, the estimated installed capital cost for a conventional gas reburn system with advanced SOFA on MRYS Unit 2 is expected to be approximately $20.5M ($43/kW), which is above the top end of the previously stated range, before adding the new underground gas pipeline capital costs. This study assumed an average unit capacity capital cost factor of $22/kW for conventional gas reburn, plus the additional costs for the advanced form of SOFA over basic SOFA +$4.5M ($9.5/kW), and the new high-pressure gas pipeline. This results in a an estimated installed capital cost for conventional gas reburn system with advanced SOFA on MRYS Unit 2 of $20.5M ($43/kW) plus the new high-pressure gas pipeline costs. Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BACT analysis.

Fuel lean gas reburn (without SOFA) capital cost estimates were based upon a late 2004 budgetary proposal[vii] by a vendor (Fuel Tech) with experience in supplying FLGR™ equipment, typically combined with an SNCR system. Estimated capital costs of $3M include budgetary numbers for the equipment installation, including installation management, material and labor, with a +6.0% price adjustment assumed for 477 vs 450 MW for a fuel lean gas reburn system without SOFA on MRY Unit 2, not including the capital cost for the gas supply pipeline. Costs for work outside the vendor's scope, such as balance-of-plant additions plus other indirect costs were estimated to add approximately $1.1M (25% plus 10% contingency) to the adjusted vendor's estimated installed cost of $3.2M for their scope of supply. These adjustments result in a total installed capital cost for FLGR (without SOFA) estimated to be $4.3M plus the capital cost for the gas supply pipeline. Adding the incremental costs for the advanced from of SOFA over no SOFA (+$10M ($21/kW) results in an estimated installed capital cost for a fuel gas reburn system with advanced SOFA on MRYS Unit 2 of $14.3M ($30.0/kW) plus the new high-pressure gas pipeline costs.

The capital cost estimates for the new high-pressure underground gas supply pipeline assumed $7 per inch of diameter per foot of length. This was calculated to be approximately $23M for conventional gas reburning and $11.5M for FLGR™. The cost analysis for each NO_X control alternative involving a particular form of gas reburn assumed that both boilers at Milton R. Young Station select the same alternative that burns natural gas. Therefore, the estimated capital costs for gas reburn alternatives reflect a capacity-based proportional share of the gas pipeline capital costs, avoiding double-counting. This results in an estimated installed capital cost for MRYS Unit 2's share of the gas pipeline to be $15M for the conventional gas reburn alternative and $7.5M for fuel-lean gas reburn alternatives.

The total installed capital costs for conventional gas reburn (with ASOFA) with MRYS Unit 2's share of the total capital cost for the gas supply pipeline estimated to be $35.5M ($74.4/kW). The total installed capital costs for FLGR™ (with ASOFA) with MRYS Unit 2's share of the total capital cost for the gas supply pipeline were estimated to be $21.8M ($45.7/kW). Confirmation of these concepts and cost estimates requires more detailed equipment design and plant layout than has been performed for the purposes of this BACT analysis.

C.2.3 SNCR Capital Cost Estimate

The alternatives that include selective non-catalytic reduction systems assume the use of urea unless noted otherwise. The SNCR systems' preliminary design and estimated capital costs were based upon a 450 MW lignite-fired cyclone boiler in a late 2004 budgetary proposal[7] by a vendor (Fuel Tech) with experience in supplying SNCR equipment. Circulation, metering, dilution, control, and injection equipment is included. A 180,000 gallon field-erected stainless steel storage tank will hold the 50% urea solution (as delivered by truck). Individual and multiple nozzle lances with multiple levels of urea reagent injection will be designed and located to optimize distribution and accommodate various boiler load conditions. Estimated capital costs of $4.9 Million include budgetary numbers for equipment installation, including installation management, material and labor assumed for a SNCR system applied to a 450 MW boiler. Costs for work outside the vendor's scope, such as outdoor reagent storage tank and building enclosure/equipment foundations and containment, and balance-of-plant additions plus other indirect costs were estimated to add approximately $1.9 Million (25% plus 10% contingency) to the vendor's estimated installed cost for their scope of supply. This results in an estimated total capital cost for SNCR (without SOFA) of $6.8M for a 450 MW lignite-fired cyclone boiler.

Applying these adjustments to a 477 MW boiler results in an estimated total installed capital cost for SNCR of $7,120,000 for MRY Station Unit 2 ($14.9/kW).

C2.5 Layered Technology Capital Cost Estimates

Capital costs were generally estimated based upon simple arithmetic addition of individual unit output capital cost factors for combinations of available NO_X reduction technologies, such as SNCR with ASOFA. An advanced form of separated overfire air system included the lignite-fired cyclone boiler equipment changes within the estimated unit capital cost factors.

Adding the advanced SOFA capital cost of $10.0 Million to the previous estimated installed capital cost of $7.12 Million yields a total estimated installed capital cost of $17.128 Million ($35.9/kW) for the SNCR with ASOFA alternative for MRYS Unit 2.

As previously discussed, Lignite (coal) reburn (CR) was assumed to be combined with advanced SOFA and a COHPAC addition considered necessary to limit the expected negative impact on opacity from this option. The installed capital cost of the COHPAC addition was estimated to be $36,013,000 for MRYS Unit 2. When the COHPAC addition was combined with the Lignite Reburn and ASOFA alternatives, the resulting total estimated capital costs were $81,167,000 for MRYS Unit 2 ($94.7 + $75.5 = $170.2/kW).

C.3 Operating and Maintenance Cost Estimates for MRY Station NO_X Control

An evaluation was performed to determine the estimated operating and maintenance cost impacts of installing and continuously operating various feasible NO_X control technologies on Milton R. Young Station Unit 2. These were estimated to be in addition to existing O&M costs to operate and maintain the MRY Station equipment.

The expected loss of electrical power sales from the operation of the specific NO_X control alternative was included as an annualized cost, assuming $35 per megawatt-hour. This was determined to include estimates for:

- Reduction in annual unit output due to an expected negative reliability (i.e. uptime availability) impact for each alternative. This generation reduction was calculated by multiplying the estimated additional numbers of outage hours per year by the average running plant capacity factor for that specific alternative, multiplied by the historic 12-month average unit gross electrical power output (MW_g) determined during the same period as the highest 12-month rolling summation NO_X pounds.
- Net additional auxiliary electric power demand for the added control equipment for each specific alternative based on assumptions for gross horsepower, plus additional power demand for existing fans caused by flue gas pressure drop (COHPAC for additional PM collection capacity), with adjustment for expected reductions in power demand (such as a decrease in existing coal crusher and feeder electric demand for the pulverized coal reburn case).
- The average running plant capacity factor for each alternative, which may also include an expected negative impact on the unit capacity from operation of the technology. This assumes that the control technique limits the gross electrical power output of the Unit (such as causing an increase in flue gas flow) such that the firing rate of the boiler cannot be maintained or raised to compensate for the load impact. Examples are lower boiler thermal efficiency (higher unit heat rate) when firing natural gas (due to higher moisture content of the flue gas).

For the SNCR alternative that involves a chemical reagent injected for NOx control, such as urea, the annual reagent consumption based on an assumed actual stoichiometric ratio (ASR) of moles of equivalent NH_3 injected per mole of uncontrolled NO_X emission estimated at the point of injection, converted to a mass rate (lbs/hr) by multiplying by the estimated annual number of hours of operation and the estimated NOx reduction fraction, and then multiplied by unit reagent cost (for a specific inlet NO_X concentration, emission reduction percentage and ammonia slip level).

General annual maintenance costs were assumed to be 1.5 percent of the estimated installed capital cost for each alternative, except for the coal conveying and grinding equipment portion of the coal reburn alternative, which was assumed to be 3 percent. The periodic bag replacement costs and other COHPAC system maintenance costs were estimated to be approximately 5.3% of the installed capital cost of the additional particulate matter collection equipment.

Additional operating labor costs directly attributable to each alternative were assumed to be zero for all alternatives.

Other operating costs include:

- Reagent dilution water for those alternatives that involve a chemical reagent injected for NOx control, typically four times the amount of urea consumption (assumes urea is a 50% solution as delivered and is injected as a 10% solution); this follows EPA OAQPS convention[1].
- Heat required for urea reagent storage, for those alternatives that involve a chemical reagent injected for NOx control; the source of heat is assumed to be auxiliary electrical power, but could be auxiliary steam (depending on heat source availability and plant preference).
- Additional coal consumption for those alternatives that involve a chemical reagent injected for NOx control to compensate for the heat of vaporization of the reagent dilution water;
  This follows EPA OAQPS convention[1], but is not accepted practice by an experienced SNCR vendor (Fuel Tech) who claims that the heat produced from the exothermic reaction of urea and NO_X is approximately equal to the heat required to evaporate the dilution water. For the purposes of this study, this additional coal consumption has been included in the annual O&M costs.

The sum of the estimated annual O&M costs was multiplied by the O&M levelization factor (1.24873) for each alternative to yield levelized total annual O&M costs.

C.3.1 Separated Overfire Air O&M Cost Estimate

Operation of SOFA is expected to add a small amount of O&M cost, primarily electricity consumed by the conventional SOFA damper electric drive actuator and airflow measuring system transmitter on each port. Using the existing forced draft, induced draft, and flue gas recirculation fans is not expected to change the overall amount of fan horsepower demand to be supplied by those fans' electric motors. Maintenance of the new overfire air ports and relocated lignite drying system vent ports (and FGR ports for Unit 2) is included, assumed to be 1.5 percent of the installed capital cost. This is included in every control alternative's estimated O&M cost.

SOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, assuming consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for MRYS boilers can be routinely established. A Unit availability reduction of 2.2% (181 hours per year), for M.R. Young Station Unit 2 was assumed, which allows for forced or extended scheduled boiler outages that may result from problematic cyclone slag tapping operational conditions encountered during substoichiometric cyclone operation with SOFA. The expected loss of electrical power sales from the reduction in annual electrical power output due to a decrease in expected Unit availability from ASOFA operation is included in every control alternative's estimated O&M cost.

Boiler furnace waterwall tube maintenance may increase slightly as a result of more fireside corrosion due to substoichiometric cyclone operation with SOFA. There may be some changes in the degradation rate of the boiler's furnace waterwall tubes resulting from exposure of more area of the furnace walls to slightly air-starved conditions during SOFA operation. Such conditions can promote corrosion from sulfur compounds in the furnace gases being created above the cyclones and below the SOFA injection ports. Due to the relatively moderate amounts of sulfur content in the lignite, modest amount of air-staging of the existing cyclones during SOFA operation, and the potential use of recirculated flue gas along the lower furnace walls, the expected change in corrosion rate of the boiler tubes should be minor. This degradation is expected to occur over many years of operation, and normally requires periodic replacement of the deteriorated sections of boiler furnace waterwall tubes to avoid forced outages to repair tube leaks or failed sections. The additional costs associated with potential change in the frequency of furnace wall tube failures and changeouts are difficult to estimate, and have not been quantified.

C.3.2 Reburn O&M Cost Estimates

The alternatives that include a new coal reburn system assume the use of new equipment for preparing the reburn fuel to replace 25% of the MRY Station Unit 2 boiler's total fuel heat input. Two additional lignite silos, with coal feeders and fine-grind pulverizers followed by dynamic classifier(s), are assumed to be located in a new separate building or powerhouse enclosure. Booster fan(s) addition was included because the existing forced draft fans were assumed to be incapable supplying the additional amount of primary air to the fine-grind pulverizers and dynamic classifier(s) for processing and conveying the reburn fuel. Using the existing forced draft, induced draft, and flue gas recirculation fans is not expected to significantly change the overall amount of fan horsepower demand to be supplied by those fans' electric motors. The expected loss of electrical power sales from the additional auxiliary electric power demand for the reburn milling equipment from an estimated 0.5% (2.5 MW) reduction in net output was included as a cost, assuming $35 per megawatt-hour for MRY Station Unit 2. Electrical power consumed by the increased load on boiler fans to overcome the higher flue gas system pressure drop, plus the COHPAC particulate collection system support equipment was estimated to be a 1.2% (5.8 MW) reduction in net output for Unit 2.

Maintenance of the separate reburn coal injectors, fuel and primary air piping, and reburn fuel milling equipment is expected to be similar to the expenses associated with typical pulverized coal burners. The estimated additional annual maintenance costs for a new micronized coal reburn system was assumed to be 3.0 percent of the installed capital cost, or roughly $1,355,000 per year, for MRY Station Unit 2. The estimated additional annual maintenance costs (inflation adjusted from 2002 to 2006 $) for the COHPAC system was approximately $1,938,000 per year for MRYS Unit 2. Boiler furnace waterwall tube and superheater/reheater tube maintenance may increase slightly as a result of more erosion due to increased particulate emissions or fouling by flyash deposits resulting from coal reburn operation with ASOFA. The additional costs associated with potential change in the frequency of boiler tube failures and changeouts are difficult to estimate, and have not been quantified.

The estimated impacts on operation and maintenance costs for the coal reburn alternative that include a new pulverized or micronized coal reburn system are approximate. The twelve (Unit 2) existing coal crushers for preparing the main (cyclone) fuel fraction will have slightly lower electrical demand. This was estimated as -0.45 MW (-0.09%) for MRYS Unit 2. Addition of new electrical loads for the micronized coal preparation equipment to the existing plant facilities will be required. For the purposes of this preliminary study, it is assumed that additional plant auxiliary electrical power will be available for powering the new pulverizers/classifiers and related new coal reburn equipment, but this has not been confirmed.

Coal Reburn with ASOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, assuming consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for MRYS boilers can be routinely established. A Unit availability reduction of 3.7% (3.8% (313 hours per year), for M.R. Young Station Unit 2 was assumed, which allows for forced or extended scheduled boiler outages that may result from problematic operational conditions encountered during coal reburn operation with ASOFA. This reduction in annual electrical power output due to a decrease in expected Unit availability is included in the coal reburn control alternative's estimated O&M cost.

A Running Plant Capacity Factor reduction of 0.5% of annual gross electrical output was assumed for the coal reburn alternative. This would result in an estimated 2.2 MW average load decrease for M.R. Young Station Unit 2. This expected loss of electrical power sales from the reduction in net output due to this plant capacity impact was included in the estimated annual O&M costs.

Conventional and fuel-lean gas reburn options will involve higher operating costs compared with the existing operation of M.R. Young Station. Natural gas supply was assumed to be available near Bismarck, ND, but this has not been confirmed. The estimated unit cost of this natural gas was assumed to average $7.98/million Btu on a levelized annual cost basis, with a "credit" of $0.71 per mmBtu for avoided cost of consumption of lignite coal reduced by the natural gas heat input. The estimated annual cost of natural gas for the conventional gas reburning alternative applied to MRYS Unit 2 is approximately $50.3M per year. The estimated annual cost of natural gas for the FLGR™ alternative applied to MRYS Unit 2 is approximately $20.8M per year.

The new gas reburn injectors, station gas main and injector gas trains would add a minor amount of expense to current maintenance requirements, assumed to be 1.5 percent of the installed capital cost. Maintenance of separated overfire air nozzles is expected to be similar to the expenses associated with Unit 2's existing flue gas recirculation ports.

C.3.3 SNCR O&M Cost Estimate

The alternatives that include selective non-catalytic reduction systems will involve higher operating costs compared with the existing operation of MRY Station Unit 2. Urea reagent supply was confirmed to be available regionally. The estimated unit cost of this 50% aqueous urea solution was assumed to average approximately $379/ton delivered (2006$). Consumption of urea reagent for SNCR with ASOFA was based upon preliminary numbers allowing for a boiler flue gas exit ammonia slip of 5 ppmvd. These were estimated as approximately 286 gph for SNCR when applied to MRY Station Unit 2 with ASOFA.

New electrical loads are required for high flow urea circulation, in-line and storage tank heating, water dilution, and reagent metering equipment. These auxiliary electrical demands and reagent dilution water usage were calculated based upon equations published in EPA Office of Air Quality Planning and

Standards (OAQPS) publication EPA/452/B-02-001, Section 4.2, NOx Controls – NOx Post-Combustion, Chapter 1 - Selective Non-Catalytic Oxidation[1]. Compressed air for reagent atomization and lance purging and cooling, as well as multiple nozzle lance water cooling are additional demands on the existing plant facilities. These powerhouse building service supplies were assumed to be available, but this has not been confirmed. The new urea reagent injection nozzle lances, reagent pumps, dilution water pumps, and distribution piping/valve trains would add a minor amount of expense to current maintenance requirements, assumed to be 1.5 percent of the installed capital cost.

SNCR with ASOFA is not expected to significantly reduce unit reliability and availability to generate electrical power, assuming urea injection does not impact the ability to maintain consistent combustion and continuous slag tapping under substoichiometric air/fuel operating conditions for MRYS boilers. A Unit availability reduction of 3.2% (263 hours per year), for M.R. Young Station Unit 2 was assumed, which allows for forced or extended scheduled boiler outages that may result from problematic operational conditions encountered during SNCR-related operation with ASOFA. This reduction in annual electrical power output due to a decrease in expected Unit availability is included in the these control alternatives' estimated O&M costs.

A Running Plant Capacity Factor reduction of 0.15% of annual gross electrical output was assumed for the SNCR with ASOFA alternative. This would result in an estimated 0.66 MW average load decrease for M.R. Young Station Unit 2. This expected loss of electrical power sales from the reduction in net output due to this plant capacity impact was included in the estimated annual O&M costs.

C.3.4 Layered Technology O&M Cost Estimates

Operating and maintenance costs for combinations of available NO_X reduction technologies were estimated based upon simple arithmetic addition of individual cost estimates. SNCR was combined with advanced SOFA, as previously shown. Pulverized coal reburn was assumed to be combined with advanced SOFA (and a COHPAC addition for PM control). The auxiliary electrical demands and reagent dilution water usage for SNCR with ASOFA were calculated based upon equations published in EPA Office of Air Quality Planning and Standards (OAQPS) publication EPA/452/B-02-001, Section 4.2, NOx Controls – NOx Post-Combustion, Chapter 1 - Selective Non-Catalytic Oxidation[1].

C.3.5 Summary of O&M Costs Estimates for MRY Station NOx Control

The results of this evaluation for estimated variable operating and maintenance costs for the individual NOx control alternatives are summarized in this section. The expected reductions in Unit availability (uptime) and capacity are included in Tables C.3-1 through C.3-7 for MRYS Unit 2. Tables C.3-5 and C.3-6 for MRYS Unit 2 include the estimated urea reagent and dilution water usage rates and costs for the alternatives that involve SNCR with ASOFA NO_X control technologies.

TABLE C.3-1 – Expected Availability Reductions for MRY Unit 2 NO_X Controls

		Estimated Annual Average Unit Operating Time			
Alt. Label(1)	**NOx Control Technique**	**Unit Availability(2)**	**Unit Operating Time(3), hrs/yr**	**Unit Outage Time(4), hrs/yr**	**Unit Operating Time Reduction(5), hrs/yr**
E	SNCR w/ ASOFA	0.909	7965	795	263
D	Gas Reburn w/ ASOFA	0.919	8048	712	181
C	Coal Reburn w/ ASOFA	0.904	7916	844	313
B	FLGR w/ ASOFA	0.919	8048	712	181
A	Advanced SOFA (ASOFA)	0.919	8048	712	181
	Baseline	0.939	8229	531	0

(1) – Alternative number has been previously assigned from least removal to highest removal percentage.
(2) – 12-month baseline availability is assumed at 93.9 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.
(3) – Annual operating time is annual average availability multiplied by 8760 hrs/yr of possible uptime.
(4) – Annual outage time is 8760 hrs/yr possible operating time minus estimated annual operating time.
(5) – Annual operating time reduction resulting from the implementation of the individual NOx control technique is the difference between the baseline and expected annual outage times.

TABLE C.3-2 – Expected Capacity Reductions for MRY Unit 2 NO_X Controls

Alt. Label(1)	NOx Control Technique	Estimated Annual Average Unit Electrical Power Generation Reduction from Operating Time Reduction		
		Unit Running Plant(2) Capacity Factor	Unit Generation Reduction(3) kW-hrs/yr	Unit Generation Reduction Cost(4), 1000$/yr
E	SNCR w/ ASOFA	0.951	110,176.095	3,856
D	Gas Reburn w/ ASOFA	0.943	81,416,590	2,850
C	Coal Reburn w/ ASOFA	0.948	130,375.506	4,563
B	FLGR w/ ASOFA	0.949	81,910,024	2,867
A	Advanced SOFA (ASOFA)	0.952	75,859.855	2,655
	Baseline	0.952	0	0

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.

(2) – 12-month baseline running plant capacity factor is assumed at 95.2 percent. These values reflect estimated amounts of negative reliability impact expected from the implementation of the individual NOx control technique.

(3) – Annual electricity generation reduction is annual operating time reduction multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the 12-month average gross output of 440 MW.

(4) – Annual electricity generation reduction cost is the annual electricity generation reduction (kW-hrs/yr) resulting from the implementation of the individual NOx control technique multiplied by the incremental value of electricity generation, assumed to be $35.00/MW-hr. All cost figures in 2006 dollars.

TABLE C.3-3 – Expected Auxiliary Electrical Power Demand Changes for MRY Unit 2 NO_X Controls

Alt. Label[1]	NOx Control Technique	Estimated Annual Average APC NOx Equipment Auxiliary Electrical Power Demand and Usage				
		Gross Demand [2] kW	**Credit[3] kW**	**Total Net Demand[4] kW**	**Power Usage[5] kW-hrs/yr**	**Power Usage Cost[6], 1000$/yr**
E	SNCR w/ ASOFA	133.2	0	133.2	1,008,704	35
D	Gas Reburn w/ ASOFA	1	(228)	(227)	(1,724,428)	(60)
C	Coal Reburn w/ ASOFA	8,342	(448)	7,894	59,217,554	2,073
B	FLGR w/ ASOFA	1	(125)	(124)	(949,051)	(33)
A	Advanced SOFA (ASOFA)	1	0	1	7,664	0.3

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.

(2) – The APC NOx equipment gross auxiliary electrical power demand of alternatives is the sum of individual technologies combined by simple addition. Actual power demands may differ from this due to positive or negative synergistic effects. Coal reburn includes 2,484 kW for feed preparation and conveying equipment demand plus 5,857 kW for the COHPAC system addition for PM control.

(3) – The APC NOx equipment auxiliary electrical power demand credit of coal reburn alternatives is the estimated result of lower cyclone coal preparation and feeder power demand due to lower boiler cyclone coal equipment loading. Actual power demands may differ from this due to accuracy of estimates for assumed amount of operating horsepower reduction.

(4) – The total net auxiliary electrical power demand is the sum of the gross demand and credit.

(5) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique.

(6) – The annual change in APC NOx equipment auxiliary electrical power demand electricity cost is the annual change in kW-hrs/yr for these alternatives resulting from the implementation of the individual NOx control technique multiplied by the incremental value of auxiliary electricity generation, assumed to be $35.00/MW-hr. All cost figures in 2006 dollars.

TABLE C.3-4 – Expected Auxiliary Electrical Power Demand and Generation Reduction Cost Changes for MRY Unit 2 NO_X Controls

Alt. Label(1)	NOx Control Technique	Estimated Annual Change in Unit Generation Due to APC NOx Equipment Auxiliary Power Electricity Demand and Generation Reduction			
		APC Electrical Power Usage(2) kW-hrs/yr	Unit Generation Reduction(3) kW-hrs/yr	Total Unit Electrical Power Generation Change(4) kW-hrs/yr	Total Unit Electrical Power Generation Change Cost(5) 1000$/yr
E	SNCR w/ ASOFA	1,008,704	110,176.095	111,184,799	3,891
D	Gas Reburn w/ ASOFA	(1,724,428)	81,416,590	79,692,162	2,789
C	Coal Reburn w/ ASOFA	59,217,554	130,375.506	189,593,059	6,636
B	FLGR w/ ASOFA	(949,051)	81,910,024	80,960,972	2,834
A	Advanced SOFA (ASOFA)	7,664	75,859.855	75,867,520	2,655

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.

(2) – The annual change in APC NOx equipment auxiliary electrical power demand electricity usage in kW-hrs/yr for these alternatives is the net power demand multiplied by the estimated annual operating time and running plant capacity factor which reflects the adjustment for any expected reliability and capacity impacts from the implementation of the control technique.

(3) – Annual electricity generation reduction is annual operating time reduction multiplied by the annual running plant capacity factor resulting from the implementation of the individual NOx control technique multiplied by the 12-month average gross output of 440 MW.

(4) – The total unit electrical power generation change is the sum of the annual change in APC NOx equipment auxiliary electrical power demand electricity usage plus the annual electricity generation reduction resulting from the implementation of the individual NOx control technique.

(5) – The total unit electrical power generation change cost is the total generation change (kw-hrs/yr) multiplied by the incremental value of electricity generation, assumed to be $35.00/MW-hr. All cost figures in 2006 dollars.

TABLE C.3-5 – Expected NOx Reagent Usage and Cost Estimates for MRY Unit 2 NO_X Controls

Alt. Label[1]	NOx Control Technique	NOx Reduction Reagent Urea Usage[2]			NOx Reduction Reagent Dilution Water Usage[3]	
		lbs/hr	tons/yr	1000$/yr	1000 gal/yr	1000$/yr
E	SNCR w/ ASOFA	2,713	9,826	3,727	9,851	10

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.
(2) – All cost figures in 2006 dollars.
(3) – Reagent dilution water usage assumes potable water is added to create a 10% urea concentration (4 parts water to 1 part urea solution at 50% concentration) prior to injection. Dilution water unit cost assumed to be $1.00 per thousand gallons.

TABLE C.3-6 – Expected Heat Input and Equivalent Coal Cost to Evaporate Aqueous Urea for MRY Unit 2 NO_X Controls

Alt. Label[1]	NOx Control Technique	Estimated Annual Average Unit Equivalent Coal Consumption Cost for Aqueous Urea Evaporation		
		Heat Required to Evaporate Aqueous Urea[2], mmBtu/yr	Equivalent Coal Consumption for Heat Input[2], Tons/yr	Coal Consumption Cost[2], 1000$/yr
E	SNCR w/ ASOFA	73,986	5,553	52

(1) – Alternative designation has been previously assigned from least removal to highest removal percentage.
(2) – Heat required to evaporate urea reagent dilution water assumes 900 Btu/lb required based on a 10% urea concentration (4 parts water to 1 part urea solution at 50% concentration) injected for the estimated amount of urea usage. Coal heat content of 6,662 Btu/lb, unit cost of $0.71/mmBtu.

EXECUTIVE SUMMARY

This document presents the Best Available Retrofit Technology (BART) analysis for each of three major pollutants: nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM) for Minnkota Power Cooperative, Inc.'s (Minnkota's) Unit 1 and Square Butte Electric Cooperative's (Square Butte's) Unit 2 at the Milton R. Young Station (MRYS) located near Center, North Dakota. On July 6, 2005, the United States Environmental Protection Agency (U.S. EPA or EPA) finalized the Regional Haze Regulations (RHR) and Guidelines for BART Determinations. The final regulations require eligible sources to be analyzed to determine a BART emission limit for nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM). The North Dakota Department of Health (NDDH) reviewed the operational history of North Dakota sources and determined which sources were BART-eligible and provided a state-specific modeling protocol for use in the analysis. Milton R. Young Station Unit 1 and Unit 2 were determined to be BART-eligible by the NDDH. As discussed in the introduction to the BART analysis, small emission units at MRYS produce emissions in levels anticipated to be too low to affect visibility in Class 1 areas and were excluded from further consideration in the study. This BART determination was conducted in accordance with the eligibility conclusion made by NDDH and follows the NDDH protocol.

Once a source is determined to be eligible, there are five predefined steps for conducting a BART analysis for each pollutant. Steps 1 through 3 include identifying control technologies, evaluating feasibility, and ranking feasible options by control effectiveness. Step 4 involves a technical evaluation of various impacts related to each feasible control technology. The evaluation reviews include economics, energy, and non-air environmental impacts. Visibility impairment impacts in the nearest Class 1 areas for the dominant controls are evaluated in Step 5. A summary ranking of control technologies for regulated pollutants that provide a cost effective system of emission reduction and visibility impact reduction is developed. The results of conducting this five step analysis is a recommendation for selection of BART, which is then translated into an emission rate constituting BART that must be achieved by the eligible source for each major regulated pollutant. Although the impacts requiring analysis are explicitly stated within the RHR and Guidelines, no methodology is provided for using the impacts to select a control technology. Thus, each State has discretion in weighing the various impacts identified in the BART analysis for emission sources within their jurisdiction based upon source characteristics, reviewed technologies, and background information used to perform the evaluation.

This analysis used several reference works, including the RACT/BACT/LAER Clearinghouse (RBLC), to identify which control technologies to evaluate. The technologies were then reviewed for feasibility and those deemed to be infeasible were eliminated from further study. The feasible control technologies were ranked by control efficiency and estimates of costs to implement, operate, and maintain such technologies were developed. Comparing average and incremental control costs allowed inferior controls to be removed from the list. Remaining technologies were evaluated based upon other impacts and predicted reductions in visibility impairment. The final BART recommendations were then made for each pollutant and are summarized in the tables below.

Prior to the completion of this analysis, Minnkota entered into a Consent Decree (CD) with the EPA and the NDDH. This CD requires Minnkota and Square Butte to perform a Best Available Control Technology (BACT) analysis for NO_X emissions controls, and establishes minimum removal rates for SO_2 and maximum PM emission rates for Unit 1 and Unit 2 at MRYS. For NO_X emissions control, certain control technologies were evaluated as required by the CD. The BART evaluation process for NO_X control technologies was modified to use the BACT analysis study. Submittal of the BACT analysis and additional support documents to the NDDH occurred on October 6, 2006, March 19, and April 23, 2007 respectively. For sulfur dioxide and particulate matter emissions, a BART analysis for each Unit at MRYS was performed.

Based upon an evaluation of the 90th percentile visibility impairment modeling results, the control technologies recommended as BACT for NO_X emissions and those recommended as BART for SO_2 and PM emissions had an acceptable impact reduction. Because there was an acceptable impact reduction in all cases, the BART recommendation consists of the control technologies at the modeled emission rates. The BART recommendations for each pollutant and each unit are summarized in the tables below. The recommended BART emission rates are presented as a 30-day rolling average to account for variations in boiler operation, fuel sulfur content and fly ash properties.

MRYS Unit 1 Recommended BART 30-Day Rolling Average

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.36*
SO_2	Wet Flue Gas Desulfurization (FGD) Process	0.15
PM	Maintain Existing Electrostatic Precipitator (ESP)	0.030

* Excludes startups. See referenced BACT analysis for a detailed discussion.

MRYS Unit 2 Recommended BART 30-Day Rolling Average

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.35*
SO_2	Upgrade of Existing Wet Flue Gas Desulfurization (FGD) Process	0.30
PM	Maintain Existing Electrostatic Precipitator (ESP)	0.030

* Excludes startups. See referenced BACT analysis for a detailed discussion.

1.0 INTRODUCTION

The United States Environmental Protection Agency (U.S. EPA or EPA) finalized the Regional Haze Regulations (RHR) and Guidelines for Best Available Retrofit Technology (BART) Determinations[1] in the Federal Register on July 6, 2005 (70 FR 39104). BART is defined as "an emission limitation based on the degree of reduction achievable through the application of the best system of continuous emission reduction for each pollutant which is emitted by a BART-eligible source. The emission limitation must be established on a case-by-case basis, taking into consideration the technology available, the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology" (70 FR 39163). This document presents the BART analysis for each of three major pollutants: nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM) for Minnkota Power Cooperative, Inc.'s (Minnkota's) Unit 1 and Square Butte Electric Cooperative's (Square Butte's) Unit 2 at the Milton R. Young Station (MRYS) located near Center, North Dakota.

1.1 BART ELIGIBILITY

A BART eligible source is one that meets three criteria identified by EPA in the RHR and Guidelines for the determination of BART. A source is BART eligible if operations fall within one of 26 specifically listed source categories (70 FR 39158), the source entered into service between August 7, 1962 and August 7, 1977, and the source has the potential to emit 250 tons per year or more of a visibility-impairing air pollutant (SO_2, NO_X or PM). The North Dakota Department of Health (NDDH) reviewed the operational history of sources within North Dakota and independently determined which of those sources are BART-eligible. The NDDH classified the electric generating units (EGUs) at Milton R. Young Station as BART-eligible. For the purposes of this report, the NDDH's determination will be used and Units 1 and 2 at MRYS are assumed to be subject to a BART analysis.

---

[1] "Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations"; Environmental Protection Agency; Federal Register, Volume 70, No. 128; July 6, 2005.

1.2 BART ANALYSIS PROCESS

Where a particular source is determined to be eligible, the general steps for determining BART for each pollutant are as follows (70 FR 39164):

STEP 1 - Identify all available retrofit control technologies (within the BART Guidelines).
STEP 2 - Eliminate technically infeasible options.
STEP 3 - Evaluate control effectiveness of remaining control technologies.
STEP 4 - Evaluate the following impacts for each feasible control technology and document results:
(70 FR 39166).

- The cost of compliance.
- The energy impacts.
- The non-air quality environmental impacts.
- The remaining useful life of the source.

STEP 5 – Evaluate the visibility impacts.

Minnkota Power Cooperative, Inc. retained Burns & McDonnell to assist in the completion of the Best Available Retrofit Technology analysis for Milton R. Young Station. Burns & McDonnell is a full service engineering, architectural, construction and environmental firm. The company plans, designs and constructs electric generating facilities and has been providing environmental services to the power industry since the 1970s. As a result of their long history providing these services, Burns & McDonnell has extensive experience in permitting, Best Available Control Technology (BACT) studies and control technology analysis similar to a BART analysis.

1.2.1 IDENTIFICATION OF RETROFIT CONTROL TECHNOLOGIES

The initial step in the BART determination is the identification of retrofit control technologies. In order to identify the applicable control technologies, several reference works are consulted. A preliminary list of control technologies and their estimated capabilities is developed.

1.2.2 FEASIBILITY ANALYSIS

The second step of the BART process is to evaluate the control processes that have been identified and determine if any of the processes are technically infeasible. The BART guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology.

A control technology is considered available, “if the source owner may obtain it through commercial channels, or it is otherwise available in the common sense meaning of the term” or “if it has reached the stage of licensing and commercial availability.” On the contrary, a control technology is not considered available, “in the pilot scale testing stages of development.” (70 FR 39165) When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” The EPA also does not “expect a source owner to conduct extended trials to learn how to apply a technology on a totally new and dissimilar source type.” (70 FR 39165) “A technology that is available and applicable is technically feasible.” (70 FR 39165)

1.2.3 EVALUATE TECHNICALLY FEASIBLE CONTROL OPTIONS BY EFFECTIVENESS

The third step in the BART analysis is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the BART analysis, the control efficiency is reviewed and presented with the description of each technology. The evaluation of the technically feasible BART alternatives concludes with the alternatives ranked in descending order of control effectiveness.

1.2.4 IMPACT ANALYSIS

Step four in the BART analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) lists four factors to be considered in the impact analysis. The BART Determination will consider the following four factors in the impact analysis:

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

The first three of the four factors considered in the impact analysis are discussed in the associated pollutant section. The remaining useful life of the source is included as part of the cost of compliance.

1.2.5 METHODOLOGY FOR ESTIMATED COSTS

The cost summary of each alternative is presented in the section for each pollutant. Installed capital and annual O&M cost estimates for each alternative are presented individually. The Levelized Total Annual Cost (LTAC) represents the levelized annual cost of procurement, construction and operation over a 20 year design life, in current (2006) dollars. The LTAC represents an annual payment in current day dollars sufficient to finance the project over its entire life.

In determining the LTAC, a Capital Recovery Factor and an O&M Levelization Factor were calculated from the project economic conditions and then applied separately to the estimated capital and O&M costs. The equation used is shown below.

$$LACC / NPV = \left(\frac{i_d (1+i_d)^n}{(1+i_d)^n - 1} \right) = CRF$$

Where,
LACC = Levelized Annual Capital Cost
NPV = Net Present Value of the capital investments required.
i_d = discount rate
n = design life in years
CRF = Capital Recovery Factor

Therefore:

LACC = CRF x NPV

For the economic conditions described in Table 1.2-1, the Capital Recovery Factor was calculated to be 0.08718.

In determining the levelized annual O&M cost the estimated annual O&M cost, the escalation rate, the discount rate, and the equipment life are taken into account. The O&M Levelization Factor (OMLF) was calculated as follows.

$$LAOMC / A_1 = \frac{\left(\frac{(1+i)^n - 1}{i} \right)}{(1+i)^n} \left(\frac{i_d (1+i_d)^n}{(1+i_d)^n - 1} \right) = OMLF$$

The inflation rate (i) used in the above calculation is determined as follows.

$$i = \left(\frac{1 + i_d}{1 + i_i} - 1 \right)$$

Where,
LAOMC = Levelized Annual O&M Cost
A_1 = Estimated annual O&M cost in current dollars
i_d = discount rate
i_i = escalation rate
i = inflation rate
n = design life in years
OMLF = O&M Levelization Factor

Therefore:

$$\text{LAOMC} = \text{OMLF} \times A_1$$

For the economic conditions described in Table 1.2-1, the Operating and Maintenance Levelization Factor was calculated to be 1.24873.

The Levelized Total Annual Cost, or LTAC is the sum of the levelized capital cost and the levelized O&M cost. Therefore:

$$\text{LTAC} = \text{LACC} + \text{LAOMC} = (\text{CRF} \times \text{NPV}) + (\text{OMLF} \times A_1) = 0.08718 \times \text{NPV} + 1.24873 \times A_1$$

The economic analyses presented in this report not only include the estimated capital and annual O&M costs for each alternative, but also the LTAC for economic comparison of the various alternatives.

Table 1.2-1 – Economic Factors[1]

Total Possible Operating Hours per Year	8,760
Plant Capacity Factor	85%
Amortization Life, Years	20
Cost of Money	6%
Property Taxes, Insurance, %	NA
Amortization Rate for APC Capital Costs	6%
Interest During Construction (IDC)	6%
Discount Rate	6%
Construction Cost Escalation	3%
Non-Fuel O&M Escalation	2.5%
Fuel (coal and natural gas) Escalation	2.5%
Operating Labor Rate, $/hr	$40.00
Auxiliary Electric Power Cost, $/MW-hr	$35.00

1. All costs are in 2006 dollars unless noted otherwise.

1.3 BART ANALYSIS APPROACH

The purpose of the Regional Haze Rule (RHR) is to address visibility impairment in mandatory Class 1 areas that results from the emission of SO_2, NO_X, PM, Volatile Organic Compounds (VOCs) and ammonia from certain major sources. The only control method for VOCs identified in the RACT/BACT/LAER Clearinghouse (RBLC) database is good combustion practices. This control technique is already in place at MRYS. If an analysis were performed for VOCs, good combustion practices would be the most probable method chosen for BART. The visibility impact of VOCs and ammonia are considered negligible for a BART analysis, according to the NDDH's November 2005 modeling protocol[2], and are not addressed further in this report. Before the actual BART analysis can begin for SO_2, NO_X, and PM, the approach used to conduct the analysis should be addressed. The following sections present specific subjects related to MRYS's background, which warrant mention due to their effects on the contents of the report.

1.3.1 BACKGROUND

Minnkota Power Cooperative, Inc. operates the Milton R. Young Station near Center, North Dakota. MRYS is a steam electric generating plant with two units. Unit No. 1 is a Babcock & Wilcox (B&W) cyclone-type coal-fired boiler burning lignite coal, serving a turbine generator with a nameplate rating of 257 MW.[3] Particulate control is provided by a Research-Cottrell Electrostatic Precipitator rated at approximately 99% control. Unit 1 has no sulfur dioxide (SO_2) control system and exhausts to a 300 foot tall stack. Unit No. 2 is a B&W cyclone-fired unit burning lignite coal, with a turbine-generator name plate rating of 477 MW.[4] Particulate control for Unit 2 is provided by a Wheelabrator-Lurgi precipitator rated at approximately 99% control. Unit 2 has a Combustion Equipment Associates wet flue gas desulfurization (FGD) system (modified by Combustion Engineering) that treats approximately 78 percent of the flue gas with the remaining flue gas by-passed for stack gas reheat. The FGD system achieves approximately 75 percent SO_2 removal and exhausts to a 550 foot tall stack. Unit 1 began commercial operation on November 20, 1970 and Unit 2 on May 11, 1977.

[4] Ibid footnote 3 reference.

On June 17, 2002, Minnkota Power Cooperative, Inc. received a Notice of Violation (NOV) from the EPA. The NOV states that Minnkota allegedly violated the Prevention of Significant Deterioration (PSD) regulations. The NOV was issued pursuant to Section 113 of the Clean Air Act. The alleged violation was caused by modifications to both Unit 1 and 2 at MRYS which allegedly resulted in a potential increase of SO_2, NO_X and PM. Without an admission of liability, Minnkota entered into a settlement in the form of a Consent Decree (CD) with the EPA and NDDH to resolve the issues. The CD requires that Minnkota perform a BACT analysis for NO_X emissions and to install controls in a two-part, phased approach. SO_2 and PM emissions for Unit 1 and Unit 2 at MRYS are required to achieve at or below the specified levels of unit emission rates (lb per million Btu), and also minimum levels of removal for sulfur dioxide emissions. The effect of the CD on the BART analysis and the requirements to install emission controls NO_X, SO_2, and PM are discussed later in the report.

1.3.2 CONTROL TECHNOLOGY EVALUATION AND BACT VS. BART

As stated above, once a source is determined to be eligible, there are general steps for conducting a BART analysis for each pollutant. All retrofit control technologies are first identified. A brief review of the processes and their capabilities is then performed to determine availability and feasibility. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to control capability and an analysis then reviews the probable impacts of each technology. The visibility impact is included in the impact analysis. Finally, the results of the analyses are tabulated and possible BART control options are listed.

As stated in the proposed BART guidelines dated 5 May 2004 (69 FR 25218), a BART analysis is similar to a Best Available Control Technology (BACT) analysis.

> “The process for a BART analysis is very similar to the BACT review as described in the New Source Review Workshop Manual (Draft, October 1990). Consistent with the Workshop Manual, the BART engineering analysis requires that all available control technologies be ranked in descending order of control effectiveness (i.e. percent control). You [meaning States] must examine the most stringent alternative first. That alternative is selected as the ‘‘best’’ unless you demonstrate and document that the alternative cannot be justified based upon the consideration of the five statutory factors discussed below. If you eliminate the most stringent technology in this fashion, you then consider the next most stringent alternative, and so on.

> Although very similar in process, BART reviews differ in several respects from the BACT review described in the NSR Draft Manual."

The proposed guidelines stated that a BART analysis is similar to a BACT review and provided a few examples of similarities and differences, but it did not explicitly state how the two analyses could be used in conjunction to obtain a determination. Because BACT and BART are similar, there are many aspects that can be combined to reduce the steps of an analysis. However, because there are some differences, a BART analysis must address some additional aspects that a BACT review does not.

A BART analysis is always conducted for existing sources and a BACT review is usually conducted for a new source. Because BACT is usually performed for a source that is a new design or reconstruction, the review must take into account all available technologies and must include the most effective controls that have been demonstrated on similar units. BACT is considered to be more stringent than BART because it usually is not limited by the design of existing equipment or current operating conditions as is required for a retrofit application. Although MRYS is eligible to perform an analysis to determine BART, the Consent Decree (CD) also requires that MRYS install levels of control equivalent to BACT. Thus, the BART analysis can be shortened to only include the BACT-level control technologies specified in the CD or technologies that are more stringent.

Although Unit 1 and Unit 2 at MRYS are BART-eligible, the Consent Decree (CD) also requires that the NDDH establish BACT for NO_X control. With the specification to establish BACT for NO_X, the BART analysis was modified to replace the first four BART evaluation steps with the NO_X BACT analysis. The first four steps of BART are usually used to identify technologies, determine feasibility and evaluate cost, energy, non-air quality and useful life impacts. Because a BACT analysis results in the selection of the best available control technology, the visibility impacts evaluation is the only remaining step in the determination that must be performed to satisfy BART for NO_X. The MRYS NO_X BACT analysis study reports and additional support documents were submitted to the NDDH on October 6, 2006, March 19, and April 23, 2007 respectively. In addition, because the CD also requires a minimum level of control for both SO_2 and PM, this analysis evaluates the visibility impairment impacts of the BACT-level control technologies specified for SO_2 and PM. The BART analysis does not review technologies that do not achieve the minimum level of control specified in the CD. The final BART recommendation is based upon an acceptable degree of visibility improvement in Class 1 areas.

1.3.3 EMISSION SOURCE APPLICABILITY

There are two subjects within the Guidelines related to the applicability of BART to emission sources. The first subject deals with the presumptive BART emission limits and their application to power plants smaller than 750 MW in size. The Guidelines for BART Determination include the following statement with regard to presumptive BART for SO_2 (70 FR 39171):

> "You [meaning States] must require 750 MW power plants to meet specific control levels for SO_2 of either 95 percent control or 0.15 lbs/mmBtu, for each EGU greater than 200 MW that is currently uncontrolled unless you determine that an alternative control level is justified based on a careful consideration of the statutory factors. For a currently uncontrolled EGU greater than 200 MW in size, but located at a power plant smaller than 750 MW in size, such controls are generally cost effective and could be used in your BART determination….."

Similarly for NO_X, the EPA states (70 FR 39171):

> "For coal-fired EGUs greater than 200 MW located at greater than 750 MW power plants and operating without post-combustion controls, we have provided presumptive NO_X limits differentiated by boiler design and type of coal burned. You may determine that an alternative control level is appropriate based on a careful consideration of the statutory factors. For coal-fired EGUs greater than 200 MW located at power plants 750 MW or less in size and operating without post-combustion controls, you should likewise presume that these same levels are cost-effective."

For power plants greater than 750 MW in size, the EPA requires state agencies to apply the presumptive limits for BART as a floor for NO_X control. However, for power plants smaller than 750 MW in size, the presumptive BART limits are described as being "cost-effective" but not set as a minimum performance requirement. Thus, BART for EGUs at power plants smaller than 750 MW in size, like MRYS, is not required to meet the presumptive limits. This BART analysis for MRYS will evaluate potential control options that achieve the control levels and are below the emission limits set forth in the Consent Decree. Because the States have final discretion in how they choose to weigh the various impacts as part of their BART determinations for each EGU emission source, the recommended BART control options may not achieve the EPA's presumptive BART limits based upon the visibility analysis.

The second part of the Guidelines that should be addressed relates to which emission units are subject to BART for a particular pollutant. The Guidelines state that:

> "Once you determine that a source is subject to BART for a particular pollutant, you must establish BART for that pollutant. The BART determination must address air pollution control measures for each emissions unit or pollutant emitting activity subject to review." (70 FR 39163)

According to this statement, the BART determination must consider any emission unit that emits the pollutant of concern (i.e., NO_x, SO_2 and PM) regardless of size. The BART analysis for MRYS will review control options for the main boilers for Unit 1 and Unit 2. Smaller emissions sources at the facility are anticipated to provide negligible contribution to visibility impacts from MRYS in Class 1 areas. Smaller sources at MRYS are discussed in Section 1.3.4 and 1.3.5.

1.3.4 SMALL SOURCE EMISSION UNITS

The BART determination must consider any emission unit that emits the pollutant of concern (i.e., NO_x, SO_2 and PM) regardless of size. However, smaller emissions sources (e.g., auxiliary boilers and emergency generators) at the facility are anticipated to provide negligible contributions to visibility impairment in Class 1 areas. The nearest Class 1 area is Theodore Roosevelt National Park (TRNP) located approximately 160 km to the west. Although technically eligible, smaller source emissions units were not reviewed because they have limited hours of operation or they are material handling sources with a level of emissions anticipated to be too low to affect visibility impact on TRNP. Consequently, small emission sources are excluded from further consideration in the study.

1.3.5 FUGITIVE DUST

The primary source of fugitive dust is from the outside coal storage area and other plant activities normally found at a coal-fired electrical generating facility. The coal stockpile, access roads and plant activities are performed and maintained with good operating practices. On the coal stockpile and on other applicable fugitive sources, dust suppression is achieved through the use of water sprays or surfactants. The level of fugitive PM emissions is not expected to affect the visibility in Class 1 areas based upon the approximate 160 km distance to the nearest Class 1 area, the large particle size and relatively small emission rates. As such, fugitive sources were not evaluated in this BART analysis for MRYS.

1.3.6 CONDENSABLE PARTICULATE

Particulate matter emissions are composed of filterable and condensable particles. Condensable particulate matter (condensable PM) may react with atmospheric or flue gas constituents as flue gas moves through the different processes and then either condenses into a droplet, coalesces into a solid particle, or forms a solid particle as more volatile components evaporate. Condensable PM may include both organic and inorganic constituents. Organic constituents in the flue gas can exist as a vapor at stack temperatures and a liquid or solid at ambient temperatures. Control technologies designed to minimize the formation of condensable organic emissions are the same technologies that are used to minimize carbon monoxide (CO) and volatile organic compound (VOC) emissions. A review of the RBLC database shows that good combustion practices are universally used to control CO/VOC emissions for similar units. Both MRYS units already practice good combustion practices while maintaining combustion efficiency in the boiler and controlling NO_X emissions. Because good combustion practices would likely be considered BART and are already in use at both units, the organic portion of condensable PM is not addressed further in this report.

Sulfuric acid (H_2SO_4) mist is the most widely recognized form of inorganic condensable PM emitted by combustion sources. Other inorganic condensable PM constituents may include to a lesser extent other acid gases, ammonium sulfate ($(NH_4)_2SO_4$), and unidentified inorganic species. Control technologies designed to reduce sulfuric acid mist will also reduce the other inorganic constituents. H_2SO_4 is typically generated in the flue gas when sulfur trioxide (SO_3) reacts with water. SO_3 is a by-product created during the combustion of fuels containing sulfur and is formed when sulfur dioxide (SO_2) in the flue gas is oxidized. Limited data is available on the quantity of SO_2 that will be converted to SO_3 in a lignite fired unit. Estimates of the conversion range from 0.2 to 1.0 percent.

Combustion controls commonly used to control NO_X (e.g., staged combustion and separated overfire air) provide a co-benefit of sulfuric acid mist control by limiting the oxygen available in the boiler and reducing formation of SO_3 in the boiler. The H_2SO_4 vapor will adsorb on the fly ash as the flue gas cools under appropriate temperature and moisture conditions. Consequently, when those conditions exist, H_2SO_4 is removed from the gas stream by particulate control equipment. Control technologies designed to remove SO_2 will also achieve SO_3 removal and reduce emissions of H_2SO_4. Typical SO_3 removal associated with a wet FGD process is 40 to 60 percent, and higher removal is typical for semi-dry FGD processes. The Southern Company estimates a minimum 50% reduction in H_2SO_4 emissions for use of a FGD process.[5] Thus, control technologies used to control NO_X, SO_2 and filterable PM are also able to provide H_2SO_4 control.

Recommended BART for condensable PM is the co-benefit of NO_X, SO_2 and filterable PM control devices to be analyzed in this report and is not addressed further. Therefore this BART analysis for particulate emissions investigates control methods to reduce filterable PM only.

1.4 METHODOLOGY FOR VISIBILITY IMPACTS DETERMINATION

In the BART Determination Guidelines, as discussed in Section 1.2 of this report, the EPA provides five basic steps for a case-by-case BART analysis. The fifth step involves evaluating visibility impacts utilizing dispersion modeling. Visibility impairment impacts for modeled pre-control and post-control emission levels and visibility improvements are to be assessed in deciViews (dV). The BART guidelines describe the thresholds for visibility impairment as:

> “A single source that is responsible for a 1.0 dV change or more should be considered to “cause” visibility impairment; a source that causes less than a 1.0 dV change may still contribute to visibility impairment..... any threshold that you (the States) use for determining whether a source “contributes” to visibility impairment should not be higher than 0.5 dV.” (70 FR 39161)

The NDDH BART protocol does not distinguish between a source that “causes” or “contributes” to visibility impairment but follows the EPA’s Regional Haze Rule threshold recommendations. Thus, 0.5 dV is the deminimis threshold level of visibility impairment impact for an otherwise BART-eligible source under the NDDH BART protocol. In other words, a BART-eligible source for which modeling predicts a visibility impairment impact of greater than 0.5 dV is deemed to have a visibility impairment impact and thus is subject to a BART analysis under the NDDH BART protocol. A BART-eligible source for which the modeling predicts less than a 0.5 dV impact would be deemed to not have a visibility impairment impact, and thus could be exempted from BART on that basis. Most

---

[5] “An Updated Method for Estimating Total Sulfuric Acid Emissions from Stationary Power Plants”; Monroe, Larry S. & Harrison, Keith E.; Southern Company Generation and Energy Marketing; Revised March, 2003.

noticeably, the EPA refrains from addressing the question of whether or not a difference in visibility impairment impact improvement of less than 0.5 dV between two BART alternatives would constitute equivalency under the visibility analysis, or if any difference in the model results, no matter how slight, should be interpreted as ranking one solution over the other. The approach taken in the BART analysis for MRYS incorporates the visibility impact analysis results as a verification of visibility improvement.

1.5 THE ROLE OF MODELING AND CALPUFF IN A BART ANALYSIS

The BART guidelines list visibility impact at a Class I area as one of the factors in a BART determination. The EPA interpreted the statutory provision of Section 169A of the Clean Air Act to require that a BART-eligible source is one that is "reasonably anticipated to cause or contribute" to regional haze if it can be shown that the source emits pollutants within a geographic area from which pollutants can be emitted and transported downwind to a Class I area (70 FR 39161). A Class I area, as listed by the EPA, is an area of the country with pristine air quality that is sensitive to changes in visibility. Two Class 1 areas have been identified for inclusion in the visibility analysis for MRYS. These are the Theodore Roosevelt National Park (TRNP), and the Lostwood National Wildlife Refuge (Lostwood NWR), which are approximately 160 and 180 km (100 and 112 miles), from Milton R. Young Station, respectively. For Class I areas more than 50 km from a source, the EPA has identified CALPUFF as a guideline model for long-range transport that is suitable for predicting potential changes in visibility. CALPUFF is a non-steady-state meteorological and air quality dispersion modeling system used to access long-range transport of pollutants.

The NDDH modeling protocol confirmed that the two Class I areas to be considered for visibility impairment analysis are the TRNP and Lostwood NWR. However, the three units or areas of the TRNP are to be treated as separate Class I areas for the analysis.

1.5.1 CALPUFF MODELING METHODOLOGY

Visibility impairment is caused by a combination of particles and gases in the atmosphere. Some particles and gases scatter light, others absorb light. The combined effect of scattering and absorption is called "light extinction" which is most commonly seen as haze. This haziness is measured in deciView (dV) units, and is related to light extinction coefficient by the following equation:

$$dV = 10 \ln(b_{ext}/10)$$

Where b_{ext} is light extinction coefficient in inverse megameters.

Visibility impairment is a function of light extinction. Light extinction occurs when light energy is either scattered or absorbed by particles in the air. The amount of moisture in the air also plays a role in light extinction. Certain gases combine with moisture in the air to form small light scattering particles. These gases, most notably SO_2 and NO_X, are significant components of coal-fired power plant emissions. Particulate Matter (PM) also contributes to light extinction. In the BART Determination Guidelines, the EPA states that “You [the State] may use PM_{10} as an indicator for particulate matter. We do not recommend the use of Total Suspended Particulates (TSP). As emissions of PM_{10} include the components of $PM_{2.5}$ as a subset, there is no need to have separate 250 ton thresholds for PM_{10} and $PM_{2.5}$; 250 tons of PM_{10} represents at most 250 tons of $PM_{2.5,}$ and at most 250 tons of any individual particulate species such as elemental carbon, crustal material, etc.” (70 FR 39160). The NDDH modeling protocol states that particulate matter emissions should be specified as either coarse (PM_{10} minus $PM_{2.5}$) or fine ($PM_{2.5}$). The distinction between coarse and fine particulate occurs in the modeling.

The NDDH modeling protocol recommends a specific version of the CALPUFF modeling system as modified by the NDDH to specifically address terrain, climate, and emission characteristics of MRYS. (CALMET and CALPUFF were recompiled by the NDDH while the CALPOST executable used for this visibility analysis was the EPA guideline executable). Along with the CALPUFF modeling system, the NDDH also provided the RUC2-MM5 gridded wind field data (2000-2002), surface, upper air, and precipitation files, and CALMET and CALPUFF input files. The input files contained the specific coordinate grid points, wind field options, terrain, dispersion options, receptor coordinates and plume characteristics and other model parameters that the NDDH has determined best represents the region. The NDDH version of CALPUFF was used for modeling.

In order to predict the change in light extinction at TRNP and Lostwood NWR areas, SO_2, NO_X, and PM were modeled with CALPUFF using pre-control and post-control emission scenarios. A variety of post-control scenarios were used to determine the reduction in visibility impact for each control technology. The NDDH identified 104 receptors allocated over both TRNP and Lostwood NWR. These receptors are location points for which CALPUFF was used to perform a visibility calculation.

The BART guideline states that a visibility improvement is based upon the modeled change in visibility impacts, measured in deciViews, for the pre-control and post-control emission scenarios.

The comparison should be made for the 98th percent days (70 FR 39170). The NDDH modeling protocol provides additional clarification about BART applicability by stating, "…the context of the 98th percentile 24-hour delta-deciView prediction is with respect to days of the year, and is not receptor specific. A 24-hour prediction greater than 0.5 delta-deciView at any receptor in a Class I area would constitute a day of exceedance, and up to 7 days of exceedance would be allowed per year per Class I area (i.e., the 98th percentile is approximated by the eighth-highest daily prediction)." In other words, visibility impacts should be compared on an annual basis using the eighth highest day for comparison (365 * (1-.98) = 7 days of acceptable exceedance). However, NDDH subsequently advised that the delta-deciView comparison should be made at the 90th percentile to be consistent with the Western Regional Air Partnership (WRAP) protocol. Therefore, the analysis of visibility impairment impact reduction presented for each control scenario in this section is based on the 90th percentile value. The predictions of 24-hour 98th percentile deciView data are also provided in Appendix A.

1.5.2 MODELING SCENARIOS

Since a BART analysis is based on the degree of reduction achieved by the application of control technologies, the CALPUFF analysis examined multiple operating scenarios based upon the feasible control technologies identified for each pollutant. These scenarios represent the emissions of SO_2, NO_X, and PM under the following conditions:

- NDDH BART Modeling Protocol emission rates
- Post-Control NO_X emissions based upon recommended NO_X BACT-level emission rates from the Consent Decree
- Post-Control SO_2 and PM emissions based upon minimum emission rates as required by the Consent Decree and more stringent emission rates representative of potential BART alternatives

The emission rates modeled in each scenario are presented in Table 1.5-1.

Table 1.5-1 – Milton R. Young Station Modeling Scenarios

Scenario	Unit 1			Unit 2		
	NO_X (lb/hr)	SO_2 (lb/hr)	PM Coarse/Fine (lb/hr)	NO_X (lb/hr)	SO_2 (lb/hr)	PM Coarse/Fine (lb/hr)
Screening	Protocol	Protocol	Protocol	Protocol	Protocol	Protocol
1	1,070.7	Protocol	Protocol	2,011.6	Protocol	Protocol
2A	Protocol	723.1	Protocol	Protocol	1,574.4	Protocol
2B	Protocol	361.6	Protocol	Protocol	773.7	Protocol
3A	Protocol	Protocol	38.5 / 5.8	Protocol	Protocol	133.7 / 21.0
3B	Protocol	Protocol	77.1 / 11.6			
4	1,070.7	361.6	77.1 / 11.6	2,011.6	1,574.0	133.7 / 21.0
5	1,070.7	361.6	77.1 / 11.6	2,011.6	1,574.0	133.7 / 21.0

These scenarios represent the emission rates evaluated for consideration in making a BART recommendation. The emission rates presented in Table 1.5-1 correspond to control options and efficiencies considering the results of the NO_X BACT analyses and BART analyses for SO_2 and PM. The screening scenario from the NDDH BART modeling protocol is based on the historical maximum 24-hour emission rates for MRYS between 2000 and 2002. These rates were supplied to the NDDH by Minnkota, but were based upon operations that were not representative of stack conditions associated with new or modified retrofit control technologies.

Due to analyses performed on plant operations and historical emissions data, Minnkota has determined that unit operating conditions associated with these protocol rates are not representative of future maximum 24-hour emissions and has requested NDDH to allow the use of an alternative stack parameters and hourly baseline conditions for modeled post-control emission rates. NDDH agreed to the use of alternative post-control conditions. The alternative post-control scenarios are based upon various control technology emission reductions being applied to maximum 24-hour average heat input of 2,955 mmBtu/hr for Unit 1 and 5,158 mmBtu/hr for Unit 2. The emission rates associated with each scenario are discussed in the section related to the controlled pollutant.

As shown in Table 1.5-1, multiple modeling scenarios were conducted to determine the specific visibility impact reduction associated with the control of each pollutant. To determine a specific visibility impact for a particular pollutant, the emission rate for the pollutant of concern was changed from the protocol rate to the post-control rate. The other two major pollutants' emission rates were modeled at the protocol rates. Thus, any visibility impairment impact reduction for that modeling scenario was due solely to the application of the individual pollutant’s control technology.

Additional modeling runs were conducted to determine the overall visibility impairment impact reduction caused by simultaneous application of all control technologies. In Table 1.5-1, modeling scenario 4 was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies for each unit individually. Modeling scenario 5 was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies for both units combined. The modeling results are summarized and discussed in the sections below.

2.0 NO_X BART EVALUATION

The BART analyses for NO_X emissions from MRYS Unit 1 and Unit 2 are described in this section. Technical descriptions of MRYS Unit 1 and Unit 2 boilers and existing air pollution control equipment are provided. As discussed in the introduction, Minnkota has entered into a Consent Decree (CD) that requires MRYS to install BACT-level NO_X control technologies on both units. For NO_X emissions control, the CD required that a complete BACT analysis be performed for MRYS to determine the applicable control technologies for each unit. The BACT analysis reports and additional support documents were submitted to the NDDH on October 6, 2006, March 19, and April 23, 2007 respectively.

It was assumed that a NO_X emissions control alternative considered as BACT would also satisfy similar ranking and non-visibility impacts of a BART determination process. Therefore, the alternative with the highest-performing, most cost-effective combination of control technologies identified by the NO_X BACT analysis for each Unit at MRYS that was not eliminated for technical infeasibility or adverse non-visibility impacts would be evaluated for impacts on the nearest Class 1 area in the subsequent BART visibility impairment analysis.

2.1 NO_X EVALUATION BASIS – UNIT 1

Milton R. Young Station Unit 1 includes a Babcock and Wilcox steam generator installed in 1970. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation. Original unit design steam generating capacity is 1.714 million lbs/hr at 1,920 psi with a fuel heat input of 2,510 mmBtu/hr. The boiler is fired by seven ten-foot diameter cyclone burners, arranged “three over four” across the front wall of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the electrostatic precipitator (ESP). Unit 1’s boiler serves a turbine generator with a nameplate rating of 257 MW[6] and has a nominal 235 MW net design output capacity rating. Unit 1 is typically capable of sustained output of approximately 253 MW gross, and has an ultimate short-term maximum gross output (URGE) rating of 278 MW. The Unit 1 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a

mine located adjacent to the site. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boiler.

2.1.1 NO_X VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 1

The remaining step for the BART NO_X analysis was to conduct a visibility improvement determination for Unit 1. Due to the association of the Consent Decree and requisite BACT analysis, the visibility analysis was the only subsequent impact evaluation necessary to establish BART. In addition, because the BACT analysis resulted in one control alternative for NO_X emissions control, only one related emission rate was modeled to determine the post-control visibility impairment impacts.

The modeling for Unit 1 uses two NO_X emission rates as a basis for the visibility impairment impacts. The NDDH BART protocol[7] NO_X emission rate of 2,855.2 lb /hr was modeled to determine a pre-control baseline visibility impact. This protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. This is equivalent to a unit NO_X emission rate of 0.898 lb/mmBtu at a boiler heat input rate of 3,180 mmBtu/hr. The baseline visibility impact was then compared with the results predicted from a modeled post-control NO_X emission rate based upon the control technology specified for Unit 1 in the BACT analysis.

According to the BACT analysis required by the Consent Decree, Selective Non-Catalytic Reduction (SNCR) post-combustion technology used in conjunction with an advanced combustion control application of Separated Overfire Air (ASOFA) was considered the best available technology and therefore was evaluated as BART for Unit 1. The second NO_X emission rate of 1,070.7 lb /hr was based upon application of SNCR with ASOFA control technologies for a reduction of approximately 62.5 percent from the protocol mass emission rate. This is equivalent to a unit NO_X emission rate of 0.362 lb/mmBtu at a more representative maximum 24-hour average boiler fuel heat input of 2,955 mmBtu/hr. The visibility modeling conditions are presented in Table 2.1-1.

Table 2.1-1 – Milton R. Young Station Unit 1 Visibility Model Conditions

	NDDH Protocol	SNCR with ASOFA[(1)]
NO_X Emission Rate lb/hr	2,855.2	1,070.7
lb/mmBtu	0.898	0.362
Heat Input, mmBtu/hr	3,180.0	2954.5

(1) – Post-control NO_X emission rate reflects recommended BACT w/ adjusted reduction.

The results of the visibility modeling at the protocol baseline NO_X emission rate for MRYS Unit 1 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control NO_X emission rate showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for all Class 1 areas at the post-control BACT-level NO_X emission rate was below the 0.50 dV threshold level. The modeling results are presented in Table 2.1-2.

Table 2.1-2 – NO_X Visibility Impairment Impacts and Reductions at NOx BACT Post-Control Emissions, MRYS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	Post-Control Emissions[2]	
TRNP-South Unit	0.549	0.377	0.172
TRNP-North Unit	0.628	0.413	0.215
TRNP-Elkhorn Ranch	0.374	0.266	0.108
Lostwood NWR	0.750	0.487	0.263

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

2 - NO_X emissions reduction by 62.5% over NDDH protocol baseline case. This scenario assumes protocol emission rates for SO_2 and PM. Refer to Appendix A for complete protocol and revised post-control visibility model results.

The number of days predicted to have visibility impairment due to MRYS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results are summarized and presented in Table 2.1-3. Similarly, the same information for the post-control NO_X emission rates is summarized and shown in Table 2.1-3. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control NO_X emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 1. The impact in terms of days exceeding 0.50 dV varies from an approximately 17% reduction for TRNP – Elkhorn in 2001 to an approximately 40% reduction for TRNP – South in 2000. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 15% for TRNP – Elkhorn in 2002 to approximately 53% for TRNP – South in 2000.

A series of bar charts showing the difference in the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the SNCR with ASOFA-controlled post-control emission rates with pre- and post-control SO_2 and PM alternatives is included in Figures 2.1-1 through 2.1-9.

2.2 NO_X EVALUATION BASIS – UNIT 2

Milton R. Young Unit 2 is a Babcock and Wilcox steam generator installed in 1977. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation assisted with circulation pumps. Original unit design steam generating capacity is 3.20 million lbs/hr at 2,620 psi with a fuel heat input of 4,696 mmBtu/hr. The boiler is fired by twelve ten-foot diameter cyclone burners, arranged “three over three” across the front and rear walls of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Unit 2’s boiler serves a turbine-generator with a name plate rating of 477 MW[8], and has a nominal 439 MW net design output capacity rating. Unit 2 is capable of sustained output of approximately 462 MW gross, and has an ultimate short-term maximum gross output (URGE) of 512 MW. The Unit 2 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a mine located adjacent to the site. This method of firing solid fuel significantly influences the resulting nitrogen oxide concentration of the flue gases emitted from the boiler.

2.2.1 NO_X VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 2

The remaining step for the BART NO_X analysis was to conduct a visibility improvement determination for Unit 2. Due to the association of the Consent Decree and requisite BACT analysis, the visibility analysis was the only subsequent impact evaluation necessary to establish BART. In addition, because the BACT analysis resulted in one recommended control alternative, only one related emission rate was modeled to determine the visibility impairment impacts.

The modeling for Unit 2 uses two NO_X emission rates as a basis for the visibility impairment impacts. The NDDH BART protocol[9] NO_X emission rate of 5,364.2 lb /hr was modeled to determine a pre-control baseline visibility impact. This protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. This is equivalent to a unit NO_X emission rate of 0.894 lb/mmBtu at a boiler heat input rate of 5,999 mmBtu/hr. The baseline visibility impact was then compared with the result predicted from a modeled post-control NO_X emission rate based upon the control technology specified for Unit 2 in the BACT analysis. According to the BACT

analysis required by the Consent Decree, Selective Non-Catalytic Reduction (SNCR) used in conjunction with Advanced Separated Overfire Air (ASOFA) was considered the best technology and therefore was evaluated as BART for Unit 2. The second emission rate of 2,011.6 lb NO_X/hr was based upon application of SNCR and ASOFA control technologies for a reduction of approximately 62.5 percent from the protocol mass emission rate. This is equivalent to a unit NO_X emission rate of 0.390 lb/mmBtu at a more representative maximum 24-hour average boiler fuel heat input of 5,158 mmBtu/hr. The visibility modeling conditions are presented in Table 2.2-1.

Table 2.2-1 – Milton R. Young Station Unit 2 Visibility Model Conditions

	NDDH Protocol	SNCR with ASOFA(1)
NOx Emission Rate lb/hr	5,364.2	2,011.6
lb/mmBtu	0.894	0.390
Heat Input, mmBtu/hr	5,999.1	5,158.0

(1) – Post-control NO_X emission rate reflects recommended BACT w/ adjusted reduction.

The results of the visibility modeling at the protocol baseline NO_X emission rate for MRYS Unit 2 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control NO_X emission rate showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for three of the Class 1 areas at the post-control BACT-level NO_X emission rate were below the 0.50 dV threshold level. The Lostwood NWR Class 1 area had a modeled visibility impairment impact of 0.543 dV. The modeling results are presented in Table 2.2-2.

Table 2.2-2 – NO_X Visibility Impairment Impacts and Reductions at NOx BACT Post-Control Emissions, MRYS Unit 2

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	Post-Control Emissions[2]	
TRNP-South Unit	0.580	0.406	0.174
TRNP-North Unit	0.619	0.438	0.181
TRNP-Elkhorn Ranch	0.360	0.278	0.082
Lostwood NWR	0.775	0.543	0.232

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

2 - NO_X emissions reduction by 62.5% over NDDH protocol baseline case. This scenario assumes protocol emission rates for SO_2 and PM. Refer to Appendix A for complete protocol and revised post-control visibility model results.

The number of days predicted to have visibility impairment due to MRYS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results are summarized and presented in Table 2.2-3. Similarly, the same information for the post-control NO_X emission rates is summarized and shown in Table 2.2-3. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control NO_X emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 2. The impact in terms of days exceeding 0.50 dV varies from an approximately 9% reduction for TRNP – Elkhorn in 2001 to an approximately 37% reduction for TRNP – South in 2000. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 15% for TRNP – Elkhorn in 2002 to approximately 50% for TRNP – North in 2000.

A series of bar charts showing the difference in the number of days with predicted visibility impairment impact greater than 0.50 and 1.00 deciViews for each Class 1 area for the SNCR with ASOFA-controlled post-control emission rates with pre- and post-control SO_2 and PM alternatives is included in Figures 2.2-1 through 2.2-9.

3.0 SO_2 BART EVALUATION

The BART determination process has five predefined steps as described in Section 1. In this section, steps 1 through 5 of the BART determination for Milton R. Young Station (MRYS) are described for SO_2 and a presentation is made of the results. Potentially applicable SO_2 control technologies are first identified. A brief description of the processes and their capabilities are then reviewed for availability and feasibility. A detailed technical description of each control technology is provided in Appendix B. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to nominal SO_2 control capability. The impacts analysis then reviews the estimated capital and O&M costs for each alternative. Following the cost determination, the energy impacts and non-air quality impacts are reviewed for each technology. The impact based on the remaining useful life of the source is reviewed as part of the cost analysis. In the final step of the analysis, feasible and available technologies are assessed for their potential visibility impairment impact reduction capability via visibility modeling results. The results of the impact analyses are tabulated and potential BART control options are listed.

3.1 IDENTIFICATION OF RETROFIT SO_2 CONTROL TECHNOLOGIES

The initial step in the BART determination is the identification of retrofit SO_2 control technologies. In order to identify the applicable SO_2 control technologies, several reference works were consulted, including “Controlling SO_2 Emissions: A Review of Technologies (EPA-600/R-00-093, October 2000) and the RACT/BACT/LAER Clearinghouse (RLBC). From these and other literature sources, a preliminary list of control technologies and their estimated capabilities for potential application to MRYS was developed. However, as discussed in the introduction, Minnkota has entered into a Consent Decree (CD) that requires MRYS to install or modify SO_2 control technologies on both units to achieve emission rates that do not exceed specified levels. The Consent Decree defines the minimum levels of SO_2 control removal efficiencies applicable for technology installation options on MRYS Unit 1 and requires that the existing wet FGD process be upgraded to maintain a 30-day rolling average SO_2 removal efficiency of ninety percent (90%) for Unit 2. Thus, the control technologies included in the BART analysis either meet the minimum level of control specified by the CD or have more stringent removal efficiency. Table 3.1-1 contains the results of this effort.

TABLE 3.1-1 – SO_2 Control Technologies Identified for BART Analysis

Control Technology	Approximate Control Efficiency
Wet Flue Gas Desulfurization (FGD)	95%
Dry Flue Gas Desulfurization (FGD)	90%
Powerspan ECO™	98%

3.2 TECHNICAL DESCRIPTION AND FEASIBLITY ANALYSIS

The second step in the BART analysis procedure is a technical feasibility analysis of the options identified in Step 1. The BART guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology. A control technology is considered available, “if it has reached the stage of licensing and commercial availability.” (70 FR 39165) On the contrary, a control technology is not considered available, “if it is in the pilot scale testing stages of development.” (70 FR 39165) When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” (70 FR 39165) The technical and feasibility analysis is presented below for each identified option.

3.2.1 WET FLUE GAS DESULFURIZATION

Wet FGD technology utilizing lime or limestone as the reagent is commonly applied to coal-fired boilers. Wet FGD utilizes am absorber, such as an open spray tower or a spray tower with a perforated plate contactor, to expose flue gas to the neutralizing slurry. Absorbed SO_2 is converted to calcium sulfite and then may be oxidized to calcium sulfate dihydrate (gypsum) which is filtered from the scrubber solution and either disposed of in a permitted disposal facility, or possibly sold for either wallboard or cement production. Lime is utilized as the reagent in the wet FGD technology analysis, because the plant currently uses lime in the Unit 2 FGD process, has existing lime reagent preparation equipment, and because limestone availability is limited in North Dakota. Note that although existing reagent preparation equipment is available, a new system is required to supply sufficient volume for controlling both EGUs.

Historically, wet FGD systems have operated with SO_2 control efficiency anywhere from 70% to 95%. Several new coal-fired power plant projects such as Thoroughbred, Trimble County and Mustang have been proposed with SO_2 control efficiency of 98 percent. However, the “EPA has concluded that 98 percent control is possible with certain control and boiler configurations under ideal conditions. The amended standard for SO_2 is based on a 30-day average that includes the variability that occurs from non-ideal operating conditions”. This comes from the NSPS “Standards of Performance for Electric Utility Steam Generating Units, Industrial-Commercial-Institutional Steam Generating Units, and Small Industrial-Commercial-Institutional Steam Generating Units; Final Rule” recently promulgated by EPA as final rule amendments to 40 CFR part 60, subparts Da, Db, and Dc emission standards effective February 27, 2006[10]. Achieving ideal operating conditions such that an average 98% level of SO_2 emissions control could be sustained for every 30-day rolling period has not been demonstrated by the new power projects mentioned. For the purposes of this analysis, wet FGD performance was evaluated at 95% SO_2 control as representative of presumptive BART requirements. Further technical characteristics associated with wet FGD are described in Appendix B.

Based on the ability of a wet FGD system to achieve 95 percent SO_2 removal efficiencies and commercial availability and applicability, wet FGD systems were found to be an acceptable BART alternative for MRYS Unit 1’s SO_2 emission control.

This report evaluates the wet FGD process currently operating on Unit 2 as a possible BART alternative. The existing wet FGD system currently treats approximately 78 percent of the flue gas with the remaining flue gas by-passed for stack gas reheat and achieves approximately 75 percent SO_2 removal. However, the Consent Decree requires that the existing wet FGD process be upgraded to maintain a 30-day rolling average SO_2 removal efficiency of ninety percent (90%) for Unit 2. Thus, the wet FGD process is evaluated at 90% SO_2 removal efficiency. Because some wet FGD systems are capable of achieving 95% control, modifications required to increase the removal efficiency of the existing wet FGD process to 95% is also evaluated as BART for Unit 2. Note that although 95% removal efficiency is evaluated as part of this analysis, a detailed engineering analysis is required to determine if the existing wet FGD process can be modified to achieve 95% control and is not included in the scope of this report.

3.2.2 DRY FLUE GAS DESULFURIZATION

As an alternative to wet FGD technology, the control of SO_2 emissions can be accomplished using dry FGD technology. The most common dry FGD system is the lime Spray Dryer Absorber (SDA) using a fabric filter for downstream particulate collection. There are several variations of the dry process in use today. This section addresses the spray dryer FGD process. Two other variations, the Flash Dryer

---

[10] Federal Register /Vol. 71, No. 38, page 9870.

Absorber (FDA) and Circulating Dry Scrubber (CDS) are similar in nature. They primarily differ by the type of reactor vessel used, the method in which water and lime are introduced into the reactor and the degree of solids recycling. Technical characteristics associated with the SDA, FDA and CDS are described in Appendix B.

No variation of dry FGD systems has clearly demonstrated the ability to achieve SO_2 removal levels similar to wet FGD systems in the U.S. Two units were recently permitted with SO_2 emission rates representing removal efficiencies of 94.5% and 95%. However, Burns & McDonnell recently completed a study of the emission reduction performance of existing, electric utility, dry FGD systems.[11] Information utilized for the evaluation was derived from EIA coal quality data and EPA SO_2 stack emissions and heat input data. The evaluation determined that the highest SO_2 removal efficiency maintained on a continuous basis was just above 90%. No dry FGD unit was able to maintain an average efficiency of 95% for continuous 30-day rolling periods. For the purpose of this BART determination, dry FGD is considered a viable alternative for Unit 1, but the upper bound on SO_2 removal efficiency was set at 90% based on a review of the historic performance of this technology.

3.2.3 POWERSPAN ELECTRO-CATALYTIC OXIDATION TECHNOLOGY

The Powerspan Electro-Catalytic Oxidation (ECO™) system is a multipollutant control technology designed to control emissions of NO_X, SO_2, fine particulate, mercury and certain Hazardous Air Pollutants (HAPs). The ECO™ process has two main process vessels; a barrier discharge reactor and a multi-level wet scrubber. Additional technical characteristics associated with the ECO™ process are described in Appendix B.

Powerspan claims a routine SO_2 removal efficiency of 98% with inlet concentrations up to approximately 2,000 ppm and testing at a pilot plant has demonstrated performance, reliability and economics. However, no full size commercial scale ECO™ systems have been installed or are operating at the time of this report. The ECO system was determined not to be a feasible BART alternative because it is not commercially available.

[11] SO_2 Removal Efficiency Achieved in Practice by U.S. Electric Utility Semi-Dry FGD Systems"; Electric Utility Environmental Conference (EUEC); Weilert, C. and Randall, D.; Tucson, AZ; January 2006.

3.2.4 RESULTS OF FEASIBILITY ANALYSIS

The evaluations of the identified BART alternatives following the feasibility analysis are summarized in Table 3.2-1.

TABLE 3.2-1 – MRYS BART SO_2 Control Feasibility Analysis Results

Control Technology	In full-scale service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable To Milton R. Young Station
Wet FGD	Yes	Yes	Yes	Yes
Dry FGD	Yes	Yes	Yes	Yes
Powerspan ECO™	No	No	No	Yes

3.3 EVALUATE TECHNICALLY FEASIBILE SO_2 CONTROL OPTIONS BY EFFECTIVENESS

The third step in the BART analysis procedure is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the BART analysis, the SO_2 control efficiency was reviewed and presented as part of the technical description for each technology. The evaluations of the remaining BART alternatives following the feasibility analysis are summarized in Table 3.3-1. The alternatives are ranked in descending order according to their effectiveness in SO_2 control.

TABLE 3.3-1 – Feasible SO_2 Control Technologies Identified for BART Analysis

Control Technology	Unit 1	Unit 2
Wet FGD	95% Control	90% and 95% Control
Dry FGD	90% Control	NA*

*Dry FGD is not evaluated for Unit 2 because the existing wet FGD can be used to achieve equivalent removal efficiency while using existing equipment.

3.4 EVALUATION OF IMPACTS FOR FEASIBLE SO_2 CONTROLS – UNIT 1

Step four in the BART analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) lists four factors to be considered in the impact analysis.

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four impacts required by the BART Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the BART determination for MRYS. In addition, as described in Section 1.4, the visibility impairment impact of each alternative was evaluated as part of the impact analysis.

3.4.1 COST ESTIMATES

Cost estimates for the wet and dry SO_2 control technologies were completed utilizing the Coal Utility Environmental Cost (CUECost) computer model (Version 1.0) available from the U.S. Environmental Protection Agency and engineering estimates based upon Burns & McDonnell's in-house experience. The CUECost model is a spreadsheet-based computer model that was specifically developed to estimate the cost of air pollution control technologies for utility power plants within +/- 30 percent accuracy. The EPA released the version of the model used for this study in February 2000. The model is available for download from the U.S. EPA website at www.epa.gov/ttn/catc/products. Operating information utilized as input into the model for the purpose of cost estimating is presented in Appendix C. Economic information utilized as input into the model is given in Table 1.2-1.

3.4.1.1 WET FGD CAPITAL COST ESTIMATE

The capital cost estimate for the wet FGD system includes the SO_2 control system, major support facilities and BOP costs. The SO_2 control system cost is representative of a typical furnish and erect contract by a wet FGD system supplier. The wet FGD system cost estimated by CUECost is broken down into the major subsystems of reagent preparation, SO_2 absorption tower, dewatering systems, flue gas handling systems (new ID fans and ductwork) and support systems. BOP costs are described below in more detail.

The addition of a wet FGD absorber to Unit 1 will require a wet stack to exhaust the flue gas. The existing Unit 1 stack is in poor physical condition and is not sufficient for wet stack operations. Although not designed for wet stack operations, it would however be possible to reuse the existing Unit 2 stack to exhaust the flue gas from Unit 1. To make the Unit 2 stack suitable for wet stack operation, the existing liner would either have to be demolished and replaced with an alloy-clad liner or it would have to be lined from the stack breeching upwards with a corrosion resistant material such as alloy wallpaper or Penngard block or similar coating. A stack drain system would be required to collect and remove moisture dropout from the flue gas. BOP costs include modifications to the existing Unit 2 stack for wet stack operation, long lengths of ductwork to the Unit 2 stack inlet, and electrical subcontract. The results of the capital cost estimate are given in Table 3.4-1.

Table 3.4-1 – Capital Cost Estimate for MRYS Unit 1 Wet Lime FGD System

DIRECT COSTS	**Estimated Cost ($2,006)**	**General Facilities Markup (10%)**	**Total Direct Cost**
Wet Lime FGD System			
Reagent Prep System	$15,748,000	$1,575,000	$17,323,000
SO_2 Absorption System	$25,640,000	$2,564,000	$28,204,000
Flue Gas Handling System	$10,185,000	$1,019,000	$11,204,000
Byproduct Handling System	$504,000	$50,000	$554,000
Support Equipment	$2,538,000	$254,000	$2,792,000
		Wet Lime Total Direct Cost =	**$60,077,000**
BOP Costs			
Electrical Subcontract	$8,055,000	NA	$8,055,000
Stack Modifications	$9,783,000	NA	$9,783,000
Additional Ductwork	$1,364,000	NA	$1,364,000
		BOP Total Direct Cost =	**$19,202,000**
		Total Direct Cost =	**$79,278,000**
INDIRECT COSTS			
		Contingency (20% of DC)	$15,856,000
		A/E Engineering and Construction Management (10% of DC)	$7,928,000
		Prime Contractor's Fee (3% of DC)	$2,378,000
		Allowance For Funds During Construction (AFDC 3.8%)	$3,013,000
		Indirect Cost Subtotal	$29,174,000
		Total Plant Investment (TPI)	**$108,452,000**
		Pre-Production Costs	$3,108,000
		Inventory	$215,000
		Total Capital Requirement	**$111,776,000**

The CUECost estimating model includes a cost estimate for a wet stack, but this estimate was deleted from the model results and a revised estimate by Burns & McDonnell was included in the BOP costs for modifications to the existing Unit 2 stack. The estimate includes the demolition of the existing stack liner and installation of a new C-276 clad liner and provisions for stack icing mitigation.

The total estimated capital cost estimate for a complete, stand-alone wet FGD system utilizing lime reagent is $111,776,000, or $430/kW.

3.4.1.2 DRY FGD CAPITAL COST ESTIMATE

Estimated direct costs for the dry FGD system include the SDA, fabric filter, major support facilities and BOP costs. The SO_2 control system cost is representative of a typical furnish and erect contract by a lime SDA/FF system supplier. The SDA/FF system costs estimated by CUECost are broken down into the major subsystems of reagent preparation, spray dryer absorber, waste handling systems, flue gas handling systems (new ID fans and ductwork) and support systems. A fabric filter is included in the estimate for the capture of entrained absorption products. BOP costs are described below in more detail.

As previously discussed, the existing Unit 1 stack is in poor physical condition and is to short for reuse. It would be possible to reuse the existing Unit 2 stack to exhaust the flue gas from Unit 1. Other than modifying the ductwork, significant modifications would not be required to make the Unit 2 stack suitable for operation with a dry FGD flue gas. BOP costs include long lengths of ductwork to the Unit 2 stack inlet and electrical subcontract. The results of the capital cost estimate are given in Table 3.4-2.

TABLE 3.4-2 – Capital Cost Estimate for MRYS Unit 1 Dry FGD/FF System

DIRECT COSTS	Estimated Cost ($2,006)	General Facilities Markup (10%)	Total Direct Cost
SDA System			
Reagent Prep System	$9,347,000	$935,000	$10,282,000
SO_2 Absorption System	$9,883,000	$988,000	$10,871,000
Flue Gas Handling System	$8,120,000	$812,000	$8,932,000
Byproduct Handling System	$1,902,000	$190,000	$2,092,000
Support Equipment	$3,078,000	$308,000	$3,386,000
		Dry FGD Total Direct Cost =	**$35,563,000**
Fabric Filter			
Fabric Filter Housing	$7,996,000	$800,000	$8,796,000
Bags	$1,268,000	$127,000	$1,395,000
Ash Handling System	$2,460,000	$246,000	$2,706,000
Instruments & Controls	$254,000	$25,000	$279,000
Freight	$636,000	$64,000	$700,000
Installation	$9,131,000	$913,000	$10,044,000
		Fabric Filter Total Direct Cost =	**$23,920,000**
BOP Costs			
Electrical Subcontract	$8,055,000	NA	$8,055,000
Additional Ductwork	$2,007,000	NA	$2,007,000
		BOP Total Direct Cost =	**$10,063,000**
		Total Direct Cost =	**$69,545,000**
INDIRECT COSTS			
		Contingency (20% of DC)	$13,909,000
		A/E Engineering and Construction Management (10% of DC)	$6,955,000
		Prime Contractor's Fee (3% of DC)	$2,086,000
		Allowance For Funds During Construction (AFDC 3.8%)	$2,643,000
		Indirect Cost Subtotal	$25,593,000
		Total Plant Investment (TPI)	**$95,138,000**
		Pre-Production Costs	$3,016,000
		Inventory	$258,000
		Total Capital Requirement	**$98,412,000**

A new stack was not included in the capital cost estimate. It was assumed for the purpose of the estimate that the existing Unit 2 stack would be reused.

The total estimated capital cost estimate for a complete, stand-alone lime SDA FGD system with a fabric filter, utilizing lime as a reagent is $98,412,000, or $383/kW.

3.4.1.3 WET FGD O&M COST ESTIMATE

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The operating labor cost was developed as part of the CUECost model and is based on unit size and an operating labor rate of $40 per hour. However, because BOP estimates were modified, administrative and support labor and maintenance where calculated as described below. Table 3.4-3 summarizes the O&M cost estimates for the wet FGD system.

The fixed costs include operating labor, administrative and support labor and the maintenance material and labor costs. The maintenance material and labor cost was estimated as approximately 3% of the wet FGD system direct capital cost in Table 3.4-1. Administrative and support labor cost was estimated as 12% of the maintenance material and labor cost plus 30% of the operating labor costs. Previous studies and guidelines for FGD O&M costs by EPRI and others are in line with these percentages.

TABLE 3.4-3 – O&M Cost Estimate for MRYS Unit 1 Wet Lime FGD System

Fixed Costs	
Operating Labor	$1,490,000
Admin and Support labor	$741,000
Maintenance Material and Labor	$2,449,000
Total Fixed O&M Costs =	$4,680,000
Variable Costs	
Lime Reagent	$3,620,000
Byproduct Disposal	$555,000
Water	$88,000
Auxiliary Power	$1,339,000
Total Variable O&M Costs =	$5,602,000
Total Annual O&M Costs	**$10,282,000**
Net Annual O&M Cost ($/MWh)	**$5.40**

Variable costs include reagent, makeup water, FGD byproduct disposal and auxiliary power costs. The estimated annual costs for these consumables are based on consumption rates modeled by the CUECost model and the unit cost information provided in Table 1.2-1 Economic Design Criteria. A cost of $6 per ton for pumping the FGD waste slurry to the disposal pond was included for waste disposal.

3.4.1.4 DRY FGD O&M COST ESTIMATE

The O&M cost estimate for the SDA/FF alternative was estimated using CUECost. Lime usage was set at 1.3 lbmol of lime (CaO) per lbmol of SO_2 removed. A ratio of 7.5 lb of recycled solids per pound of lime added and 30% solids slurry were set as design conditions. A total of 13” w.g. pressure drop across the combined SDA/FF system was also specified. The Fabric Filter was sized for a gas-to-cloth ratio of 3.5 $ACFM/Ft^2$. A three year bag life was assumed. The purposes of this study, it was assumed that the ESP would be completely de-energized and result in a cost savings as shown. The results of the SDA/FF O&M cost estimate are summarized in Table 3.4-4.

TABLE 3.4-4 – O&M Cost Estimate for MRYS Unit 1 SDA/FF System

Fixed Costs	
Operating Labor	$1,199,000
Admin and Support Labor	$467,000
Maintenance Material and Labor	$3,233,000
Total Fixed O&M Costs =	**$4,899,000**
Variable Costs	
Lime Reagent	$4,806,000
Byproduct Disposal	$1,213,000
Water	$88,000
ESP Power Savings	($125,000)
Auxiliary Power	$1,208,000
Total Variable O&M Costs =	**$7,190,000**
Total Annual O&M Costs	**$12,089,000**
Net Annual O&M Cost ($/MWh)	**$6.32**

3.4.1.5 LEVELIZED TOTAL ANNUAL COST

In order to effectively compare the cost of installing, operating and maintaining each of the SO_2 control systems, capital and O&M costs can be evaluated on a levelized basis.

A Net Present Value (NPV) was calculated for the each alternative utilizing the estimated costs in Tables 3.4-1 through 3.4-4 and the economic conditions given in Table 1.2-1. The NPV calculation was based on a two year construction period, followed by a 20 year service life ending December 31, 2031. Estimated capital costs were split evenly over a two year construction period for all alternatives.

A system startup date of December 31, 2011 was used based upon the requirements of the Consent Decree. O&M costs were included through the end of the calendar year 2031. No salvage value was assumed at the end of the service life for any of the alternatives. The NPV for all SO_2 control technology alternatives are presented in Table 3.4-5.

The Levelized Total Annual Cost (LTAC) for all alternatives was calculated based on the same economic conditions and a 20 year project life and are presented below in Table 3.4-6 along with the emissions reduction, resultant emissions rate and the Unit Control Cost. The Unit Control Cost is the LTAC divided by the annual tons of SO_2 emissions that would be controlled by implementation of the respective alternative.

Table 3.4-5 – NPV of SO_2 Control Alternatives for MRYS Unit 1

SO_2 Control Alternative	Control Efficiency	Net Present Value (NPV) ($2006)
Wet FGD	95%	**$222,742,000**
Dry FGD	90%	**$232,880,000**

Service Life:	Through 2031
Interest:	6%
Construction Period:	2 years
Startup Date:	Dec. 31, 2011
Inflation Rate:	3% For Construction and 2.5% for O&M

Table 3.4-6 – Levelized Total Annual Cost of SO_2 Control Alternatives for MRYS Unit 1

SO_2 Control Alternative	Control Efficiency[4]	Annual Emission Reduction (tpy)	Installed Capital Cost ($2006)[1]	Annual O&M Cost ($2006)	Levelized Total Annual Cost ($2006)[2]	Actual Unit Control Cost ($/ton)[3]
Wet FGD	95%	20,460	$111,776,000	$10,282,000	**$22,584,000**	$1,104
SDA/FF	90%	19,383	$98,412,000	$12,089,000	**$23,676,000**	$1,221

1. All Costs in 2006 dollars.
2. For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1.24873.
3. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.
4. SO_2 removal is across the FGD system.

The annual tons of SO_2 reduction in this BART analysis are calculated as the difference between the pre-controlled emissions from the historic highest 24-month rolling average pre-control baseline (firing lignite fuel at the historic 24-month average heat input with the historic 24-month average sulfur and heat contents and the historic 24-month average unit operating time) and the controlled emissions assumed to be at the same input conditions and unit operating time.

The Levelized Total Annual Cost and Unit Control Cost are used to evaluate the technology alternatives on a cost effectiveness basis. As can be seen from a review of Tables 3.4-5 and 3.4-6, the wet lime FGD alternative is the highest capital cost alternative but the lowest levelized total annual cost and net present value. Because the accuracy of the estimate (± 30%) is greater than the variance of the estimated LTACs (± 4%) and the Unit Control Costs (± 10%) for all post combustion control alternatives, none of the alternatives were excluded from further analysis on a cost basis.

The next step in the cost effectiveness analysis for the BART alternatives is to review the incremental cost effectiveness between the remaining alternatives. Table 3.4-7 contains a repetition of the cost and control information from Table 3.4-6 and the incremental cost effectiveness for each control alternative.

TABLE 3.4-7 – Incremental Cost Effectiveness of Unit 1 SO_2 BART Control Alternatives

BART Alternative	Levelized Total Annual Cost(1)	Annual Emission Reduction (tpy)	Incremental Cost Effectiveness ($/ton)
Wet FGD	$22,584,000	20,460	-$1,014
Dry FGD	$23,676,000	19,383	NA

(1) - For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1. 24873.

In the BART Determination guidelines, EPA does not provide definition, or even discussion of reasonable, or unreasonable, Unit Control Costs. Similarly, EPA does not address reasonable or unreasonable ranges for the incremental cost effectiveness. The incremental cost effectiveness is a marginal cost effectiveness between two specific alternatives. The incremental cost effectiveness for wet FGD versus dry FGD in Table 3.4-7 is within the range of reasonable costs used in other regulatory analyses and thus does not indicate that wet FGD is prohibitively expensive relative to the dry FGD alternative.

The cost analysis portion of the BART determination for MRYS Unit 1 has shown that none of the Unit Control Costs for the remaining alternatives are exceedingly expensive on a Unit Control Cost basis. From an economic analysis viewpoint, wet FGD appears to be the most cost effective evaluated SO_2 control alternative for MRYS Unit 1. However, because the capital costs of all of these technologies are subject to market conditions at the time of purchase, such as; alloy pricing, major equipment lead times (i.e., slurry pumps, ID fans, etc.) the relative closeness of the estimated capital costs is a good indicator that the cost ranking of these alternatives might even be reversed at the time of actual purchase.

3.4.2 ENERGY IMPACTS

The energy impacts of each alternative, in terms of both estimated kW of energy usage and the percent of total generation, are given in Table 3.4-8. The primary energy impacts of the wet FGD alternative consists of the additional electrical load resulting from pumps, blowers, booster fans, reagent preparation and vacuum pumps for byproduct slurry dewatering. The largest energy users for the dry FGD are pumps, blowers, atomizers, reagent preparation, additional fabric filter and ID fans. Building HVAC and interior and exterior lighting loads are also included, but the major energy consumption is due to the primary systems described above.

TABLE 3.4-8 – Energy Requirements of MRYS Unit 1 BART SO_2 Control Alternatives

BART Alternative	Energy Demand (kW)	Percent of Nominal Generation
Wet FGD	5,140	2.2%
Dry FGD	4,113	1.8%

3.4.3 NON-AIR QUALITY ENVIRONMENTAL IMPACTS

Non-air quality environmental impacts of the installation and operation of the various BART alternatives include hazardous waste generation, solid and aqueous waste streams, and salable products that could result from the implementation of various BART alternatives.

Captured mercury in the solid waste stream from any post combustion alternative would be present as a trace contaminant in the solid waste, not affecting disposal options as long as the waste passes the Toxic Characteristic Leaching Procedure (TCLP), which FGD system wastes have historically.

A wet FGD system for MRYS Unit 1 is estimated to produce approximately 12 tons per hour of solid waste. The waste stream would consist of solids and inerts in a slurry at approximately 10-15% solids. Over the course of a year, the total solid waste quantity from the wet FGD is estimated to be approximately 105,000 tons of solids which would be landfilled in the current permitted solid waste disposal facility near the plant. A dry FGD system for MRYS Unit 1 is estimated to produce approximately 28 tons per hour of solid waste or approximately 245,000 tons per year. The dry FGD waste stream contains approximately 95% solids and the majority is carried through to downstream particulate control. The increase in solids is mainly attributed to mixing with the fly ash which most likely has insufficient quality for sale. Thus, the dry FGD solids would be landfilled in the current permitted disposal facility.

3.4.4 SO_2 VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 1

The remaining step for the BART SO_2 analysis was to conduct a visibility improvement determination for Unit 1. The NDDH Modeling Protocol[12] SO_2 emission rate of 7,231.2 lb/hr was modeled to determine a pre-control baseline visibility impact for MRYS Unit 1. This protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. The baseline visibility impact was then compared with the results predicted from a modeled post-control SO_2 emission rate based upon a 90% control dry scrubbing technology alternative SO_2 emission rate and a 95% control wet scrubbing technology alternative SO_2 emission rate relative to the protocol Unit 1 pre-control SO_2 emission rate.

According to the BART non-visibility impact analysis, wet flue gas desulfurization (FGD) was considered the most effective technology and therefore was evaluated as BART for Unit 1. The lowest post-control SO_2 emission rate of 361.6 lb/hr was based upon application of wet FGD control technology for a reduction of approximately 95 percent from the protocol mass emission rate. The next lowest post-control SO_2 emission rate of 723.1 lb/hr was based upon application of dry FGD control technology for a reduction of approximately 90 percent from the protocol mass emission rate.

The results of the visibility impairment modeling at the protocol baseline SO_2 emission rate for MRYS Unit 1 showed that three of the four Class 1 areas had a 90th percentile visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The 90th percentile visibility modeling results for the post-control 90% and 95% SO_2 reduction emission rates showed reductions in visibility impairment impact for all four Class 1 areas. In addition, the modeled 90th percentile visibility impairment impacts for all Class 1 areas at the post-control SO_2 emission rates were below the 0.50 dV threshold level. The predicted visibility impairments from the

---

[12] Ibid NDDH Final BART Protocol; November 2005.

modeling are presented in Table 3.4-9. This value is the average visibility impairment impact reduction over the three modeled years (2000-2002) for each affected Class 1 area. The predictions of 24-hour 98th percentile deciView data are also provided in Appendix A.

Table 3.4-9 – SO_2 Visibility Impairment Impacts and Reductions, MRYS Unit 1

Federal Class 1 Area	**Visibility Impairment Impacts[1] (deciView)**			**Visibility Impairment Reduction (deciView)**	
	Protocol Emissions	**Post-Control Emissions[2]**		**Post-Control Emissions[2]**	
		90% Control	**95% Control**	**90% Control**	**95% Control**
TRNP-South Unit	0.549	0.250	0.173	0.299	0.375
TRNP-North Unit	0.628	0.269	0.165	0.359	0.463
TRNP-Elkhorn Ranch	0.374	0.160	0.111	0.214	0.263
Lostwood NWR	0.750	0.322	0.248	0.428	0.502

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

2 - SO_2 emissions reduction by 90% and 95% over protocol baseline case. This scenario assumes protocol emission rates for NO_X and PM.

The number of days predicted to have visibility impairment due to MRYS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model. The results for the predicted protocol and post-control 90% and 95% SO_2 reduction emission rates from MRYS Unit 1 are summarized in Table 3.4-10 and Table 3.4-11, respectively. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control SO_2 emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

Table 3.4-10 – Visibility Impairment Improvements – MRYS Unit 1 Dry FGD SO_2 Control Impacts (Days)

Class 1 Area	**SO_2 Control Technique**	**Days[2] Exceeding 0.5 dV in 2000**	**Days[2] Exceeding 0.5 dV in 2001**	**Days[2] Exceeding 0.5 dV in 2002**	**Days[2] Exceeding 1.0 dV in 2000**	**Days[2] Exceeding 1.0 dV in 2001**	**Days[2] Exceeding 1.0 dV in 2002**	**Consecutive Days[2] Exceeding 0.5 dV 2000**	**Consecutive Days[2] Exceeding 0.5 dV 2001**	**Consecutive Days[2] Exceeding 0.5 dV 2002**

2 - Number of days for predicted visibility impairment impacts provided in Appendix A.

3.5 EVALUATION OF IMPACTS FOR FEASIBLE SO_2 CONTROLS – UNIT 2

Step four in the BART analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) lists four factors to be considered in the impact analysis.

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four impacts required by the BART Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the BART determination for MRYS. In addition, as described in Section 1.4, the visibility impairment impact of each alternative was evaluated as part of the impact analysis.

As previously stated in Section 3.2.1, the Consent Decree requires MRYS to modify the existing wet FGD system on Unit 2 to achieve a removal efficiency of at least 90%. Modifications to the existing wet FGD were evaluated as the minimum level of control for BART. In addition, because some wet FGD systems are capable of achieving 95% removal efficiency, modifications required to achieve 95% control were also evaluated for the wet FGD process.

3.5.1 COST ESTIMATES

The two wet FGD scenarios at 90 and 95 percent control involve modifications to the existing FGD process. Because the two control scenarios involve modifications to existing technology, the CUECost was not used to estimate costs for the Unit 2 SO_2 control alternatives. Instead, costs for retrofitting and operating the two BART alternatives were estimated from various literature sources and Burns & McDonnell's in-house experience and resources. Information from such sources was adjusted for known local conditions. Modifications to the existing wet FGD system and support equipment were identified and costs were estimated for comparison of the two wet FGD alternatives.

A Net Present Value (NPV) and Levelized Total Annual Cost (LTAC) was calculated for the each alternative utilizing the costs presented in the following sections, the same methodology presented in Section 3.4.1.5 and the economic conditions given in Table 1.2-1.

3.5.1.1 WET FGD COST ESTIMATE FOR 90% REMOVAL

The Consent Decree requires MRYS to upgrade the existing Unit 2 FGD system to achieve and maintain 90% SO_2 removal on a 30-day rolling average including any flue gas routed though a bypass duct. This analysis assumes that to achieve 90% removal, the bypass will be eliminated and lime reagent usage will increase. If the flue gas bypass is eliminated, the flue gas exiting the wet FGD will be at a saturated condition. Because the existing stack is not designed for saturated conditions and modifications to the existing stack require an extended outage that is incompatible with MRYS operations, the recommended solution is to construct a new stack suitable for saturated flue gas. Due to the arrangement of existing equipment, the new stack would be located approximately 220 feet from the existing stack and new ductwork would be required. Scrubbing 100% of the flue gas will also increase the volume of flow through each absorber module, thus increasing the velocity inside the vessel. New high velocity mist eliminators should be installed to account for the higher velocity and prevent corrosion issues caused by mist carryover into the ductwork and stack. The cost estimate for a wet FGD system achieving 90% control is summarized in Table 3.5-1.

Table 3.5-1 – Cost Estimate for MRYS Unit 2 Wet FGD System at 90% Control

Retrofit Capital Costs	
New Stack	$ 16,850,000
New Ductwork	$ 1,565,000
New Mist Eliminators	$ 810,000
Total Capital Costs =	**$ 19,225,000**
Annual O&M Costs	
Lime Reagent	$ 2,816,000
Byproduct Disposal	$ 477,000
Water	$ 163,000
Auxiliary Power	$ 1,074,000
Total O&M Costs =	**$ 4,530,000**
Net Present Value (NPV)	**$ 71,752,000**
Levelized Total Annual Cost (LTAC)	**$ 7,333,000**

3.5.1.2 WET FGD COST ESTIMATE FOR 95% REMOVAL

To modify the existing wet FGD system to achieve and maintain 95% SO_2 removal on a 30-day rolling average will require the bypass to be eliminated and cause lime reagent usage to increase. The capital improvements and associated costs will include the same new stack, new ductwork and new mist eliminators that were required to achieve 90% control. To modify the existing process to achieve the additional 5% control requires a detailed engineering analysis and design review which is outside the scope of this evaluation. However, at a minimum, the absorber modules would require the addition of perforated trays to increase the removal efficiency. The addition of trays in the absorber will increase the pressure drop across the system and will require ID fan modifications. Thus, Table 3.5-2 includes additional capital costs associated with the addition of trays and modification to the existing ID fans.

Table 3.5-2 – Cost Estimate for MRYS Unit 2 Wet FGD System at 95% Control

Retrofit Capital Costs	
New Stack	$ 16,850,000
New Ductwork	$ 1,565,000
New Mist Eliminators	$ 810,000
Absorber Trays	$ 853,000
ID Fan Modifications	$ 4,911,000
Total Capital Costs =	**$ 24,989,000**
Annual O&M Costs	
Lime Reagent	$ 2,964,000
Byproduct Disposal	$ 502,000
Water	$ 172,000
Auxiliary Power	$ 1,355,000
Total O&M Costs =	**$ 4,993,000**
Net Present Value (NPV)	**$ 82,424,000**
Levelized Total Annual Cost (LTAC)	**$ 8,414,000**

The next step in the analysis for the BART alternatives is to review the unit control cost and incremental cost effectiveness of the remaining scenarios. Table 3.5-3 contains a repetition of the cost information from Tables 3.5-1 and 3.5-2.

Because Unit 2 has existing SO_2 control, the historic highest 24-month rolling average represents a controlled emission rate. Thus, the baseline annual tons of SO_2 for Unit 2 in this BART analysis are calculated as the pre-controlled emissions from firing lignite fuel containing 1% sulfur at a heat input of 5,158 mmBtu/hr with the unit operating at 85% capacity. The resulting uncontrolled emissions are 15,600 pounds per hour or 58,000 tons per year. The controlled emissions assumed application of the respective removal efficiency to the baseline emission rate with the same input conditions and unit operating time. The annual tons of SO_2 reduction for Unit 2 are calculated as the difference between the protocol emissions and the controlled emissions associated to the respective removal efficiency.

TABLE 3.5-3 – Incremental Cost Effectiveness of Unit 2 SO_2 BART Control Alternatives

BART Alternative	Levelized Total Annual Cost[1]	Annual Emission Reduction (tpy)	Actual Unit Control Cost ($/ton)[2]	Incremental Cost Effectiveness ($/ton)
95% Control Wet FGD	$8,414,000	22,700	$371	$373
90% Control Wet FGD	$7,333,000	19,800	$370	NA

1. For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1. 24873.
2. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.

The Levelized Total Annual Cost and Unit Control Cost are used to evaluate the technology alternatives on a cost effectiveness basis. Because this is a comparison of the same technology at different removal efficiencies, one would expect the LTAC to be greater with the higher removal efficiency option.

In the BART Determination guidelines, EPA does not provide a definition, or even discussion of reasonable, or unreasonable, Unit Control Costs. Similarly, EPA does not address reasonable or unreasonable ranges for the incremental cost effectiveness. The incremental cost effectiveness is a marginal cost effectiveness between two specific alternatives. The incremental cost effectiveness for 95% control versus 90% control in Table 3.5-3 is within the range of reasonable costs used in other regulatory analyses and thus does not indicate that wet FGD at 95% control is prohibitively expensive relative to the 90% control alternative.

The cost analysis portion of the BART determination for MRYS Unit 2 has shown that none of the Unit Control Costs for the remaining alternatives are exceedingly expensive on a Unit Control Cost basis.

3.5.2 ENERGY AND NON-AIR QUALITY IMPACTS

The primary energy impacts of the wet FGD process consist of the additional electrical load resulting from pumps, blowers, booster fans, reagent preparation and vacuum pumps for byproduct slurry dewatering. Because the 90% control alternative evaluated for Unit 2 only includes modifications to existing equipment, the energy impacts are due to operational differences created by the modifications and are difficult to quantify. Thus, the energy impacts are estimated in terms of total system energy usage in kW and are included as part of the cost evaluation. An increase in energy usage for the 95% control alternative is a result of installing perforated trays and increasing the pressure drop of the absorber modules. The increase in pressure drop requires approximately 733 kW of additional ID fan power. A new category of non-air quality impact is not caused by the modifications to the existing system. The non-air quality impacts include increases to existing waste generation, are considered in the cost analysis portion of the analysis and no additional evaluation was performed.

3.5.3 SO_2 VISIBILITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 2

The remaining step for the BART SO_2 analysis was to conduct a visibility improvement determination for Unit 2. The NDDH BART protocol[13] SO_2 emission rate of 6,879.0 lb/hr was modeled to determine a pre-control baseline visibility impact for MRYS Unit 2. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. The baseline visibility impact was then compared with the results predicted from a modeled post-control SO_2 emission rate based upon 90% and 95% control wet scrubbing technology alternatives that utilize the modified, existing wet FGD system.

According to the BART non-visibility impact analysis, modifications to the existing wet FGD achieving 95% removal efficiency was the most effective technology and therefore was evaluated as BART for Unit 1. The 95% removal efficiency equates to an emission rate of 773.7 lb/hr SO_2. The next lowest post-control SO_2 emission rate of 1,574.4 lb/hr was based upon an upgrade of the existing wet FGD process to achieve 90% SO_2 reduction. The post-control CALPUFF model scenario for MRYS Unit 2 was conducted with the protocol NO_X and PM emission rates and the post-control SO_2 emission rate as discussed in Section 1.5.5 and Table 1.5-1.

---

[13] Ibid, NDDH Modeling Protocol.

The results of the visibility impairment modeling at the protocol baseline SO_2 emission rate for MRYS Unit 2 showed that three of the four Class 1 areas had a 90th percentile visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The 90th percentile visibility modeling results for the post-control 90% and 95% SO_2 reduction emission rates showed reductions in visibility impairment impact for all four Class 1 areas. In addition, the modeled 90th percentile visibility impairment impacts for all Class 1 areas at the post-control SO_2 emission rates were below the 0.50 dV threshold level. The predicted visibility impairments from the modeling are presented in Table 3.5-4. This value is the average visibility impairment impact reduction over the three modeled years (2000-2002) for each affected Class 1 area.

Table 3.5-4 – SO_2 Visibility Impairment Impacts and Reductions, MRYS Unit 2

Federal Class 1 Area	**Visibility Impairment Impacts[1] (deciView)**			**Visibility Impairment Reduction (deciView)**	
	Protocol Emissions	**Post-Control Emissions[2] 90% and 95% Control**		**Post-Control Emissions[2] 90% and 95% Control**	
TRNP-South Unit	0.580	0.390	0.304	0.190	0.276
TRNP-North Unit	0.619	0.370	0.271	0.249	0.348
TRNP-Elkhorn Ranch	0.360	0.225	0.171	0.135	0.189
Lostwood NWR	0.775	0.493	0.405	0.282	0.370

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

2 - SO_2 emissions reduction by 90% and 95% over protocol baseline case. This scenario assumes protocol emission rates for NO_X and PM.

The number of days predicted to have visibility impairment due to MRYS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model. The results are summarized and presented in Table 3.5-5 and 3.5-6. The visibility impairment impact and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control 90% and 95% SO_2 reduction emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

4.0 PARTICULATE MATTER BART EVALUATION

Steps 1 through 5 of the BART analyses for PM emissions from MRYS Unit 1 and Unit 2 are described in this section. Potentially applicable SO_2 control technologies are first identified. A brief description of potential control options and their capabilities, including MRYS Unit 1 and Unit 2 existing PM air pollution control equipment, is provided. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to nominal PM control capability. The impacts analysis then reviews the estimated capital and O&M costs for each alternative, including taking a look at Balance Of Plant (BOP) requirements. Following the cost determination, the energy impacts and non-air quality impacts are reviewed for each technology. The impact based on the remaining useful life of the source is reviewed as part of the cost analysis. In the final step of the analysis, feasible and available technologies are assessed for their potential visibility impairment impact reduction capability via visibility modeling results. The results of the impact analyses are tabulated and potential BART control options are listed.

4.1 IDENTIFICATION OF RETROFIT PM CONTROL TECHNOLOGIES

The initial step in the BART determination is the identification of retrofit PM control technologies. In order to identify the applicable PM control technologies, several reference works were consulted, including the RACT/BACT/LAER Clearinghouse (RLBC). A preliminary list of control technologies and their estimated capabilities for potential application to MRYS was developed. As discussed in the introduction, Minnkota has entered into a Consent Decree (CD). The CD requires MRYS to maintain or upgrade the existing PM controls on both units to achieve specified emission rates. Because the CD specified the PM emission rate, the control technologies included in the BART analysis either meet the minimum emission rate specified by the CD or have more stringent emission rate. Table 4.1-1 contains the results of this effort.

TABLE 4.1-1 – PM Control Technologies Identified for BART Analysis

Control Technology	Approximate Control Efficiency
Fabric Filter or Baghouse	99.7%
COHPAC Baghouse	99.7%
New Electrostatic Precipitator	99.7%
Existing Electrostatic Precipitator	99.0%

4.2 TECHNICAL DESCRIPTION AND FEASIBLITY ANALYSIS

The second step in the BART analysis procedure is a technical feasibility analysis of the options identified in Step 1. The BART guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology. A control technology is considered available, “if it has reached the stage of licensing and commercial availability.” (70 FR 39165) On the contrary, a control technology is not considered available, “if it is in the pilot scale testing stages of development.” (70 FR 39165) When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” (70 FR 39165) All PM control technologies identified for this analysis are proven technologies that are technically feasible for review as a potential BART alternative for either Unit 1 or 2. The identified BART alternatives following the feasibility analysis are summarized in Table 4.2-1.

TABLE 4.2-1 – MRYS BART PM Control Feasibility Analysis Results

Control Technology	In full-scale service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable To Milton R. Young Station
Fabric Filter or Baghouse	Yes	Yes	Yes	Yes
COHPAC Baghouse	Yes	Yes	Yes	Yes
New Electrostatic Precipitator	Yes	Yes	Yes	Yes
Existing Electrostatic Precipitator	Yes	Yes	Yes	Yes

4.3 EVALUATE TECHNICALLY FEASIBILE PM CONTROL OPTIONS BY EFFECTIVENESS

The third step in the BART analysis procedure is to evaluate the control effectiveness of the technically feasible alternatives. The PM control efficiency was reviewed and presented as part of the technology identification in Step 1 of the analysis. The alternatives are summarized in Table 4.3-1 and are ranked in descending order according to their effectiveness in PM control.

TABLE 4.3-1 – Feasible PM Control Technologies Identified for BART Analysis

Control Technology	Unit 1	Unit 2
Fabric Filter or Baghouse	0.015	0.015
COHPAC Baghouse	0.015	0.015
New Electrostatic Precipitator	0.015	0.015
Existing Electrostatic Precipitator	0.030	0.030

4.4 EVALUATION OF IMPACTS FOR FEASIBLE PM CONTROLS – UNIT 1

Step four in the BART analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) lists four factors to be considered in the impact analysis.

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four impacts required by the BART Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the BART determination for MRYS. In addition, as described in Section 1.4, the visibility impairment impact of each alternative was evaluated as part of the impact analysis.

4.4.1 COST ESTIMATES

Cost estimates for the PM control technologies were completed utilizing the Coal Utility Environmental Cost (CUECost) computer model (Version 1.0) available from the U.S. Environmental Protection Agency and engineering estimates based upon Burns & McDonnell's in-house experience. The CUECost model is a spreadsheet-based computer model that was specifically developed to estimate the cost of air pollution control technologies for utility power plants within +/- 30 percent accuracy. The EPA released the version of the model used for this study in February 2000. The model is available for download from the U.S. EPA website at www.epa.gov/ttn/catc/products. Operating information utilized as input into the model for the purpose of cost estimating is presented in Appendix C. Economic information utilized as input into the model is given in Table 1.2-1. The cost estimates for a PM control alternatives are summarized in Table 4.4-1. A Net Present Value (NPV) and Levelized Total Annual Cost (LTAC) were calculated for the each alternative utilizing the costs summarized in Table 4.4-1.

TABLE 4.4-1 – Cost Estimates for Unit 1 PM Control Alternatives

	FF	COHPAC[1]	NEW ESP	EXISTING ESP[2]
Capital Costs				
Direct Costs	$21,133,000	$13,684,000	$23,112,000	$0
Indirect Costs	$8,453,000	$5,474,000	$9,245,000	$0
Total Capital Costs	**$29,856,000**	**$19,158,000**	**$32,357,000**	**$0**
O&M Costs				
Includes Maintenance Costs, Power Costs, and Replacement Costs (if any)				
Total O&M Costs	**$2,166,000**	**$1,571,000**	**$1,459,000**	**$1,459,000**
Net Present Value (NPV)	**$52,232,000**	**$35,862,000**	**$46,106,000**	**$17,667,000**
Levelized Total Annual Cost (LTAC)	**$5,284,000**	**$3,632,000**	**$4,643,000**	**$1,822,000**

1. COHPAC costs are scaled down to represent a similar fabric filter with a flue gas to cloth ratio of 6 ACFM/ft^2.
2. Costs associated with the operation of the existing ESP are assumed equal to the operating costs for a new ESP.

The next step in the analysis for the BART alternatives is to review the unit control cost and incremental cost effectiveness of the remaining scenarios. Table 4.4-2 contains a repetition of the cost information from Table 4.4-1.

Because Unit 1 has existing PM control, the historic highest 24-month rolling average represents a controlled emission rate. Thus, the baseline annual tons of PM for Unit 1 in this BART analysis are calculated as the pre-controlled emissions from firing lignite fuel with an ash content of 9.6% at a heat input of 2,955 mmBtu/hr with the unit operating at 85% capacity. Using the conservative approach that 50% of the ash is emitted as fly ash and 50% of the ash becomes bottom ash; the resulting uncontrolled emissions are approximately 32,100 tons per year. The controlled emissions assumed application of the respective removal efficiency to the baseline emission rate with the same input conditions and unit operating time. The annual tons of PM reduction for Unit 1 are calculated as the difference between the protocol emissions and the controlled emissions associated to the respective removal efficiency.

TABLE 4.4-2 – Incremental Cost Effectiveness of Unit 1 PM BART Control Alternatives

BART Alternative	Levelized Total Annual Cost[1]	Annual Emission Reduction (tpy)	Actual Unit Control Cost ($/ton)[2]	Incremental Cost Effectiveness ($/ton)
Fabric Filter or Baghouse	$5,284,000	61	$86,600	$56,800
New Electrostatic Precipitator	$4,643,000	61	$76,100	$46,200
COHPAC Baghouse	$3,632,000	61	$59,500	$29,700
Existing Electrostatic Precipitator	$1,822,000	Baseline	Baseline	Baseline

1. For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1. 24873.
2. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.

The Levelized Total Annual Cost and Unit Control Cost are used to evaluate the technology alternatives on a cost effectiveness basis. As can be seen from a review of Table 4.4-1 and 4.4-2, the fabric filter alternative is in the middle range for capital cost but has the highest levelized total annual cost and net present value.

In the BART Determination guidelines, EPA does not provide definition, or even discussion of reasonable, or unreasonable, Unit Control Costs. Similarly, EPA does not address reasonable or unreasonable ranges for the incremental cost effectiveness. The incremental cost effectiveness is a marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits between successively less effective alternatives. Because all the alternatives requiring new equipment for Unit 1 have the same removal rate, the incremental cost effectiveness is not effective for ranking the different technologies. However, the incremental cost is calculated for comparison between the existing ESP alternative and the other control options. The incremental cost effectiveness for each new control alternatives in Table 4.4-2 is above the range of reasonable costs used in other regulatory analyses and indicates that each new technology is prohibitively expensive. However, due to the lack of guidance on reasonable costs, the visibility analysis is conducted to determine if the additional controls are necessary to reduce visibility impacts.

4.4.2 PM VISIBLITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 1

The remaining step for the Unit 1 BART PM analysis was to conduct a visibility improvement determination. The modeling for Unit 1 uses two PM emission rates that distinguish between coarse and fine particulate as a basis for the visibility impairment impacts. One baseline emission rate representing the NDDH Modeling Protocol values of 36.7 lb PM_{Coarse}/hr and 5.5 lb PM_{Fine}/hr was modeled. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. However, as discussed in Section 1.5.5, the protocol emission rates are based upon actual maximum historical 24-hour emissions that are not representative of future maximum 24-hour emissions. After obtaining approval from NDDH to use alternative emission rates based upon representative stack conditions, Minnkota based the post-control emission rates upon application of CD specified rates applied to a more representative maximum heat input of 2,955 mmBtu/hr.

The Consent Decree requires MRYS to maintain or upgrade the PM controls on Unit 1 to achieve an emission rate of 0.015 lb PM/mmBtu if a dry FGD process is selected for SO_2 control or 0.030 lb PM/mmBtu if a wet FGD process is selected. A detailed engineering evaluation is required to determine if the existing ESP can achieve an emission rate of 0.015 lb PM/mmBtu for an extended period of time and that evaluation is outside the scope of this analysis. For the purposes of this report, it is assumed that the existing equipment will be able to meet the 0.030 lb PM/mmBtu emission rate specified by the CD. Post-control rates of 38.5 lb PM_{Coarse}/hr and 5.8 lb PM_{Fine}/hr were calculated and modeled based upon the CD emission rate of 0.015 lb PM/mmBtu and post-control rates of 77.1 lb PM_{Coarse}/hr and 11.6 lb PM_{Fine}/hr were calculated and modeled based upon the CD emission rate of 0.030 lb PM/mmBtu.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 1. The post-control CALPUFF model scenarios for MRYS Unit 1 were conducted with the protocol NO_X and SO_2 emission rates and the post-control PM emission rates as discussed previously in this section and in Table 1.5-1.

The results of the visibility impairment modeling at the protocol baseline PM emission rate for MRYS Unit 1 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for both post-control PM emission rates showed a reduction in visibility impairment impact for all Class 1 areas. In addition, the modeled visibility impairment impact for two of the Class 1 areas at both post-control PM emission rates was below the 0.50 dV threshold level. The TRNP – North and Lostwood Class 1 areas had a modeled visibility impairment impact above the 0.50 dV threshold level. The modeling results are presented in Table 4.4-3.

Table 4.4-3 – PM Visibility Impairment Impacts and Reductions, MRYS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)			Visibility Impairment Reduction (deciView)	
	Protocol Emissions	Post-Control Emissions[2] 0.030 and 0.015 Emission Rates		Post-Control Emissions[2] 0.030 and 0.015 Emission Rates	
TRNP-South Unit	0.549	0.466	0.465	0.083	0.084
TRNP-North Unit	0.628	0.503	0.500	0.125	0.128
TRNP-Elkhorn Ranch	0.374	0.328	0.328	0.046	0.046
Lostwood NWR	0.750	0.591	0.587	0.159	0.163

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

2 - PM emissions corresponding to the 0.030 and 0.015 lb/mmBtu rates specified in the CD. This scenario assumes protocol emission rates for NO_X and SO_2.

The number of days predicted to have visibility impairment due to MRYS Unit 1 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol and post-control emission rates. The results are presented in Appendix A. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control PM emission rates were reduced in all cases. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

4.5 EVALUATION OF IMPACTS FOR FEASIBLE PM CONTROLS – UNIT 2

Step four in the BART analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) lists four factors to be considered in the impact analysis.

- The costs of compliance;
- Energy impacts;
- Non-air quality environmental impacts; and
- The remaining useful life of the source.

Three of the four impacts required by the BART Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the BART determination for MRYS. In addition, as described in Section 1.4, the visibility impairment impact of each alternative was evaluated as part of the impact analysis.

4.5.1 COST ESTIMATES

Cost estimates for the PM control technologies were completed utilizing the Coal Utility Environmental Cost (CUECost) computer model (Version 1.0) available from the U.S. Environmental Protection Agency and engineering estimates based upon Burns & McDonnell's in-house experience. The CUECost model is a spreadsheet-based computer model that was specifically developed to estimate the cost of air pollution control technologies for utility power plants within +/- 30 percent accuracy. The EPA released the version of the model used for this study in February 2000. The model is available for download from the U.S. EPA website at www.epa.gov/ttn/catc/products. Operating information utilized as input into the model for the purpose of cost estimating is presented in Appendix C. Economic information utilized as input into the model is given in Table 1.2-1. The cost estimates for a PM control alternatives are summarized in Table 4.5-1. A Net Present Value (NPV) and Levelized Total Annual Cost (LTAC) were calculated for the each alternative utilizing the costs summarized in Table 4.5-1.

TABLE 4.5-1 – Cost Estimates for Unit 2 PM Control Alternatives

	FF	**COHPAC[1]**	**NEW ESP**	**EXISTING ESP[2]**
Capital Costs				
Direct Costs	$31,774,000	$20,445,000	$37,251,000	$0
Indirect Costs	$12,710,000	$8,178,000	$14,900,000	$0
Total Capital Costs	**$44,484,000**	**$28,623,000**	**$52,151,000**	**$0**
O&M Costs				
Includes Maintenance Costs, Power Costs, and Replacement Costs (if any)				
Total O&M Costs	**$3,500,000**	**$2,552,000**	**$2,381,000**	**$2,381,000**
Net Present Value (NPV)	**$81,479,000**	**$56,059,000**	**$74,667,000**	**$28,832,000**
Levelized Total Annual Cost (LTAC)	**$8,249,000**	**$5,682,000**	**$7,520,000**	**$2,973,000**

1. COHPAC costs are scaled down to represent a similar fabric filter with a flue gas to cloth ratio of 6 ACFM/ft^2.
2. Costs associated with the operation of the existing ESP are assumed equal to the operating costs for a new ESP.

The next step in the analysis for the BART alternatives is to review the unit control cost and incremental cost effectiveness of the remaining scenarios. Table 4.5-2 contains a repetition of the cost information from Table 4.5-1.

Because Unit 2 has existing PM control, the historic highest 24-month rolling average represents a controlled emission rate. Thus, the baseline annual tons of PM for Unit 2 in this BART analysis are calculated as the pre-controlled emissions from firing lignite fuel with an ash content of 9.6% at a heat input of 5,158 mmBtu/hr with the unit operating at 85% capacity. Using the conservative approach that 50% of the ash is emitted as fly ash and 50% of the ash becomes bottom ash; the resulting uncontrolled emissions are approximately 56,100 tons per year. The controlled emissions assumed application of the respective removal efficiency to the baseline emission rate with the same input conditions and unit operating time. The annual tons of PM reduction for Unit 2 are calculated as the difference between the protocol emissions and the controlled emissions associated to the respective removal efficiency.

TABLE 4.5-2 – Incremental Cost Effectiveness of Unit 2 PM BART Control Alternatives

BART Alternative	Levelized Total Annual Cost[1]	Annual Emission Reduction (tpy)	Actual Unit Control Cost ($/ton)[2]	Incremental Cost Effectiveness ($/ton)
Fabric Filter or Baghouse	$8,249,000	602	$13,700	$8,700
New Electrostatic Precipitator	$7,520,000	602	$12,500	$7,600
COHPAC Baghouse	$5,682,000	602	$9,400	$4,500
Existing Electrostatic Precipitator	$2,973,000	Baseline	Baseline	Baseline

1. For LTAC calculation, Capital Recovery Factor = 0.08718 and O&M Levelization Factor = 1. 24873.
2. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.

The Levelized Total Annual Cost and Unit Control Cost are used to evaluate the technology alternatives on a cost effectiveness basis. As can be seen from a review of Table 4.5-1 and 4.5-2, the fabric filter alternative is in the middle range for capital cost but has the highest levelized total annual cost and net present value.

In the BART Determination guidelines, EPA does not provide definition, or even discussion of reasonable, or unreasonable, Unit Control Costs. Similarly, EPA does not address reasonable or unreasonable ranges for the incremental cost effectiveness. The incremental cost effectiveness is a marginal cost effectiveness between two specific alternatives. Alternatively, the incremental cost effectiveness analysis identifies the rate of change of cost effectiveness with respect to removal benefits between successively less effective alternatives. Because all the alternatives requiring new equipment for Unit 2 have the same removal rate, the incremental cost effectiveness is not effective for ranking the different technologies. However, the incremental cost is calculated for comparison between the existing ESP alternative and the other control options. The incremental cost effectiveness for each new control alternatives in Table 4.5-2 is above the range of reasonable costs used in other regulatory analyses and indicates that each new technology is prohibitively expensive. However, due to the lack of guidance on reasonable costs, the visibility analysis is conducted to determine if the additional controls are necessary to reduce visibility impacts.

4.5.2 PM VISIBLITY IMPAIRMENT IMPACTS ANALYSIS – UNIT 2

The remaining step for the Unit 2 BART PM analysis was to conduct a visibility improvement determination. The modeling for Unit 2 uses two PM emission rates that distinguish between coarse and fine particulate as a basis for the visibility impairment impacts. One baseline emission rate representing the NDDH Modeling Protocol values of 178.7 lb PM_{Coarse}/hr and 28.1 lb PM_{Fine}/hr was modeled. The protocol rate was based upon maximum 24-hour emission rates from the 2000-2002 modeling period. However, as discussed in Section 1.5.5, the protocol emission rates are based upon actual maximum historical 24-hour emissions that are not representative of future maximum 24-hour emissions. After obtaining approval from NDDH to use alternative emission rates based upon representative stack conditions, Minnkota based the post-control emission rates upon application of CD specified rates applied to a more representative maximum heat input of 5,158 mmBtu/hr.

The Consent Decree requires MRYS to maintain or upgrade the PM controls on Unit 2 to achieve an emission rate of 0.030 lb PM/mmBtu. To achieve an emission rate greater than the 0.030 lb PM/mmBtu for an extended period of time may require the use of new control technology and would require a detailed engineering determination that is outside the scope of this analysis. For the purposes of this analysis, it is assumed that the existing equipment will be able to meet the 0.030 lb PM/mmBtu emission rate specified by the CD. Post-control rates of 133.7 lb PM_{Coarse}/hr and 21.0 lb PM_{Fine}/hr were calculated and modeled based upon the CD emission rate of 0.030 lb PM/mmBtu. No other PM emission rates were modeled based upon the results of the cost analysis.

Visibility impairment impact modeling was performed using the CALPUFF model with the difference between the impacts from protocol baseline and post-control hourly emission rates representing the visibility impairment impact reduction for MRYS Unit 2. The post-control CALPUFF model scenario for MRYS Unit 2 was conducted with the protocol NO_X and SO_2 emission rates and the post-control PM emission rate as discussed previously in this section and in Table 1.5-1.

The results of the visibility impairment modeling at the protocol baseline PM emission rate for MRYS Unit 2 showed that three of the Class 1 areas had a visibility impairment impact above the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. The visibility modeling results for the post-control PM emission rate showed a reduction in visibility impairment impact for all Class 1 areas. The modeling results are presented in Table 4.5-3.

Table 4.5-3 – PM Visibility Impairment Impacts and Reductions, MRYS Unit 2

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction (deciView)
	Protocol Emissions	**Post-Control Emissions[2]**	
TRNP-South Unit	0.580	0.563	0.017
TRNP-North Unit	0.619	0.570	0.049
TRNP-Elkhorn Ranch	0.360	0.345	0.015
Lostwood NWR	0.775	0.739	0.036

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

2 - PM emissions corresponding to the 0.030 lb/mmBtu specified in the CD. This scenario assumes protocol emission rates for NO_X and SO_2.

The number of days predicted to have visibility impairment due to MRYS Unit 2 emissions that were greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area were determined by the visibility model for the protocol emission rates. The results were summarized and presented in Table 4.5-4. Similarly, the same information for the post-control PM emission rates was summarized and is shown in Table 4.5-4. The number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area between protocol and post-control PM emission rates were reduced in the majority of cases. The TRNP – South Class 1 area in 2001 and 2002 each had one additional day with a visibility impairment impact exceeding 0.50 dV. The number of consecutive days exceeding 0.50 dV of impact was either the same or was reduced.

The magnitude of predicted visibility impairment and number of days predicted to have visibility impairment greater than 0.50 and 1.00 deciViews at any receptor in a Class 1 area varied significantly between years and Class 1 areas, for Unit 2. The TRNP – South Class 1 area in 2001 and 2002 each had a impact increase of one day in terms of days exceeding 0.50 dV. The approximate visibility impact increase for 2001 was 4% and for 2002 was 2%. The impact reduction in terms of days exceeding 0.50 dV varies from approximately 0% in multiple areas and years to approximately 14% for TRNP – North in 2001. The impact reduction in terms of days exceeding 1.00 dV varies from approximately 0% in multiple areas and years to approximately 13% for Lostwood NWR in 2000.

There are several plausible explanations for an increase in the number of days with a visibility impairment impact exceeding 0.50 dV for TRNP – South in 2001 and 2002. One possible cause could be the reduced exit velocity that was due to an increase in stack diameter and an increased flow rate caused by scrubbing of all of the flue gas. Because the modeling results presented in Table 4.5-3 showed a reduction in visibility impairment impacts for all Class 1 areas, additional research was not conducted to determine the cause of the increase.

Table 4.5-4 – Visibility Impairment Improvements – MRYS Unit 2 PM Scenarios

Class 1 Area	PM Control Technique	Days[2] Exceeding 0.5 dV in 2000	Days[2] Exceeding 0.5 dV in 2001	Days[2] Exceeding 0.5 dV in 2002	Days[2] Exceeding 1.0 dV in 2000	Days[2] Exceeding 1.0 dV in 2001	Days[2] Exceeding 1.0 dV in 2002	Consecutive Days[2] Exceeding 0.5 dV 2000	Consecutive Days[2] Exceeding 0.5 dV 2001	Consecutive Days[2] Exceeding 0.5 dV 2002
TRNP South	Protocol	41	28	51	18	14	27	3	3	4
	Maintain ESP	37	29	52	16	13	27	3	3	4
TRNP North	Protocol	32	43	47	18	21	29	2	4	4
	Maintain ESP	29	37	45	18	21	29	2	4	4
TRNP Elkhorn	Protocol	31	23	36	11	14	20	2	3	4
	Maintain ESP	29	23	36	11	13	19	2	3	4
Lostwood NWR	Protocol	52	51	48	30	31	25	3	3	5
	Maintain ESP	50	48	45	27	27	25	3	3	4

1 - Predicted visibility impairment impacts (90th percentile) for 2000-2002 for protocol and post-control PM emission levels.
2 - Number of days for predicted visibility impairment impacts provided in Appendix A.

5.0 BART RECOMMENDATIONS

This report presents the analysis of control technologies for each of three major pollutants (nitrogen oxides (NO_X), sulfur dioxide (SO_2), and particulate matter (PM)) for Minnkota Power Cooperative Inc.'s (Minnkota's) Milton R. Young Station (MRYS) Units 1 and 2. The final result of this analysis is a recommendation of the Best Achievable Retrofit Technology (BART) for each unit based upon "the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology" (70 FR 39163). The presented emission rates in this section are the BART recommendation.

As stated previously in Section 1.3.2, this report uses the requirements of the Consent Decree (CD) and associated NO_X BACT analysis as part of the analysis. Although Unit 1 and Unit 2 at MRYS are BART-eligible, the CD also requires that the NDDH establish BACT for NO_X control. With the specification to establish BACT for NO_X, the BART analysis was modified to replace the first four BART evaluation steps with the NO_X BACT analysis. The first four steps of BART are usually used to identify technologies, determine feasibility and evaluate cost, energy, non-air quality and useful life impacts. Because a BACT analysis results in the selection of the best available control technology, the visibility impacts evaluation is the only remaining step in the determination that must be performed to satisfy BART for NO_X. The MRYS NO_X BACT analysis study reports and additional support documents were submitted to the NDDH on October 6, 2006, March 19, and April 23, 2007 respectively. In addition, because the CD also requires a minimum level of control for both SO_2 and PM, this analysis evaluates the visibility impairment impacts of the BACT-level control technologies specified for SO_2 and PM in the CD and control technologies that exceed the specified level of control. The BART analysis does not review technologies that do not achieve the minimum level of control specified in the CD.

5.1 UNIT 1 BART RECOMMENDATIONS

As stated in previous sections of the report, the steps of the technology evaluation provided in the BART Determination Guidelines were completed for Unit 1. Each pollutant required a different approach in order to determine BART. This section provides a brief description of the approach used for each pollutant and summarizes the results for Unit 1.

The Consent Decree required a NO_X BACT analysis. Because a BACT analysis results in the selection of the best available the control technology, the visibility impacts evaluation is the only remaining step in the determination that must be performed to satisfy BART for NO_X. According to the BACT analysis, Selective Non-Catalytic Reduction (SNCR) post-combustion technology used in conjunction with Advanced Separated Overfire Air (ASOFA) was considered the best available technology and therefore was evaluated as BART for Unit 1. The results of the visibility impact analysis for this combination of NO_X control technologies demonstrate a visibility impairment impacts reduction in all Class 1 areas to levels below the discernable 0.5 dV threshold levels. Based upon the BACT analysis and the visibility impact analysis, SNCR in conjunction with ASOFA is recommended as BART for NO_X emissions.

For SO_2 emissions, the CD requires MRYS to install either a dry FGD process at 90% control or a wet FGD process at 95% control. Thus, both of these technologies were evaluated. The Powerspan Electro-Catalytic Oxidation (ECO™) system would meet the CD requirements but was determined infeasible because it is not commercially proven in a full scale unit. The cost analysis for Unit 1 resulted in wet FGD technology being the most cost effective alternative due to its lower levelized total annual cost and higher control efficiency. The energy and non-air quality impacts for dry and wet FGD were similar in quantity and nature and considered negligible in differentiating between the two technologies. The visibility impairment impacts for both dry and wet FGD were reduced to levels below the discernable 0.5 dV threshold levels. Based upon the impact analyses, the technology recommended as BART for SO_2 emissions is the wet FGD process.

The Consent Decree requires MRYS to maintain or upgrade the PM controls on Unit 1 to achieve an emission rate of 0.015 lb PM/mmBtu if a dry FGD process is selected for SO_2 control or 0.030 lb PM/mmBtu if a wet FGD process is selected. Both emission rates were evaluated as part of this analysis. Based solely on the cost estimates for the Unit 1 PM control alternatives, the options requiring new equipment would be eliminated from the analysis due to their excessive expense. However, because the BART guidelines do not provide a specific value associated with eliminating individual control alternatives, visibility impacts were evaluated to verify the necessity of the more restrictive PM emission rate. The visibility impact analysis indicates that either evaluated emission rate reduces visibility impairment in the Class 1 areas. The maximum additional improvement in visibility impairment impact provided by the more stringent emission rate is less than 1% of the 0.50 dV threshold level for discernable impacts that contribute to visibility impairment. Thus, based upon the cost and visibility impact analyses, the technology recommended as BART for PM emissions is maintaining the existing ESP.

Table 5.1-1 summarizes the control technologies and associated emission rates that are recommended as BART for each pollutant. The recommended BART emission rates are presented as a 30-day rolling average to account for variations in boiler operation, fuel sulfur content and fly ash properties.

Table 5.1-1 – Recommended BART 30-Day Rolling Average, MRYS Unit 1

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.36*
SO_2	Wet Flue Gas Desulfurization (FGD) Process	0.15
PM	Maintain Existing Electrostatic Precipitator (ESP)	0.030

* Excludes startups. See referenced BACT analysis for a detailed discussion.

The pollutant specific modeling results for MRYS Unit 1 described previously in the analysis represent the visibility impairment impact reduction attributable to a technology used to control an individual pollutant of concern. While this result supports an individual technology in terms of visibility impact reduction, the result is not representative of actual plant-wide operations. Application of the BART-recommended technologies will result in simultaneous control of all pollutants. Thus, a comparison of the visibility impairment reduction due to reducing the protocol emission rates to post-control emission rates for all pollutants on Unit 1 simultaneously is more representative of actual expected results. A modeling scenario was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies to Unit 1 and the results are presented in Table 5.1-2.

Table 5.1-2 – Visibility Impairment Impacts for Control of all Pollutants, MRYS Unit 1

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction
	Protocol Emissions	Post-Control Emissions	
TRNP-South Unit	0.549	0.077	0.472
TRNP-North Unit	0.628	0.075	0.553
TRNP-Elkhorn Ranch	0.374	0.050	0.324
Lostwood NWR	0.750	0.112	0.638

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

The simultaneous control of all pollutants for MRYS Unit 1 results in visibility impairment impacts that are less than one fourth of the threshold the EPA designates as contributing to visibility impairment. These modeling results provide additional support for proposing the control technologies recommended in this report for NO_X, SO_2 and PM emissions as BART.

5.2 UNIT 2 BART RECOMMENDATIONS

As stated in previous sections of the report, the steps of the technology evaluation provided in the BART Determination Guidelines were completed for Unit 2. Each pollutant required a different approach in order to determine BART. This section provides a brief description of the approach used for each pollutant and summarizes the results for Unit 2.

As stated previously in the report, the Consent Decree required a NO_X BACT analysis. Because a BACT analysis results in the selection of the best available the control technology, the visibility impacts evaluation is the only remaining step in the determination that must be performed to satisfy BART for NO_X. According to the BACT analysis, Selective Non-Catalytic Reduction (SNCR) post-combustion technology used in conjunction with Advanced Separated Overfire Air (ASOFA) was considered the best available technology and therefore was evaluated as BART for Unit 2. The results of the visibility impact analysis for this combination of NO_X control technologies demonstrate a visibility impairment impacts reduction for three of the Class 1 areas to levels below the discernable 0.5 dV threshold levels. The Lostwood NWR Class 1 area had a modeled visibility impairment impact of 0.543 dV. Based upon the BACT analysis and the visibility impact analysis, SNCR in conjunction with ASOFA is recommended as BART for NO_X emissions.

For SO_2 emissions, the CD requires MRYS to modify the existing wet FGD system on Unit 2 to achieve a removal efficiency of at least 90%. Modifications to the existing wet FGD at 90% control were evaluated as the minimum level of control for BART. In addition, because some wet FGD systems are capable of achieving 95% removal efficiency, modifications required to achieve 95% control were also evaluated for the wet FGD process. The Powerspan Electro-Catalytic Oxidation (ECO™) system would meet the CD requirements but was determined infeasible because it is not commercially proven in a full scale unit. The cost analysis for Unit 2 resulted in 90% control wet FGD technology being the most cost effective alternative due to its lower levelized total annual cost. The energy and non-air quality impacts for both wet FGD control levels were similar in quantity and nature and considered negligible in differentiating between the two technologies. The visibility impairment impacts for 90% and 95% wet FGD processes were reduced to levels below the discernable 0.5 dV threshold levels.

Because this is an evaluation of the same technology at different control levels, the evaluated impacts are relatively similar. Thus, an additional parameter was evaluated to determine which control level should be recommended as BART. The levelized total annual cost (LTAC) and the average visibility impact reduction for the 4 areas were combined to obtain dollars per deciView of improvement. The difference between LTAC is $795,000. The average difference in visibility impact reduction is 0.082 dV. Thus, the cost for the additional impact reduction is approximately $9,700,000 per deciView of improvement. The cost to achieve relatively little visibility improvement is exceedingly high because either control level already improves visibility impact to below the discernable threshold levels. Based upon the impact analyses, the technology recommended as BART for SO_2 emissions is the wet FGD process at 90% removal efficiency.

The Consent Decree requires MRYS to maintain or upgrade the PM controls on Unit 2 to achieve an emission rate of 0.030 lb PM/mmBtu. Control technologies meeting this emission rate and a more stringent emission rate of 0.015 lb PM/mmBtu were evaluated as part of this analysis. Based solely on the cost estimates for the Unit 2 PM control alternatives, the options requiring new equipment would be eliminated from the analysis due to their excessive expense. However, because the BART guidelines do not provide a specific value associated with eliminating individual control alternatives, visibility impacts were evaluated to verify the necessity of more restrictive PM controls. The visibility impact analysis indicates that an emission rate of 0.030 lb PM/mmBtu reduces visibility impairment in the Class 1 areas. Thus, based upon the incremental cost and visibility impact analyses, the technology recommended as BART for PM emissions is maintaining the existing ESP.

Table 5.2-1 summarizes the control technologies and associated emission rates that are recommended as BART for each pollutant. The recommended BART emission rates are presented as a 30-day rolling average to account for variations in boiler operation, fuel sulfur content and fly ash properties.

Table 5.2-1 – Recommended BART 30-Day Rolling Average, MRYS Unit 2

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO_X	Advanced Separated Over Fire Air (ASOFA) and Selective Non-Catalytic Reduction (SNCR)	0.35*
SO_2	Upgrade of Existing Wet Flue Gas Desulfurization (FGD) Process	0.30
PM	Maintain Existing Electrostatic Precipitator (ESP)	0.030

* Excludes startups. See referenced BACT analysis for a detailed discussion.

The pollutant specific modeling results for MRYS Unit 2 described previously in this analysis represent the visibility impairment impact reduction attributable to a technology used to control an individual pollutant of concern. While this result supports an individual technology in terms of visibility impact reduction, the result is not representative of actual plant-wide operations. Application of the BART recommended technologies will result in simultaneous control of all pollutants. Thus, a comparison of the visibility impairment reduction due to reducing the protocol emission rates to post-control emission rates for all pollutants simultaneously is more representative of actual expected results. A modeling scenario was run to determine the visibility impairment impact reduction resulting from simultaneous application of all control technologies and the results are presented in Table 5.2-2.

Table 5.2-2 – Visibility Impairment Impacts for Control of all Pollutants, MRYS Unit 2

Federal Class 1 Area	Visibility Impairment Impacts[1] (deciView)		Visibility Impairment Reduction
	Protocol Emissions	Post-Control Emissions	
TRNP-South Unit	0.580	0.173	0.407
TRNP-North Unit	0.619	0.169	0.450
TRNP-Elkhorn Ranch	0.360	0.104	0.256
Lostwood NWR	0.775	0.243	0.532

1 - Average 90th percentile predicted visibility impairment impact versus background visibility. A summary of the modeling scenarios is provided in Table 1.5-1 and the modeling results are presented in Appendix A.

The simultaneous control of all pollutants for MRYS Unit 2 results in visibility impairment impacts that are less than one half of the threshold the EPA designates as contributing to visibility impairment.

These modeling results provide additional support for proposing the control technologies recommended as BACT for NO_X emissions and those recommended for SO_2 and PM emissions as BART.

In addition to the visibility impairment impact modeling scenario conducted to determine the effects of simultaneous control of all pollutants for the individual units, another modeling scenario was conducted to combine the effects of both units. The modeling showed that the visibility impairment impact for all Class 1 areas was reduced to below the threshold the EPA designates as contributing to visibility impairment. Results of this scenario (labeled Run 5) are provided in Appendix A.

Appendix B

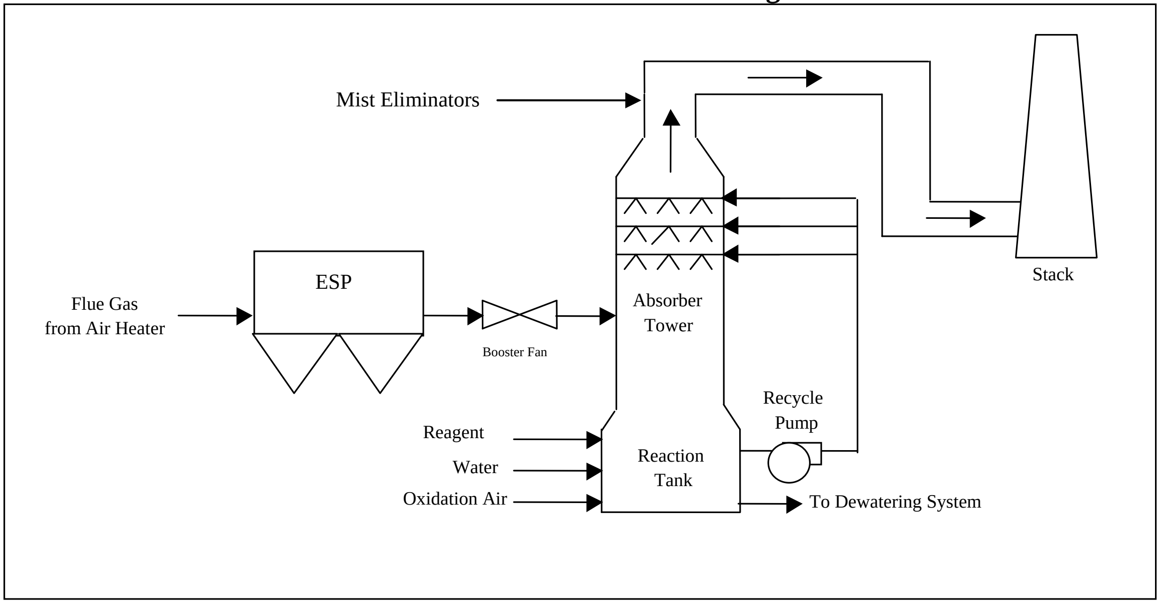
Detailed Description of SO_2 Control Technologies

Conventional Wet Scrubber (Wet FGD)

Wet FGD technology utilizing lime or limestone as the reagent and employing forced oxidation to produce gypsum (calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$) as the byproduct, is a common method of SO_2 control for coal-fired boilers. The gypsum byproduct is either landfilled or sold for commercial reuse.

A flow diagram of the wet FGD process is provided in the below figure. In the wet FGD process, a slurry of finely ground reagent (typically limestone or lime) in water is recirculated through an absorber tower where it is brought into turbulent contact with the flue gas. The contact between the flue gas and the slurry cools and saturates the gas via evaporation of water from the slurry. SO_2 is simultaneously absorbed into the slurry where it forms sulfurous acid which reacts with the reagent, forming calcium sulfite hemihydrate ($CaSO_3 \bullet \frac{1}{2}H_2O$), which can then be disposed of as a waste product or oxidized to calcium sulfate dihydrate, or gypsum, ($CaSO_4 \bullet 2H_2O$) before disposal or for commercial reuse. No commercial uses for sulfite waste products have been identified. Disposal of the sulfite waste can be somewhat difficult because of the thixotropic nature of the material. Sulfite wastes are often combined with fly ash to form a more easily handled waste solid. Disposal of the sulfate, or gypsum, as a waste is a bit more straightforward. The gypsum, depending upon its cleanliness, can be sold as a raw material for the manufacture of wallboard or cement. Where a gypsum product is desired, the most common approach is to sparge the reaction tank, or a separate holding tank with compressed air to convert the sulfite waste. Such systems are often referred to as Limestone Forced Oxidation (LSFO) systems.

Wet FGD Process Flow Diagram



In a limestone scrubber, as the limestone in the recirculating slurry is depleted, it is replenished with fresh slurry prepared by wet grinding of crushed limestone using reclaimed liquid from the dewatering system. Fresh water is also required to replace water lost to evaporation in the flue gas cooling process. Fresh water is often used to wash the mist eliminators; devices located at the scrubber exit to capture slurry droplets entrained in the exiting flue gas stream and return them to the scrubber. The mist eliminator wash removes accumulated materials from the mist eliminator chevrons, thus preventing solids buildup and pluggage. In addition, depending upon the mineral content of the coal, a portion of the reclaimed liquid may be blown down, or disposed of, to prevent excessive accumulation of mineral salts in the slurry which could result in mineral scaling or corrosion within the absorber equipment. The blow down rate varies with each plant. Fresh water makeup, both through the mist eliminator wash system and in the limestone grinding process, replaces the blow down and evaporative losses.

Lime scrubbers are very similar to limestone scrubbers. The use of lime rather than limestone can reduce the liquid-to-gas ratio and/or absorber size required to achieve a given SO_2 removal rate. Lime is sometimes used in wet FGD systems where extremely high SO_2 removal rates are desired or where limestone is not readily available. However, since lime is more expensive than limestone, the reagent cost is much higher for a lime system. Therefore, the vast majority of wet FGD systems are designed to use limestone as the neutralizing reagent.

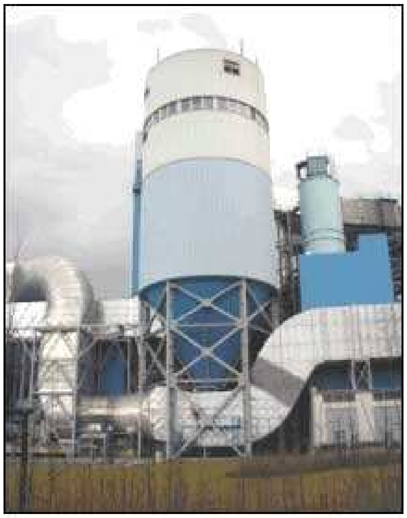
Advantages of the wet FGD systems include lower operating costs, primarily due to the ability to use limestone instead of lime as a reagent, the production of a salable by-product and high removal efficiency. Also, wet FGD systems have a high turndown capability and plant operational flexibility is not hindered to the same degree as the semi-dry, CFB and FDA processes. This last advantage is important where wet FGD systems are applied to load following units.

Disadvantages of wet FGD systems include corrosion due to a wet environment with corrosive chemicals including salts of sulfurous and sulfuric acid and hydrochloric acid. Also, because the wet systems are more mechanically complex, they typically require larger maintenance staff than some of the other alternatives. The greater mechanical complexity also contributes to a greater capital cost for wet FGD systems. Finally, because wet FGD systems completely saturate the flue gas stream, nearly all the SO_3 or H_2SO_4 vapor in the entering flue gas is condensed into aerosol droplets which are too small to be efficiently captured in the scrubber. Fifty percent or more of these droplets pass through the scrubber. Where units are burning high sulfur fuels, this can cause a plume opacity problem.

Wet FGD systems saturate the flue gas stream with moisture and as a result, operate with a wet stack. Two problems can occur with a wet stack. The first is entrainment of condensed liquids from the stack liner interior. The pressure of the flue gas changes as it traverses the stack and additional moisture condenses as a result. Some of that condensation occurs on the interior of the stack liner because it is normally a bit cooler than the flue gas. The condensed liquid runs down the interior of the liner and a significant fraction can become entrained in the flue gas stream, especially where droplets gather on liner surface irregularities such as mortar joints between bricks. Wet stacks are typically designed to have full load flue gas velocities of no more than approximately 60 feet per second to combat this reentrainment.

Conventional Dry Scrubbers (Dry FGD)

As an alternative to wet FGD technology, the control of SO_2 emissions can be accomplished using semi-dry FGD technology. The most common semi-dry FGD system is the lime Spray Dryer Absorber (SDA) using a Fabric Filter (FF) for downstream particulate collection. The semi-dry FGD process became popular in the U.S. beginning in the late 1970s as a way to comply with the New Source Performance Standards (NSPS) for electric utility steam generating units for which construction commenced after September 18, 1978 (40 CFR Part 60, Subpart Da). These standards require that all new coal-fired electric utility boilers be equipped with a “continuous system of emission reduction” for SO_2. However, the standards allowed SO_2 removal efficiency as low as 70 percent for facilities burning low-sulfur coal. The semi-dry FGD process could meet this requirement, and was often selected as the SO_2 control technology for many new coal-fired power plants that were built in the 1970s and 1980s and designed to burn low-sulfur western coal. In the late 1980s and through the 1990s, most of the new coal-fired boilers built in the U.S. were for small Independent Power Producer (IPP) projects, and many of these also selected the semi-dry FGD process.



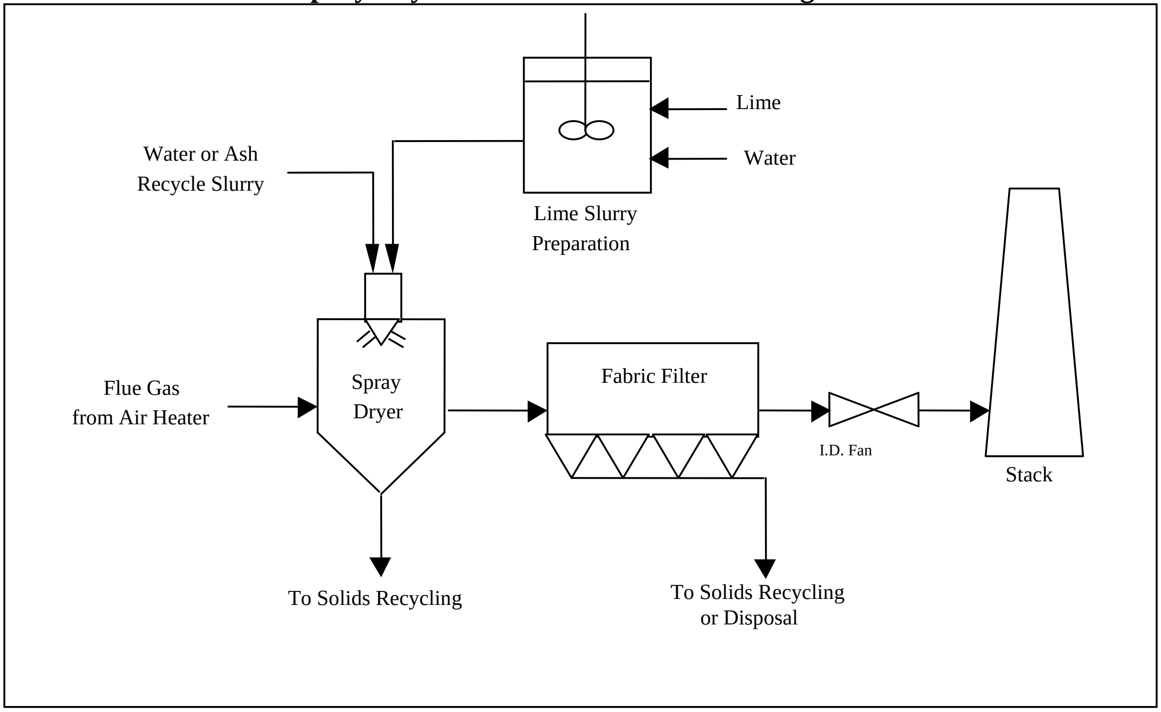
Typical SDA at a 533 MWe power plant in the Czech Republic.

Spray Dryer Absorber

There are several variations of the semi-dry process in use today. This section addresses the spray dryer absorber (SDA) process. Two other variations, the Flash Dryer Absorber (FDA) and Circulating Fluidized Bed (CFB) Scrubber are addressed in following sections. They primarily differ by the type of reactor vessel used, the method in which water and lime are introduced into the reactor and the degree of solids recycling.

A schematic diagram of the spray dryer absorber process is provided in the below figure. In the spray dryer absorber process, boiler flue gas is introduced into a Spray Dryer Absorber (SDA) into which hydrated lime (calcium hydroxide, $Ca(OH)_2$) and water are added as dispersed droplets. The $Ca(OH)_2$ reacts with SO_2 that has been absorbed into the water to form primarily calcium sulfite and some calcium sulfate. The heat from the flue gas causes the water to evaporate, cooling the gas and drying the reaction products. Because the total water feed rate is much lower than that of the wet FGD process, the reaction products are dried in the SDA and the flue gas is only partially saturated. The amount of water added to the process is carefully controlled so that the flue gas temperature is maintained well above the saturation, or dewpoint, temperature (typically 30-40 ^{0}F above saturation) to avoid corrosion problems. Cooling the gas to this point significantly increases the SO_2 control efficiency over injection of lime into hot, dry flue gas. The reaction product leaves the SDA as fine dry particles entrained in the flue gas. The flue gas enters the SDA at the top and flows downward, co-current with the introduced lime slurry. This characteristic is the opposite of the wet FGD system which introduces flue gas into the bottom of the absorber, countercurrent to the falling slurry spray.

Spray Dryer Absorber Process Flow Diagram



In the lime spray drying process, quicklime (CaO) is slaked with water to form lime slurry which is then injected into the SDA along with additional water through a rotary atomizer or dual fluid nozzle or similar apparatus. Recycled particulate matter (PM) from the PM control equipment downstream of the SDA is often mixed with the lime slurry before injection into the SDA to provide additional surface area for SO_2 absorption. The flue gas is introduced into the SDA in a manner designed to maximize the contact between the gas and the droplets and to prevent slurry impingement on the walls of the SDA. The turbulent mixing of the flue gas and the slurry droplets promotes rapid absorption of SO_2 into the water of the slurry droplets. The chemical reactions between the absorbed SO_2 and the calcium hydroxide take place within the droplet as the flue gas moves through the SDA. The flue gas is cooled and partially humidified as the water evaporates, leaving a mixture of fly ash and dry powdered reaction product entrained in the flue gas. Some of the solid particles fall to the bottom of the reactor and are collected by a waste handling system. Entrained particles are collected in an electrostatic precipitator (ESP) or fabric filter (FF) downstream of the SDA.

An additional distinguishing characteristic of the SDA is that it must be located upstream of a particulate control device, as opposed to the wet FGD process which is normally the last flue gas treatment process before discharge to the stack. For new plants, this point is not of such great importance. However, when retrofitting FGD equipment to an existing coal-fired plant, which already has particulate control equipment installed, this becomes an important point. If a suitable location exists for the insertion of a new SDA upstream of an existing PM control device, and if the performance of the existing PM control device would not be overly degraded by the additional PM loading, then the retrofit process would consist only of installation of the SDA, reagent preparation and waste handling systems. However, many times one, or both, of these conditions do not exist and the choice to utilize an SDA requires the installation of a new PM control device, such as an ESP or fabric filter. Where this situation exists, the capital cost of the SDA option increases significantly.

Semi-dry processes have some notable advantages compared to wet FGD processes including a dry byproduct which can be handled with conventional ash handling systems. Because the semi-dry system does not have a truly wet zone, corrosion problems in the SDA are eliminated, or significantly reduced, to the point exotic materials of construction are not required. Spray dryer systems utilize less complex equipment resulting in a reduced capital cost and allowing somewhat smaller operations and maintenance staff. Where a fabric filter is utilized as the downstream particulate control device for a semi-dry process, the lime content of the filter cake on the fabric filter reacts with condensed SO_3 in the flue gas stream capturing and neutralizing much of the acid aerosol. Consequently, semi-dry FGD options, paired with a fabric filter for PM control, have very low emissions of acid aerosols.

The primary disadvantages of the lime spray dryer process make it less likely to be applied to large power plant boilers, especially those firing high-sulfur coal. The lime spray dryer requires the use of lime, which is typically much more expensive than limestone. While lime contains approximately 1.8 times more calcium than limestone on a mass basis, lime can cost up to five times more than limestone on a mass basis. Therefore, reagent costs for a lime based process are typically higher than a limestone-based process for a given application.

Wastes from semi-dry processes have very limited possibility for reuse due to fly ash contamination. Also, where fly ash might be sold for other uses, contamination with the semi-dry FGD reaction products typically eliminates commercial options for reuse. Where fly ash sales are to be maintained, a second PM control device would be required for the semi-dry FGD system exhaust stream, increasing both capital and O&M costs.

Spray dryer absorbers have much more stringent size limitations than wet FGD scrubbers. Typically units larger than 250 to 300 MW will require at least two SDA vessels, thus driving up capital costs and system complexity for larger units, while wet FGD systems can handle up to 1000 MW in a single absorber module. SDAs do not have the same turndown capabilities as wet FGD absorbers, further limiting applicability for load following units. Finally, lime spray dryer systems do not have the same level of experience with high SO_2 removal requirements in high sulfur applications that wet FGD systems have.

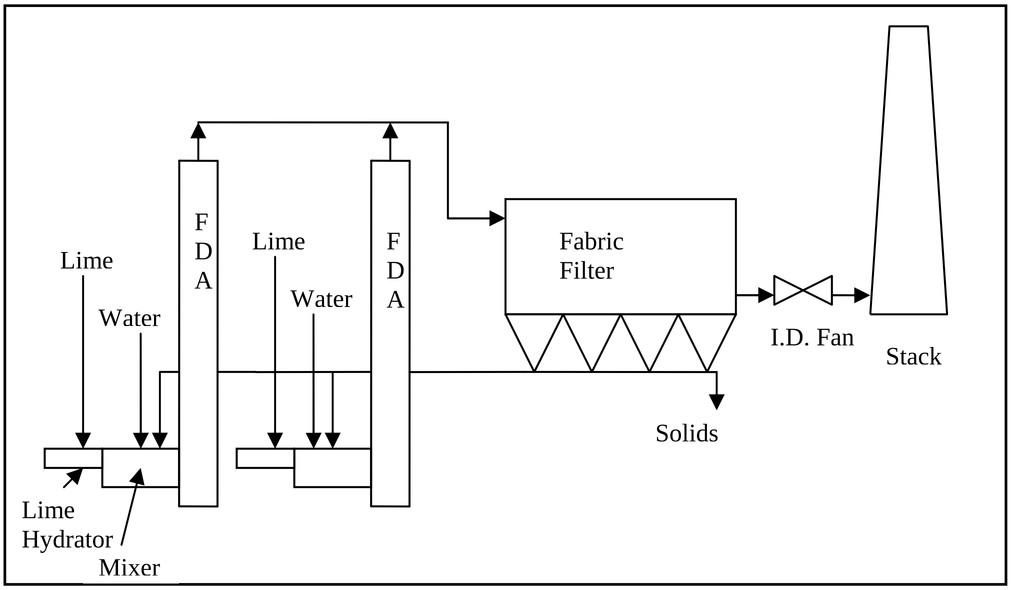
Flash Dryer Absorber

The Flash Dryer Absorber (FDA) is a further development of the lime spray dryer process. The approach is similar in that the flue gas is only partially saturated during the process and thus corrosion problems are either reduced or eliminated. Like the SDA, waste solids from the particulate control process can be added to the reagent feed stream to the reactor. Similar to the SDA, the FDA mixes lime, water and recycled PM for enhanced surface area. Recycled PM, along with absorption products and unreacted lime, are collected downstream of the FDA and a sizable fraction recycled to the FDA. Unlike the SDA, the FDA recycles a very high fraction of the captured PM. Because of this, the ratio of solids to liquid in the reagent stream injected into the FDA reactor is much higher than the SDA. The ratio is so much higher that the wetted recycled solids appear to be a relatively dry free flowing stream after wetting in the mixing stage.[14] Because the reagent stream starts off much higher in solids, the liquid film thickness on the wetted solids is much thinner and the drying time for the injected solids is much shorter than a typical SDA. This allows the FDA to function with a significantly smaller reactor compared to the typical SDA absorber vessel. Like the SDA, the water injection rate of the FDA is controlled to lower the flue gas temperature to optimize the SO_2 control efficiency while avoiding saturation and the accompanying corrosion problems. Unlike the SDA, the flue gas flows vertically upward in the FDA. The figure below is a schematic presentation of the FDA design.

---

[14] "Use of a Circulating Fluid Bed for Flue Gas Desulfurization"' Toher, John, G. Lurgi-Lentjes N. America.

Flash Dryer Absorber FGD Process Flow Diagram



The FDA utilizes quicklime (CaO) instead of hydrated lime as a reagent. The reasoning given for this by the designers is that when purchasing lime, although the price per ton is similar, the quicklime has 32% more calcium (SO_2 neutralization component) per ton than hydrated lime. Also, because quicklime is denser (900-1,200 kg/m^3 for quicklime vs. 450-640 kg/m^3 for hydrated lime), both transport and onsite storage capacity requirements can be smaller. However, direct injection of quicklime has resulted in less efficient reagent utilization compared to hydrated lime use. This is theorized to be due to hot spots created in the reaction zone by the hydration of the quicklime. The heat of hydration of quicklime is approximately 1.1 mmBtu/ton, so there is considerable heat evolved during the hydration step. To avoid adding this heat to the flue gas or creating hot spots that could reduce lime utilization, the FDA design incorporates a separate lime hydration stage where more than the stoichiometrically required amount of water is added to the quicklime in stages. The super stoichiometric water is heated during the slaking process and evaporates, leaving dry hydrated lime. The hydrated lime, recycled solids and water are then combined in a mixing vessel just prior to injection into the reactor.

Like the SDA, the FDA must be followed by a PM control device to capture the dry solids in the FDA exhaust. The great majority of these solids are recycled back to the FDA. The non recycled fraction is a mixture of calcium sulfite/sulfate solids, unreacted lime and fly ash for which limited possibilities for reuse exist. Also, in those instances where fly ash sales produce an income for the power plant, addition of the FDA solids to the fly ash will likely render the waste solids stream without value. Where the plant receives revenue from fly ash sales, the lost revenue would be an additional cost of FDA implementation.

The FDA is a relatively recent modification of the semi-dry FGD concept and as such, has not established a significant field record at this time. In their paper on FDA technology in 2002[15] Alstom cited a 280 MW plant in China with an 85% SO_2 removal efficiency. This plant had an FDA installed upstream of an ESP. Dry and semi-dry scrubbers installed upstream of a fabric filter have been consistently shown to achieve approximately 5-10% greater acid gas removal efficiency due to absorption and neutralization taking place in the filter cake of the fabric filter. Typically ESPs downstream of an FDA or other dry or semi-dry SO_2 scrubbing system are attributed no more than 5% SO_2 removal efficiency.

Advantages of the FDA over wet FGD systems are similar to those for the semi-dry process described previously, including ease of byproduct handling, much less aggressive corrosion conditions allowing the use of more common, less expensive materials of construction, less complex equipment, and potentially enhanced SO_3 control when combined with a fabric filter. FDA advantages also include a significantly smaller reactor/absorber which translates into a lower area requirement than either wet or semi-dry FGD systems, though manufacturers often provide multiple FDA's, even on smaller units.

Disadvantages of the FDA, when compared to the wet FGD system are similar to those described for the semi-dry process, including reactor size limitations, lower turndown ratio, more expensive reagent, and lack of byproduct market value.

Circulating Fluidized Bed Absorber (CFB)

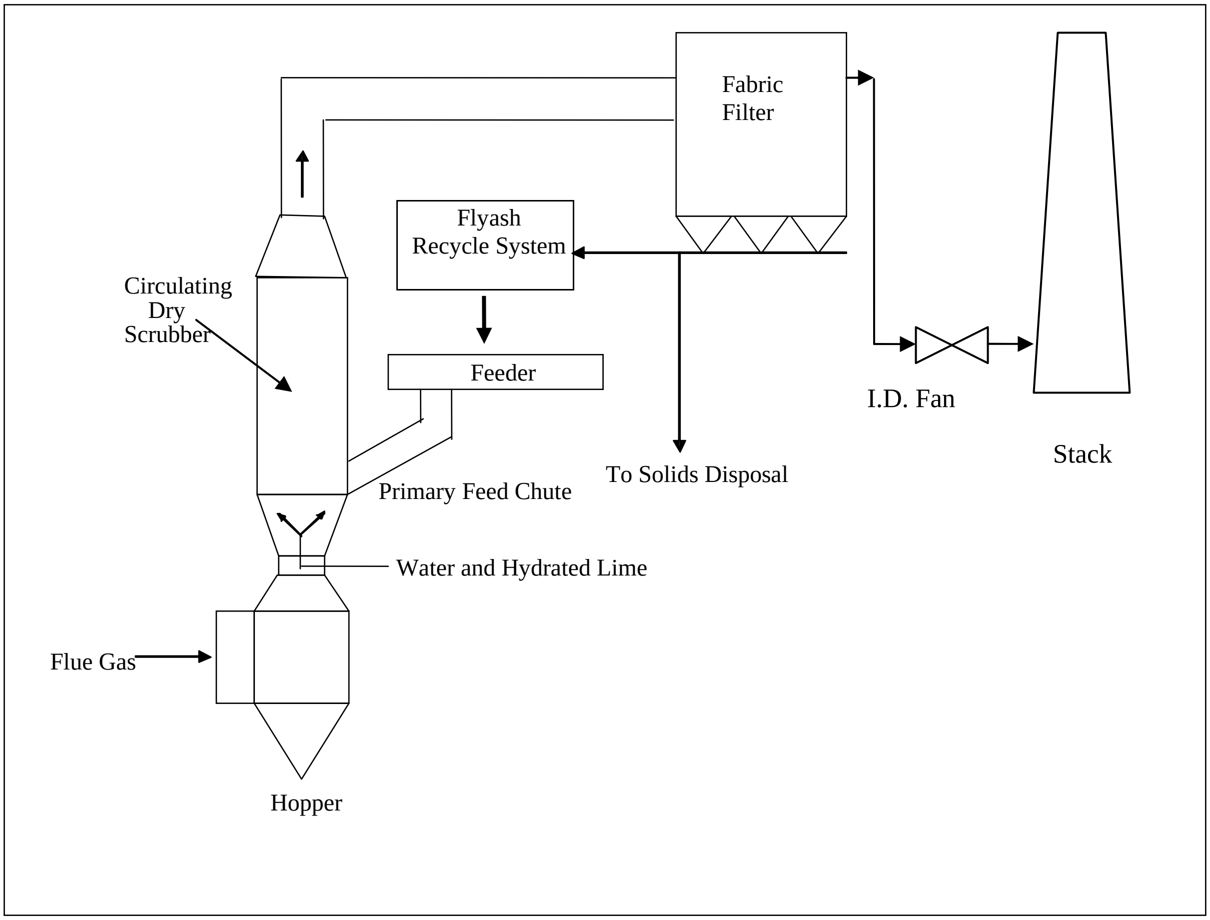
In the circulating fluidized bed dry scrubbing process, the flue gas is introduced into the bottom of a reactor vessel at high velocity through a venturi nozzle, and mixed with water, hydrated lime, recycled flyash and FGD reaction products. High velocity movement of the gas through the reactor suspends the solids creating a fluidized bed. A CFB absorber vessel would be a smaller diameter than the SDA discussed previously in this report. A schematic representation of the CFB process is shown in the below figure. The smaller diameter absorber helps maintain higher flue gas velocities required to maintain the fluidized bed. Water injected into the venturi throat cools the flue gas and wets the recycled solids similar to the process described previously for the FDA. Dry, powdered, hydrated lime is injected into the bed near the bottom of the absorber vessel, above the venturi, and dissolves in the thin water film on the recycled solids. SO_2 from the flue gas is also absorbed into the evaporating water film and reacts with the lime to produce both calcium sulfite and sulfate reaction products. Flue gas temperatures are typically

---

[15] "Alstom Power's Flash Dryer Absorber For Flue Gas Desulfurization", Ahman, Barranger and Marin, Proceedings of IJPGC '02, June 24-26, 2002.

reduced from 300 ^{0}F to approximately 160 ^{0}F to optimize SO_2 removal efficiency. The evaporation of the water cools and partially humidifies the flue gas and maintains the bed in a slightly moist, powdery condition. The continuous motion of the bed helps prevent solids deposition inside the absorber and promotes regeneration of the particle surfaces, exposing additional lime to react with absorbed SO_2. Particles that are entrained in the flue gas leaving the top of the reactor are collected in an ESP or fabric filter downstream of the CFB absorber. A large portion of the collected particles is recycled to the reactor, sustaining the bed and improving lime utilization. CFB absorbers have been installed with both fabric filters and ESPs for particulate control.

Circulating Fluidized Bed FGD System



The CFB absorber dry scrubbing process utilizes a bed of fluidized particles to provide an extended surface area for wetting, evaporation and SO_2 absorption. The extended surface decreases the time required for SO_2 absorption. Even though the gas velocity is higher than a wet FGD absorber or an SDA, the CFB absorber is not taller than either of these vessels.

The CFB has many of the same advantages of the SDA and FDA such as a dry byproduct, simplified waste handling systems and conventional materials of construction. CFBs also have less rotating equipment than wet FGD or SDA systems, thus simplifying maintenance requirements somewhat. Like the SDA and FDA, the CFB application with a fabric filter for particulate collection will also achieve very good acid aerosol control. Unlike the SDA the CFB does not require dual fluid nozzles or atomizers in the absorber. This feature simplifies the absorber maintenance of a CFB over that of the SDA. Also, because lime and water are injected separately into the CFB, increased reagent requirements can be met without increasing saturation of the flue gas.

Disadvantages of the CFB process include higher reagent cost and lower utilization than SDAs in similar applications and more limited turndown capability. In a recent study[16] the National Lime Association determined that compared to CFBs in similar applications, the SDA achieved slightly lower SO_2 removal with slightly better reagent utilization. Because CFBs must maintain gas velocities within a fluidizing range, a flue gas recycle duct from the absorber exhaust to the inlet is sometimes included to allow for partial recycle of flue gas to maintain bed velocity and improve the turndown ratio. Similar to the SDA and FDA processes, CFBs are size limited and multiple absorbers are required for applications larger than 250-300 MW.

An additional disadvantage of the CFB is pressure drop. Because the CFB must maintain the fluidized bed condition, the pressure drop across the absorber is typically 8-10 in. w.g. compared to an SDA at 6-8 in. w.g. and a wet FGD system at approximately 6 in. w.g.

Powerspan Electro-Catalytic Oxidation (ECO™) System

The Powerspan Electro-Catalytic Oxidation (ECO™) system is a multipollutant control technology designed to control emissions of NO_x, SO_2, fine particulate, mercury and certain Hazardous Air Pollutants (HAPs). The ECO™ process has two main process vessels, a barrier discharge reactor and a multi-level wet scrubber.

Powerspan is also making the technology available for systems that do not require NO_x removal by removing the barrier discharge reactor. Powerspan claims a routine SO_2 removal efficiency of 98% with inlet concentrations up to approximately 2,000 ppm.

---

[16] "Economics of Lime and Limestone for Control of Sulfur Dioxide"; DePriest, William & Gaikwas, Rajendra P; National Lime Association (www.lime.org/NLADryFGD.PDF); September, 2002.

The system utilizes aqueous ammonia as a reagent in two scrubber loops, with varying pH to control collection efficiency in the lower and upper loops. The ammonia reacts with the collected SO_2 in aqueous solution to produce ammonium sulfate as a byproduct.

50-MW ECO Demo at FirstEnergy's R.E. Burger Plant

The ammonium sulfate is then salable as fertilizer, thus turning byproduct disposal into a profitable venture for system operators. Captured mercury and other oxidized metals are removed from the scrubber bleed stream with activated carbon and disposed of as a hazardous waste. Ash and insoluble metals are filtered from the scrubber bleed stream before fertilizer production and disposed of with other particulate wastes from upstream particulate control equipment. The ammonium sulfate can be sold as an aqueous product or crystallized, granulated and sold.

Subject: Milton R. Young Station
BART Conference –11/21/2007

Dear Mr. O'Clair:

This letter is to follow-up on our discussions during the above subject meeting. As I indicated during the meeting, the methodologies the Department is pursuing with respect to the various emission limitations has merit. However, we do take exception to some of the actual limitations proposed. These are addressed below.

Unit 1

The Department proposed a SO_2 limitation of 95% removal (30 d.r.a.) or 0.12 lb/10^6 Btu (30 d.r.a.). The Department may wish to remove the lb/10^6 emission rate provision, as Minnkota is subject to a Consent Decree which stipulates that the removal shall be 95%.

The Department has proposed a NO_x limitation of 0.36 lb/10^6 Btu (30 d.r.a.), except during startups. Minnkota requests the exception be extended to startups, shutdowns, and malfunctions. Unless all cyclones are in operation over-fired air and selective non-catalytic reduction technologies are ineffective or of limited effectiveness. During startups and shutdowns, individual cyclones are put in service or taken out of service as the Unit generation is increased or decreased. A malfunction can also cause cyclones to be taken out of operation.

The Department proposed a NO_x startup limitation of 1070.7 lb/hr (24-hr rolling avg.) Utilizing a NO_x lb/hr emission rate for startups that is derived from data obtained when the Unit is at full load is not appropriate; The NO_x controls are effective at full load conditions whereas the NO_x controls are ineffective or of limited effectiveness during startup. Based upon the information presented previously in the NO_x BACT analysis, Minnkota requests a NO_x startup/shutdown/malfunction limitation of 2070.2 lb/hr (24-hr rolling average).

Unit 2

The Department proposed a SO_2 limitation of 95% removal (30 d.r.a.) or 0.12 $lb/10^6$ Btu (30 d.r.a.). The limitation of 0.12 $lb/10^6$ Btu (30 d.r.a.) is not acceptable to Minnkota. During periods of time when the sulfur content of the coal being burned is lower than normal, wet FGD systems can not remove as high a percentage of the SO_2 as would normally be removed, due to mass transfer limitations. Minnkota requests the SO_2 emission limitation be increased to 0.15 $lb/10^6$ Btu (30 d.r.a.). As Minnkota has a SO_2 limitation of 90% removal requirement under a Consent Decree, the Department may wish to add this restriction for clarity. Therefore, the revised limitation would be 95% SO_2 removal (30 d.r.a.) or 0.15 $lb/10^6$ Btu (30 d.r.a.), whichever is least restrictive, but not less than 90% removal (30 d.r.a.)

The Department has proposed a NO_x limitation of 0.35 $lb/10^6$ Btu (30 d.r.a.), except during startups. Minnkota requests the exception be extended to startups, shutdowns, and malfunctions. Unless all cyclones are in operation over-fired air and selective non-catalytic reduction technologies are ineffective or of limited effectiveness. During startups and shutdowns, individual cyclones are put in service or taken out of service as the Unit generation is increased or decreased. A malfunction can also cause cyclones to be taken out of operation.

The Department proposed a NO_x startup limitation of 2011.6 lb/hr (24-hr rolling avg.) Utilizing a NO_x lb/hr emission rate that is derived from data obtained when the Unit is at full load is not appropriate; The NO_x controls are effective at full load conditions whereas the NO_x controls are ineffective or of limited effectiveness during startup. Based upon the information presented previously in the NO_x BACT analysis, Minnkota requests a NO_x startup/shutdown/malfunction limitation of 3995.6 lb/hr (24-hr rolling average).

As discussed, a more exact definition of startup is needed than initially proposed by the Department. Minnkota proposes the following:

Startup is that period of time from initial fuel combustion to the point in time when:

- The measured heat input to the boiler on a 6-hour rolling average basis is greater than or equal to (2500 million Btu/hr for Unit 1, or 4800 million Btu/hr for Unit 2); or
- The amount of time reported for the longest individual startup period during actual operation between January 1, 2001 and December 31, 2005 (61 hrs. for Unit 1, or 115 hrs. for Unit 2) elapses, whichever occurs first; or
- Fuel firing is discontinued prior to satisfying either previous criteria.

The above definition was included in our previously submitted BACT analysis.

A definition of "shutdown" may also be appropriate. Minnkota proposes the following definition (if a definition is required):

> Shutdown is that period of time beginning when the Unit's generation is reduced in a continuous manner with the intention of discontinuing fuel firing, until fuel firing is discontinued.

Because the anticipated NO_x emissions are based upon computer modeling of the boiler and the chemistry associated with the particular NO_x control technology, the NO_x emissions may be more or less than indicated in the BACT and BART analyses. Therefore, Minnkota reserves the right to request changes to an operating permit which may be issued, or the State Implementation Plan, which incorporates NO_x limitations.

Minnkota thanks the Department for its attention to the issues raised during our recent meeting and those in this letter. Should you have any questions concerning the above, please contact me at 701-795-4221 or at jgraves@minnkota.com.

Sincerely,

John T. Graves

Subject: SCR Pilot Testing

Dear Mr. O'Clair:

Enclosed, please find a report entitled "APPROPRIATENESS OF CONDUCTING PILOT TESTING OF SELECTIVE CATALYTIC REDUCTION (SCR) TECHNOLOGY AT MILTON R. YOUNG STATION UNITS 1 AND 2, FOR USE IN A NO_X BACT ANALYSIS". This report is submitted response to the Department's request that Minnkota consider a pilot test of SCR catalysts, at Milton R. Young Station, to gather additional data for use in Minnkota's previously submitted NOx BACT analysis. This report addresses three aspects that must be considered when making a decision to pursue SCR catalyst pilot test. The aspects are: 1) the legal basis for the testing; 2) is there a reasonable expectation that the results would be different than the results of previous testing; 3) could the testing be accomplished in the required amount of time.

Based upon the information presented in the enclosed report, Minnkota has decided not to pursue SCR pilot testing at Milton R. Young Station, as elaborated in the document.

Should you have any questions concerning the above, or the enclosed document, please contact me by telephone at 701-795-4221 or by email at jgraves@minnkota.com.

Yours truly,

August 14, 2007

BACKGROUND

The North Dakota Department of Health (NDDH) has requested that Minnkota Power Cooperative (Minnkota) consider performing a pilot test at the Milton R. Young Station (MRYS) to investigate the technical feasibility of Selective Catalytic Reduction (SCR) technology for control of emissions of nitrogen oxides (NO_x) from the North Dakota lignite-fired cyclone boilers at that power plant. The results of the pilot test would be used in the NOx BACT analysis for MRYS. Technical feasibility of SCR application to utility boilers firing this fuel is a principal issue in the determination of best available control technology (BACT) for NO_x emission control at MRYS. The determination of BACT for NO_x emission control at MRYS is a requirement of the Consent Decree (CD) filed in the case *United States of America and State of North Dakota v. Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative.*

Minnkota has evaluated NDDH's request and has decided not to pursue SCR pilot testing at MRYS for three reasons as elaborated in this document, below. The reasons for not conducting further pilot testing prior to the BACT determination are:

1. Pilot testing is specifically not required by the BACT determination procedures established by the U.S. Environmental Protection Agency (EPA).
2. Previous research, including previous SCR pilot testing conducted at the Coyote Station, indicates that there is not sufficient reason to believe that the pilot testing suggested by NDDH will produce results any different from those obtained from the prior pilot test.
3. The compliance schedule for installation of NO_x BACT technology at MRYS as established by the CD cannot be met if pilot testing of SCR, followed by installation of SCR, is selected as the basis for BACT.

Each of these points is explained further in the text that follows.

REGULATORY BASIS FOR MINNKOTA'S DECISION NOT TO CONDUCT PILOT SCR TESTING

Minnkota's decision not to conduct pilot testing of SCR technology is supported on a regulatory basis for the following reasons:

1. EPA Guidance Specifically Describes When an Emission Control Technology is "Technically Feasible"

EPA has prepared a New Source Review Workshop Manual (Draft, October 1990) that explains, in detail, the evidence and analysis necessary to support a BACT determination. This process of defending a particular BACT recommendation is summarized in the Workshop Manual as follows:

> The applicant's role is primarily to provide information on the various control options and, when it proposes a less stringent control option, provide a detailed

> rationale and supporting documentation for eliminating the more stringent options. It is the responsibility of the permit agency to review the documentation and rationale presented and: (1) ensure that the applicant has addressed all of the most effective control options that could be applied; and (2) determine that the applicant has adequately demonstrated that energy, environmental, or economic impacts justify any proposal to eliminate the more effective control options. Where the permit agency does not accept the basis for the proposed elimination of a control option, the agency may inform the applicant of the need for more information regarding the control option. However, the BACT selection essentially should default to the highest level of control for which the applicant could not adequately justify its elimination based on energy, environmental and economic impacts. If the applicant is unable to provide to the permit agency's satisfaction an adequate demonstration for one or more control alternatives, the permit agency should proceed to establish BACT and prepare a draft permit based on the most effective control option for which an adequate justification for rejection was not provided. [Workshop Manual at B.53.]

The Workshop Manual requires an applicant to "make a good faith effort to compile appropriate information from available information sources, including any sources specified as necessary by the permit agency." [*Id.* at B.11]. This analysis should at least identify technologies that may be potentially transferable to the particular source, though later those technologies may prove technically infeasible or economically cost-ineffective.

For each alternative emission control technique, the applicant should analyze whether the control technique is feasible. EPA defines a *technically feasible alternative as one that is available* (i.e., commercially available for the application in question) *and applicable* (i.e., whether the available controls may reasonably be deployed on the source in question). The Workshop Manual provides a detailed analysis of the availability and applicability of a control technology, which bears quoting at length:

> In step 2, the technical feasibility of the control options identified in step 1 is evaluated. This step should be straightforward for control technologies that are demonstrated—if the control technology has been installed and operated successfully on the type of source under review, it is demonstrated and technically feasible. For control technologies that are not demonstrated in the sense indicated above, the analysis is somewhat more involved.
>
> Two key concepts are important in determining whether an undemonstrated technology is feasible: "availability" and "applicability." As explained in more detail below, a technology is considered "available" if it can be obtained by the applicant through commercial channels or is otherwise available within the common sense meaning of the term. An available technology is "applicable" if it can reasonably be installed and operated on the source type under consideration. A technology that is available and applicable is technically feasible.

> Availability in this context is further explained using the following process commonly used for bringing a control technology concept to reality as a commercial product:
>
> - Concept stage;
> - Research and patenting;
> - Bench scale or laboratory testing;
> - Pilot scale testing;
> - Licensing and commercial demonstration; and
> - Commercial sales.
>
> A control technology is considered available, within the context presented above, if it has reached the licensing and commercial sales stage of development. A source would not be required to experience extended time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required to experience extended trials to learn how to apply a technology on a totally new and dissimilar source type. *Consequently, technologies in the pilot scale testing stages of development would not be considered available for BACT review.* An exception would be if the technology were proposed and permitted under the qualifications of an innovative control device consistent with the provision of 40 CFR 52.21(v) or, where appropriate, the applicable SIP.
>
> Commercial availability by itself, however, is not necessarily sufficient basis for concluding a technology to be applicable and therefore technically feasible. Technical feasibility, as determined in Step 2, also means a control option may reasonably be deployed on or "applicable" to the source type under construction.
>
> Technical judgment on the part of the applicant and the review authority is to be exercised in determining whether a control alternative is applicable to the source type under consideration. In general, a commercially available control option will be presumed applicable if it has been or is soon to be deployed (e.g., is specified in a permit) on the same or a similar source type. Absent a showing of this type, technical feasibility would be based on examination of the physical and chemical characteristics of the pollutant-bearing gas stream and comparison to the gas stream characteristics of the source types to which the technology had been applied previously. Deployment of the control technology on any existing source with similar gas stream characteristics is generally sufficient basis for concluding technical feasibility barring a demonstration to the contrary. [*Id.* at B.17–B.18] (emphasis added).

The *proper method for showing technical infeasibility* is identified by the Workshop Manual as follows:

> [T]he applicant should make a factual demonstration of infeasibility based on commercial unavailability and/or unusual circumstances which exist with application of the control to the applicant's emission units. Generally, such a demonstration would involve an evaluation of the pollutant-bearing gas stream characteristics and the capabilities of the technology. Also a showing of unresolvable technical difficulty with applying the control would constitute a showing of technical infeasibility (e.g., size of the unit, location of the proposed site, and operating problems related to specific circumstances of the source). Where the resolution of technical difficulties is a matter of cost, the applicant should consider the technology as technically feasible. The economic feasibility of a control alternative is reviewed in the economic impacts portion of the BACT selection process.
>
> A demonstration of technical infeasibility is based on a technical assessment considering physical, chemical and engineering principles and/or empirical data showing that the technology would not work on the emissions unit under review, or that unresolvable technical difficulties would preclude the successful deployment of the technique. Physical modifications needed to resolve technical obstacles do not in and of themselves provide a justification for eliminating the control technique on the basis of technical infeasibility. However, the cost of such modifications can be considered in estimating cost and economic impacts which, in turn, may form the basis for eliminating a control technology (see later discussion at V.D.2). [*Id.* at B.19–B.20.]

Each of the elements of demonstrating technical infeasibility, along with background and supporting information as necessary, must be decisively documented.

2. Following the Guidance from the Workshop Manual, Minnkota has Decisively Documented that SCR is Technically Infeasible at Milton R. Young Station

SCR has not been demonstrated on any North Dakota lignite-fired cyclone unit. In light of this lack of demonstration, NDDH has asked Minnkota to consider conducting pilot testing of SCR to determine the life expectancy of a particular SCR catalyst. However, the 1990 Workshop Manual concludes that pilot testing of an undemonstrated technology cannot be required as a part of a BACT analysis.

The Workshop Manual addresses technical feasibility in the context of both demonstrated technologies (not applicable to Minnkota here) and undemonstrated technologies (Minnkota's situation). As set forth in detail above, the key questions in determining whether the undemonstrated technology is feasible are whether the technology is "available" and "applicable." Most importantly, the Workshop Manual states:

> "A source would not be required to experience extended time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required to experience extended trials to learn how to apply a technology on a totally new and dissimilar source type.

> Consequently, technologies in the pilot scale testing stages of development would not be considered available for BACT review." [*Id.* at B.18].

As Minnkota has demonstrated in its previous filings, EERC and Burns & McDonnell have demonstrated SCR cannot be reasonably installed and operated on the Milton R. Young Station. SCR is therefore unavailable and inapplicable, and NDDH may not require Minnkota to conduct extensive pilot testing as a part of a BACT analysis to experiment with the availability or applicability of SCR to North Dakota lignite-fired cyclone boilers.

In conclusion, Minnkota has demonstrated that SCR is not technically feasible, that that SCR is not "available" under the EPA guidance, that SCR is not "applicable" under the EPA guidance, and that a pilot test is not allowed under the EPA guidance for BACT.

TECHNICAL BASIS FOR MINNKOTA'S DECISION NOT TO CONDUCT PILOT SCR TESTING

In order to determine if additional pilot testing of SCR catalysts on lignite fueled cyclone-fired boiler would produce similar or potentially different results from previous testing, the fouling and poisoning mechanisms must be examined. This is necessary in order to evaluate design changes that could be made to reduce or eliminate the fouling and poisoning of the SCR catalysts.

Fouling and poisoning of SCR catalysts are affected by the following:

- Lignite properties
- Combustion processes
- Partitioning of sodium and other elements during combustion
- SCR catalyst characteristics and properties
- Chemical and physical mechanisms of pore plugging

The primary concern for lignite coals from the Northern Great Plains of North America is blinding and poisoning of SCR catalysts because of the presence of alkali and alkaline elements in the coal and their fate upon combustion. Mussatti (2002) indicated in the "EPA Air Pollution Control Cost Manual – Sixth Edition" the following primary mechanisms for catalyst deactivation:

> "Poisoning - Certain fuel constituents which are released during combustion act as catalyst poisons. Catalyst poisons include **calcium oxide and magnesium oxide**, potassium, **sodium**, arsenic, chlorine, fluorine, and lead. These constituents deactivate the catalyst by diffusing into active pore sites and occupying them irreversibly. Catalyst poisoning represents the main cause of catalyst deactivation."
>
> "Blinding/Plugging/Fouling - Ammonia-sulfur salts, fly ash, and other particulate matter in the flue gas cause blinding, plugging or fouling of the catalyst. The particulate matter deposits on the surface and in the active pore sites of the catalyst. This results in a decrease

of the number of sites available for NO_x reduction and an increase in flue gas pressure loss across the catalyst."

Based on research, development, and demonstration testing to date these challenges have not been overcome. Significant fundamental research is required to further develop NO_x reduction technologies for lignite coals.

Lignite Properties

Lignite from the Center Mine in North Dakota is part of the Fort Union region. The Fort Union region represents the lignite bearing reserves in North America. The age of lignite in the Fort Union ranges from late Cretaceous through Eocene. The younger lignite coals have higher levels of oxygen as compared to higher ranked coals. Lignites can contain as high as 20% oxygen on a moisture and ash free basis. The most important oxygen containing group in lignite is the carboxylic acid group accounting for up to 65% of the oxygen (Schobert, 1995). The carboxylic acid groups act as bonding sites for various elements such as Ba, Ca, Mg, Na, and Sr and are enriched in lignite coals as compared to bituminous coals (Schobert, 1995). As coal rank increases the oxygen functional groups are lost due to the coalification process. The carboxylic acids act as ion exchange sites for sodium and other elements such as Mg, Ca, Sr, and Ba that are accumulated from ground water. The abundance of sodium and other elements that are associated with the carboxylic acid groups in the coal are determined using chemical fractionation (Benson and Holm, 1985). The chemical fractionation results for Center lignite indicates that 76% of the total sodium is ion-exchangeable indicating an organic association in the coal with the remaining in a water soluble form (Schobert, 1995). In addition to the organic and water associated impurities, lignites contain significant levels of mineral grains. The types of minerals present in lignite consist of pyrite, quartz, clay minerals, sulfates, carbonates, and others (Benson and others, 1993).

Lignite fired at the Milton R. Young (MRY) plant is mined from three seams at the Center mine of the Fort Union Region, the Kinneman Creek (KC), Hagel A (HA), and Hagel B (HB). The coal fired in the Units 1 and 2 represent some blending of the coal through handling and delivery. The variability selected coal quality components for the as-fired Center lignite is shown in Table 1. The average, maximum, and minimum as well as the percentiles were derived from analysis of the as-fired coal database. The database consists of 1316 samples of coal collected using sampling systems on Unit 2. The elements that are largely organically associated as described above are highlighted. These elements are largely organically associated and can contribute to the formation of reactive fine particulate during combustion and gas cooling.

Table 1. Center lignite composition (moisture, ash, sulfur, and heating value expressed on an as-received basis; and ash composition expressed as weight percent equivalent oxide of the ash produced at 750 °C).

	Moisture, %	Ash, %	Sulfur %	Btu/lb	Al_2O_3	BaO	CaO	Fe2O3	MgO	P_2O_5	K_2O	SiO_2	Na_2O	SO_3

* High value may be an analysis or reporting error. Sample could not be reanalyzed to verify.

Figures 1 - 3 show the frequency distributions with the 10th, 50th, and 90th percentile values for sodium, base-to-acid ratio, and ash content in the as-fired database. In addition, the future Center lignite characteristics in ten-year averages for % sodium oxide in ash, base/acid ratio, and % ash are plotted on the frequency distribution diagrams in Figures 1-3. The future Center lignite characteristics are based on weighted averages of analysis conducted for drill cores. This information was used to calculate the weighted averages for 10-year spans. The frequency distribution of the sodium content of the ash is shown in Figure 1. The projections for the future have similar sodium levels to the upper mode of sodium contents. The sodium content of the future coals appears to be decreasing initially from the upper mode and then increasing from 2036–2064. The base-to-acid ratio shown in Figure 2 indicates coals typical of lower ash contents and high levels of sodium, calcium, potassium, and iron relative to silicon, aluminum, and titanium. This information indicates that the future coals will have a higher propensity on average to cause low-temperature fouling than coals fired over the past several years. Lower ash content and higher base-to-acid ratio coals produce more low temperature fouling due to sulfate formation. Figure 3 shows the projected ash values compared to the as-fired database. The data from 2006–2015 show similar data to the as-fired database with decreasing levels of ash in the latter years.

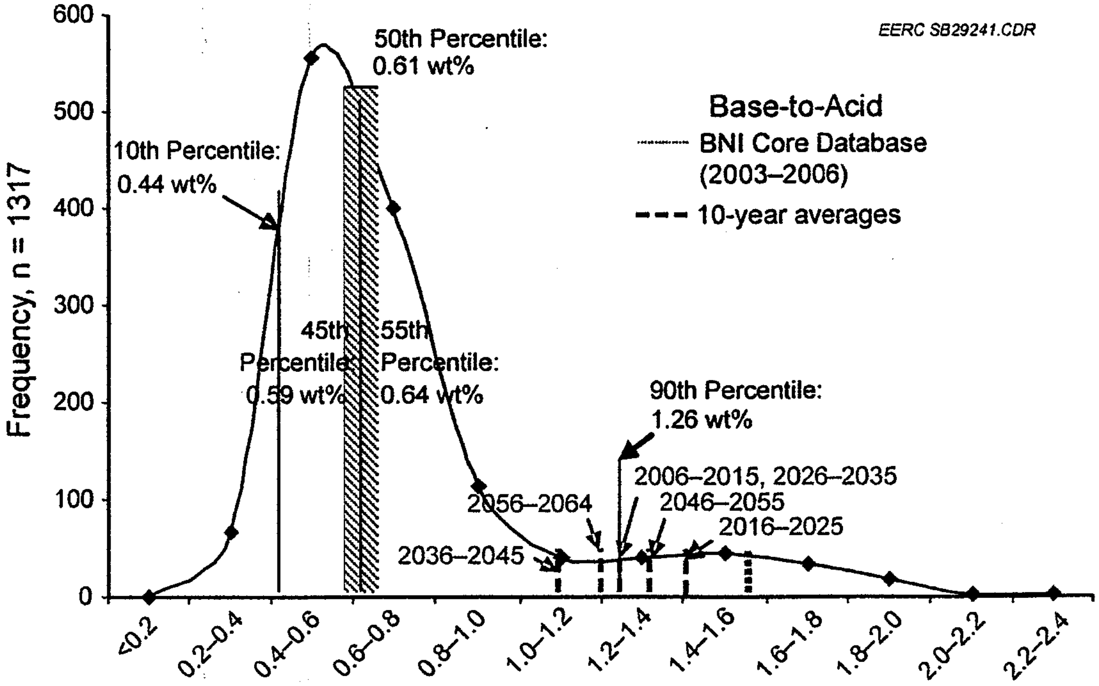

Figure 2. Base-to-acid ratio of ash frequency distribution for as-fired database compared to10-year averages and weighted Core Database values.

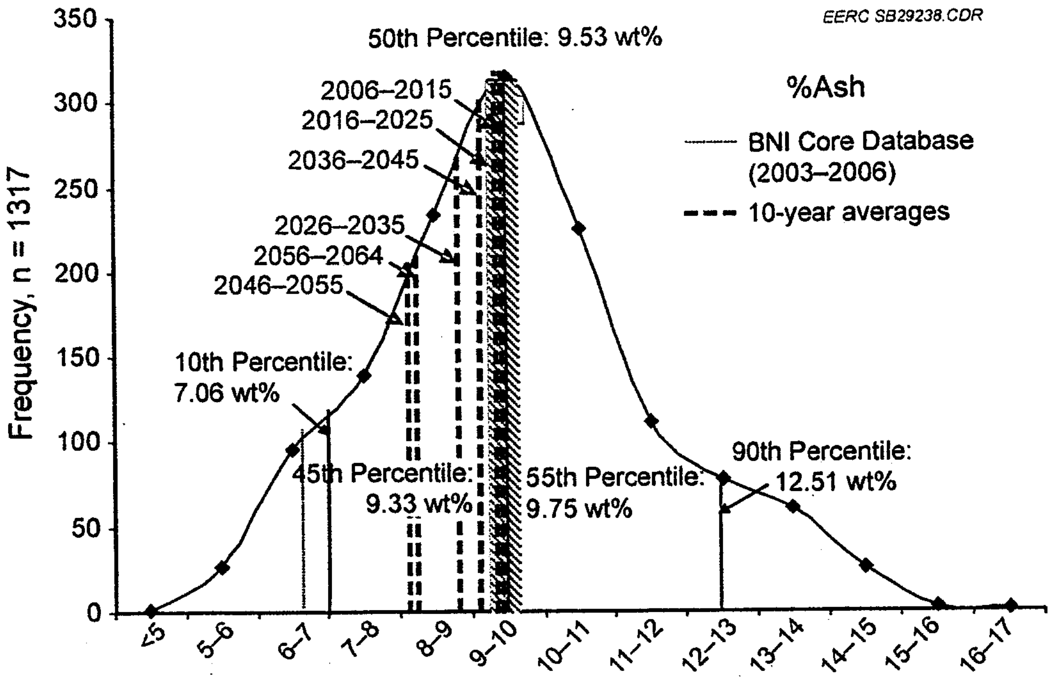

Figure 3. Ash frequency distribution for as-fired database compared to 10-year averages and weighted Core Database values.

Combustion Processes and Partitioning

The inorganic coal components undergo complex chemical and physical transformations during combustion to produce intermediate ash species in the form of inorganic vapors, liquids, and solids. The partitioning of the inorganic components during combustion to form ash intermediates depends upon the association and chemical characteristics of the inorganic components, the physical characteristics of the coal particles, the physical characteristics of the coal minerals, and the combustion conditions. The physical transformations involved in fly ash formation illustrated in Figure 4 include 1) coalescence of individual mineral grains within a char particle, 2) shedding of the ash particles from the surface of the chars, 3) incomplete coalescence due to disintegration of the char, 4) convective transport of ash from the char surface during devolatilization, 5) fragmentation of the inorganic mineral particles, 6) formation of cenospheres, and 7) vaporization and subsequent condensation of the inorganic components upon gas cooling. As a result of these interactions, the resulting ash composition and mass distribution as a function of size is also shown in Figure 4. Typical ash derived from coal combustion has a bimodal to multimodal size distribution that consists of a submicron and supermicron size fraction as shown in Figure 5. The submicron component is largely a result of the condensation of flame-volatilized inorganic components such as sodium. The intermediate size mode at about 2 micrometers is derived from the more refractory organically associated elements such as calcium and magnesium. The larger particles at approximately 12 to 15 μm are derived from the mineral grains present in the coal. The larger-size particles have been called the residual ash by some investigators (Sarofim and others, 1977) because these ash particles resemble, to a limited degree, the original minerals in the coal. During the gas-cooling processes in the boiler, the gas-phase species condense and the liquid-phase materials solidify. The abundance of these gas-phase and liquid materials entrained in the bulk gas flow is highly dependent upon coal composition and system operating conditions.

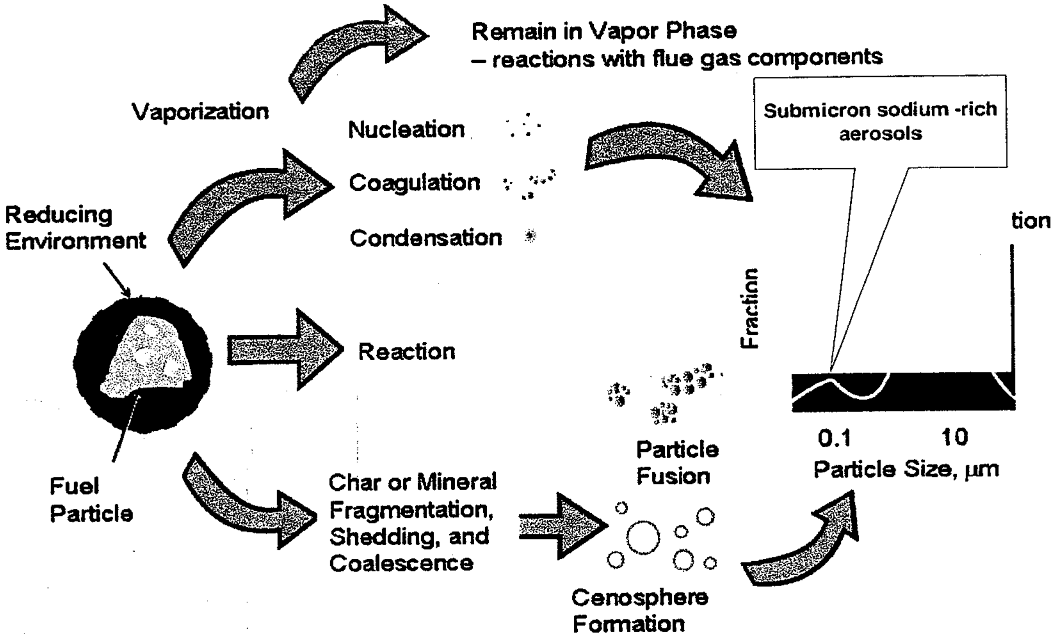

Figure 4. Transformation of inorganic components present in coal during combustion.

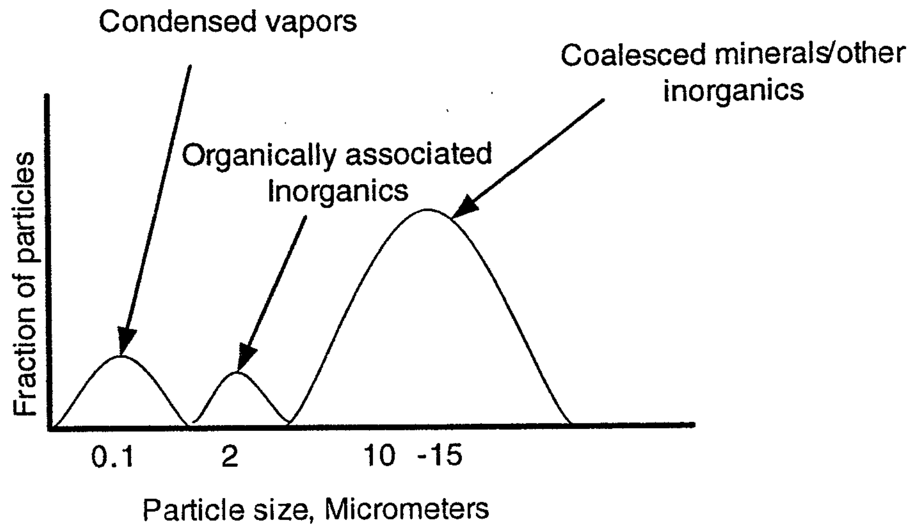

Figure 5. Final size distribution of ash particles produced upon combustion of lignitic coals (Benson and Laumb, 2007).

Cyclone fired systems enhance the partitioning of the inorganic components both by high temperatures and cyclonic action. The partitioning of sodium between the slag and coal is shown in Figure 6. The results show the sodium present in the as-fired coal ash presented with and without SO_3. The retention of sulfur in the ash is an artifact of the ashing procedure. In comparing the level of sodium in the slag to the coal fired for the high-sodium cases, only about half of the sodium is retained in the slag. The slag samples were recovered from the slag tap for the boiler. These slag samples include deposits that fall from the walls and the high-temperature convective pass.

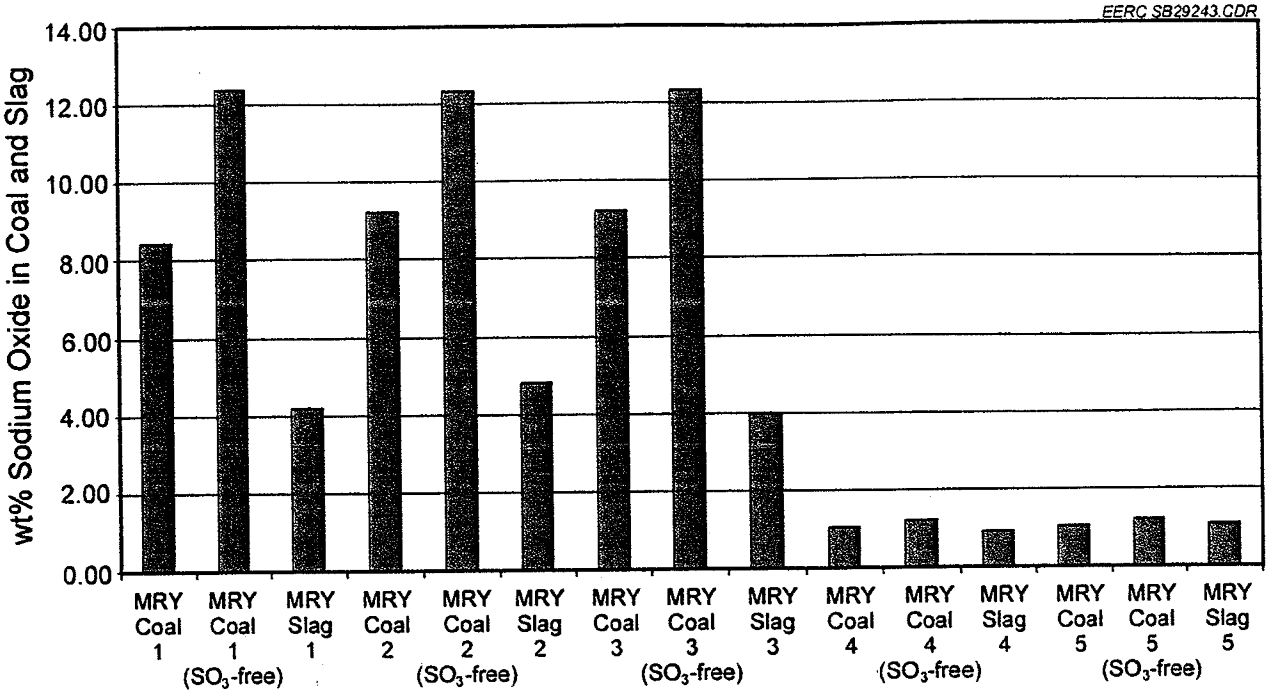

Figure 6. Comparison of sodium levels in Center lignite coal and slag samples.

The transport of intermediate ash species (i.e., inorganic vapors, liquids, and solids) to surfaces within a combustion system (combustion and air pollution control system) is a function of the state and size of the ash species and system conditions such as gas flow patterns, gas velocity, and temperature. Several processes are involved in the transport of ash particles to surfaces in the combustion system. These processes have been described in detail by Raask (1985) and Rosner (1986). The primary transport mechanisms are illustrated in Figure 7. For larger particles inertial impaction and eddy impaction in turbulent regions are the dominant mechanisms. The small particles (<1 μm) and vapor-phase species are transported by the vapor phase and small particle diffusion. The inorganic materials are transported to heat-transfer and catalyst surfaces by diffusion, electrophoresis, and inertial impaction. Thermophoresis is not a significant contributor to the transport of particles as it related to SCR materials. However, thermophoresis is a contributor to particle transport on heat transfer surfaces because of the temperature gradient.

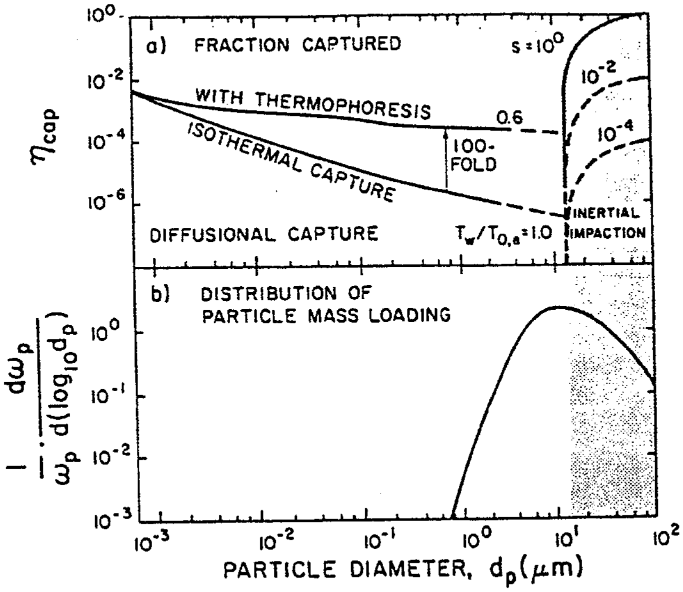

Figure 7. Overview of ash transport mechanisms (Rosner, 1986); (a) particle size dependence of captured fraction n_{cap}; (b) size distribution of the mainstream particle mass loading. The accumulation rate will involve a combination of a and b.

The vapor phase and small particles are characteristically rich in flame-volatilized species that condense upon gas cooling in the bulk gas or in the gas boundary layer next to the surface. The diffusion mechanisms important with respect to the transport of vapor species and small particles to the surface of SCR catalysts include:

1. Fick diffusion – molecular level.
2. Brownian diffusion – particles suspended by a host liquid.
3. Eddy diffusion – turbulent systems.

SCR Catalyst Characteristics and Properties

SCR catalysts for coal combustion applications consist of ceramic material with high porosity that contains imbedded active catalytic sites. The NO_x reduction occurs on the active surface of the catalyst. The active surface of the catalyst consists of flat surfaces and pores within the flat surface of the catalyst. The flat surfaces and pores in the catalyst are designed to provide gas contact with the active surface of the catalyst. The pores consist of open macropores and micropores that occur on the surface of the catalyst structures.

The size of the openings in honey comb catalyst impacts the velocity of the gases flowing through the catalyst. Pitch is the term used to describe the openings between the flat surfaces of the catalyst. Figure 8 illustrates the pitch, p and the wall thickness, a. Lower gas velocities will result for higher pitch numbers while small numbers will result in higher gas velocities through the catalyst. Catalyst vendors have methods to identify the proper pitch for specific fuel types and ash characteristics to minimize bridging or plugging where the dominant transport mechanism is inertial impaction and eddy impaction for the large particles. Selecting a pitch that will minimize the transport of small particles and vapor phase species is not as straightforward. High pitch catalysts will result in lower velocity gas flow through the catalyst and will create a thicker boundary layer resulting in an increased potential for small particle transport. Catalyst geometry plays a significant impact on gas flow patterns through the catalyst. Evaluation of the literature and information provided by catalyst vendors indicate that the geometries of catalysts have not been improved to minimize small particle and vapor phase deposition on the surface and within the pores of catalyst (Hansen, 2007).

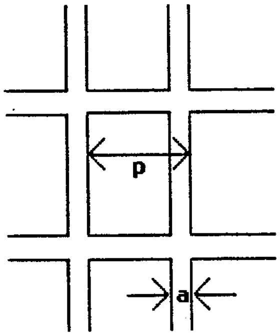

Figure 8. Catalyst pitch (Mussatti, 2002).

An example of the macropore structure is shown in Figure 9 for an actual surface for a honeycomb type catalyst. The openings in the catalysts create porosity and surface area to expose the reactive components of the catalyst to gas phase components. These openings are prone to filling with small particles and large particles through the transport processes of diffusion and impaction, respectively. Once these particles are transported to the surfaces they will be held in place by weak electrostatic and van der Waals forces and they will react with vapor phase sulfur oxide species.

Chemical and physical mechanisms of pore plugging

The most significant problems that limit the successful application of SCR catalysts to lignite coal is the formation of low-temperature sodium–calcium–magnesium sulfates that will form on the surfaces of catalysts and the carryover of deposits that will plug the catalyst openings, resulting in increased pressure drop and decreased efficiency. Studies conducted at Coyote station (Benson and others, 2005) found significant blinding and filling of the pores with small particles as shown in Figure 9. Rapid filling of the pores occurred with the catalyst pitch of 6 mm. These materials were subjected to air pulsing that did not remove the materials from the catalyst. The characteristics of the materials filling the pore were rich in sodium and calcium sulfates. A high magnification image of the materials coating the catalyst and filling the pore is shown in Figure 10. This image shows the importance of the very small particles less than 1 micrometer and their impact on the bonding of the deposited materials. These small particles readily interact with gas phase SO_2 and SO_3 expanding to create a bonded matrix as shown in Figure 11 that completely fills the pores of the catalyst with a continuous bonded phase. A high magnification cross-section is shown in Figure 12 of a highly sulfated bonded matrix.

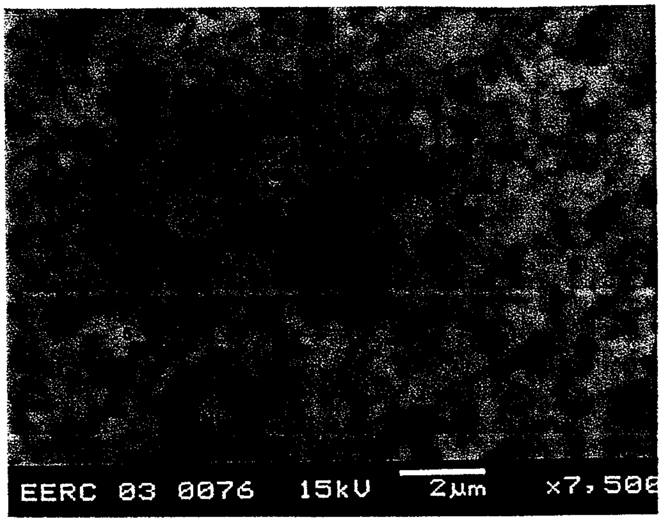

Figure 10. High magnification secondary electron image of ash filling pores and covering catalysts.

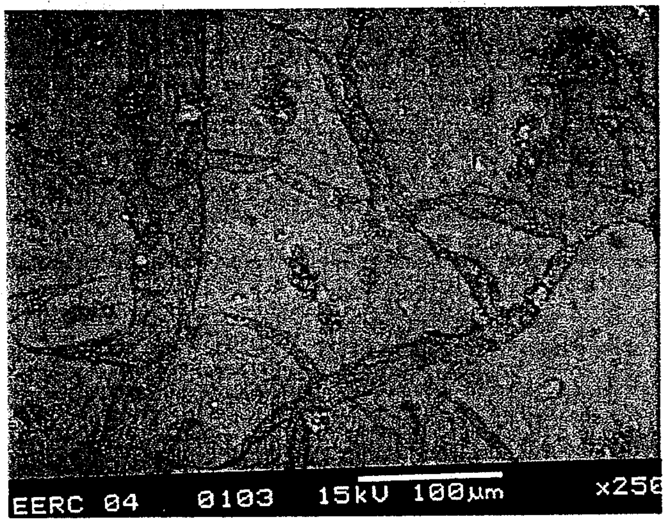

Figure 11. Scanning electron microscopy image of ash materials filling the pores of catalyst exposed to flue gases derived from the firing of Beulah lignite at Coyote Stations (Benson and others, 2005).

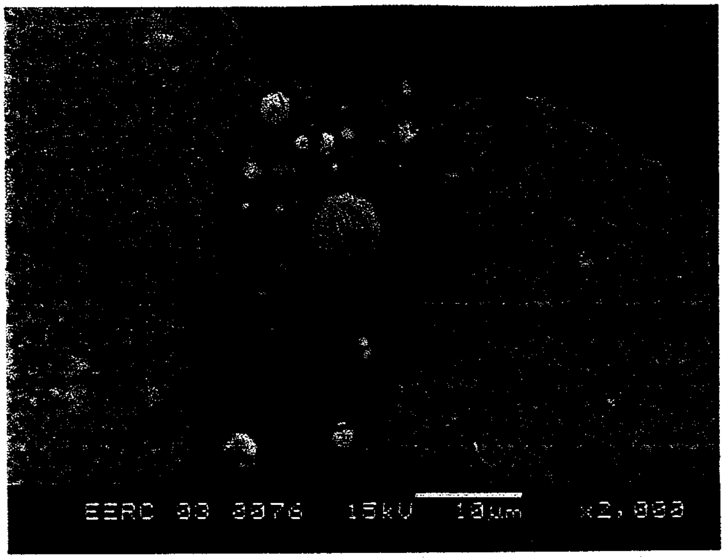

Figure 12. High magnification image of materials typical of ash filling pores that has sulfated and bonded.

Pyrosulfates are present in ash deposits and will likely form in SCR catalysts. Melting points for pyrosulfates between 535° and 770°F have been reported in the literature (Singer, 1981). Much of the past work has focused on the formation of these phases on tube surfaces. These species contribute to the corrosion of heat-transfer surfaces in coal-fired power plants. The exact melting point depends on the relative amounts of sodium and/or potassium. The melting points of selected pyrosulfate phases are shown in Table 2.

The formation of pyrosulfates involves the following processes

1. Formation of sulfates such as Na_2SO_4 and K_2SO_4
2. Conversion of SO_2 to SO_3 in the bulk gas phase – catalytically active surface such as an SCR catalyst – $SO_2 + \frac{1}{2} O_2 \rightarrow SO_3$
3. Pyrosulfate formation – $Na_2SO_4 + SO_3 \rightarrow Na_2S_2O_7$

A diagram depicting the physical and chemical reactions involved in the filling and plugging of catalyst pores is shown in Figure 13 (Benson and others, 2005).

Table 2. Melting Points of Selected Pyrosulfate Compounds

A. Compound	Temperature, °C	Temperature, °F
$K_3Fe(SO_4)_3$	618	1144
$K_3Al(SO_4)_3$	654	1209
$KFe(SO_4)_2$	694	1281
$Na_3Fe(SO_4)_3$	624	1155
$Na_3Al(SO_4)_3$	646	1195
$NaFe(SO_4)_2$	690	1274
$Na_2S_2O_7$	401	754
$K_2S_2O_7$	300	572
$(K_{1.5}Na_{0.5})S_2O_7$	279	535

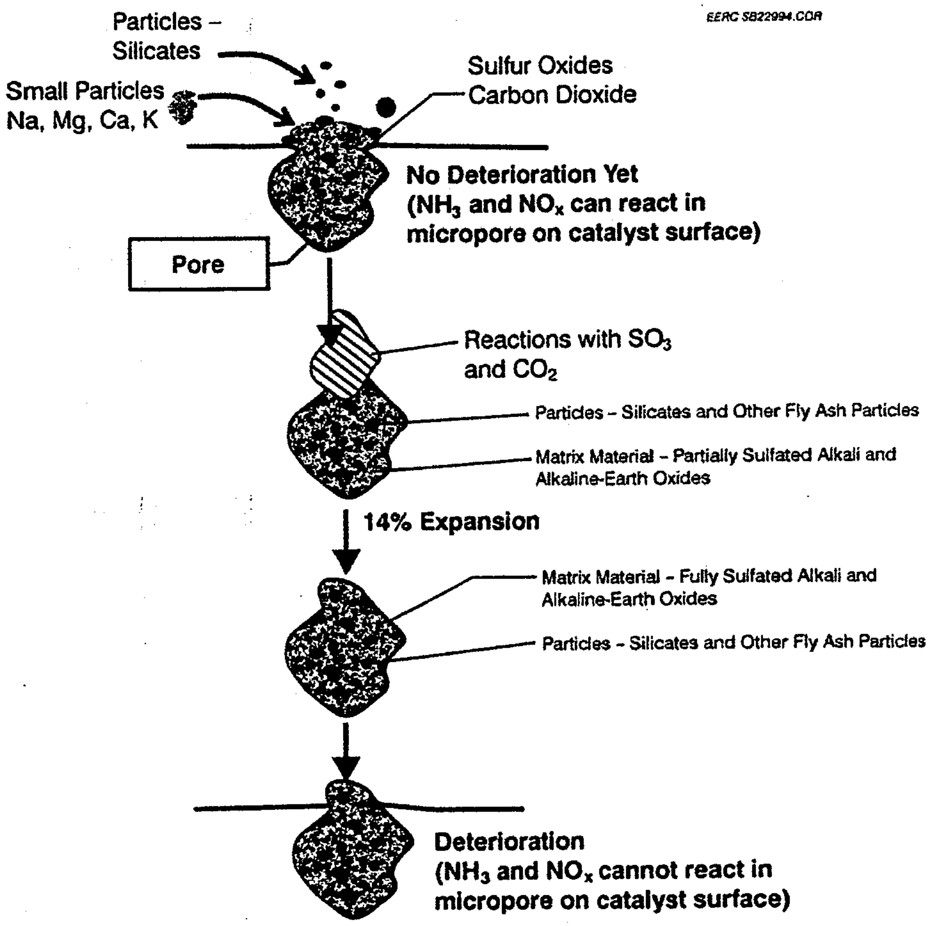

Figure 13. Overall mechanism of SCR Catalyst blinding (modified after Pritchard and others (1995)).

Sodium-related catalyst deactivation mechanisms

Alkali elements such as sodium and potassium are known to cause catalyst deactivation. Prichard and others (1995) indicate that the alkali elements can interact with the catalyst active sites and cause them to lose their activity as shown in Figure 14. They indicate that the degree of deactivation is dependent upon the concentration of alkali elements and the form of the alkali. Based on the evaluations conducted and/or reported by Cormetech (Prichard and others, 1995), Topsoe (1999), EPRI (Broske, 2005), and EPA (Mussatti, 2002) the water soluble form of the alkali is the problematic form since these alkali species are highly mobile allowing them to migrate into the catalyst. Cormetech (Prichard and others, 1995) incorrectly indicate the following:

> *"For the subject catalyst in coal-fired applications, it is our experience that this type of poisoning has a small impact, since most of the alkaline metals in the coal ash are not water soluble."*

This comment is very surprising and is likely indicative of catalyst vendor's level of understanding of lignite coals. Much work has been conducted for decades on the solubility of alkali and alkaline earth elements in coal ash. Sodium in Center lignite is associated in the groundwater and with the organic matrix of the coal (Benson and Holm, 1985; Schobert, 1995). Very little of the sodium is associated with the mineral fraction of the coal such as clays. During combustion, the sodium in the water soluble and organic association will vaporize and become dispersed in the gas stream and react with sulfur oxides to form soluble sodium sulfates species. Combustion Engineering conducted an analysis of the impact of soluble and organically associated sodium with fouling potential (Singer, 1981). The results of the analysis are summarized in Table 3. The soluble alkali shown for lignite and subbituminous coals is very high, with North Dakota lignite and Montana high-sodium subbituminous coals having the highest available sodium for low-temperature fouling processes.

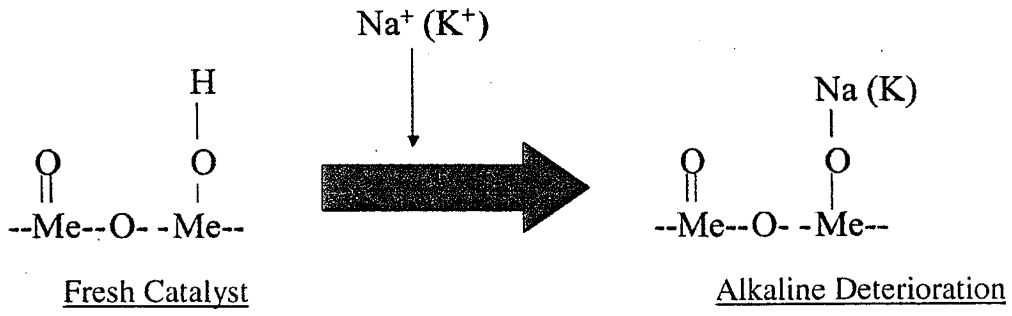

Figure 14. Alkaline (alkali) SCR catalyst deterioration mechanism (Prichard and others, 1995).

The following summarizes the state-of-the-art relative to the application of SCR for use in high sodium lignite combustion systems such as at the MRY plant.

- Coal properties
    - Center lignite coal contains organically associated sodium, magnesium and calcium
    - The levels of sodium in the Center lignite will remain constant and will likely increase in the future years
- Ash formation
    - Sodium vaporizes during combustion to form very small particles
    - Sodium is in a soluble form

- Catalyst properties
  - Catalysts have high porosity in the form of macropores and micropores that have active components dispersed within them allowing for NOx reduction reaction
  - Pitch of the catalyst appears to be the only change in geometry available to minimize deposition
  - Catalyst are prone to deactivation because of the presence of soluble sodium
- Ash transport in SCR catalyst
  - Ash particle transport mechanisms are dependent upon gas velocity
  - Particles greater than approximately 10 micrometers are transported to the surfaces of catalysts by inertial impaction mechanisms
  - Vapor phase and small particles are transported through diffusion processes into the pores of the catalyst across the stagnant gas boundary layer next to the surface
  - Small ash particles rich in sodium, calcium, and sulfur infiltrate deep into the catalyst pores causing blinding and plugging and possibly deactivation

The following are changes that could be made in future pilot testing and, based on the previously presented information, the impacts of those changes that could reasonably be anticipated to occur.

- Test catalysts with larger openings (greater Pitch)

  Impacts: The current recommendation (for the coal-fired industry in general) by catalyst vendors is to use catalysts that have a larger pitch. Using catalysts with a larger pitch will likely decrease the velocity through the catalyst and decrease the impaction rates of the larger particles. However, this does not address the key problem of vapor phase and small particle diffusion into the pores of the catalysts that is associated with the combustion of high sodium Center lignite. By decreasing the velocity, the gas boundary layer may be larger resulting in an increase in the diffusion processes resulting in increased deposition of the smaller particles into the pores. In addition, decreasing gas velocity will decrease the scrubbing action of impacting particles that aids in removing deposited ash particles.

- Test catalyst with modified pore structure that does not accumulate small particles

  Impacts: The use of these catalysts should have a positive impact on reducing catalyst poisoning and pore plugging. However, discussions with catalyst vendors and literature searches indicate that little or no work has been conducted on such formulations. Most of the work being conducted by catalyst vendors is focused on reducing SO_3 production and enhancements for mercury oxidation. As a result, these catalysts are not available.

- Enhanced cleaning technologies for removal of particles in the pores of catalysts

  Impacts: The use of acoustic horns appears to clean the surfaces as well as sootblowers on subbituminous and bituminous fueled boilers. However, this technology has not been demonstrated on lignite fueled boilers. There is significant uncertainty in the ability of acoustic horns to clean the ash particles from the pores of the catalyst.

There does not appear to be a catalyst material that has shown significantly improvement over the past catalyst relative to the performance in high sodium containing system. The specific question was asked to Flemming Hansen (Hansen, 2007) as to whether improvements have been made in catalysts over the ones tested at Coyote station that warrant further testing. He indicated that no formulation or design changes have been made to improve their performance in high sodium containing flue gases.

The testing at Coyote station indicated that the macropores and the catalyst openings were plugged. The blinding of the catalyst from the Coyote station testing was so severe that the catalyst vendor could not make deactivation measurements. Cleaning the catalyst and measuring deactivation was not performed based on recommendation of the catalyst vendor. The reason for not cleaning and conducting the measurements were based on concerns expressed by the vendor that the results of such deactivation testing after cleaning would not provide meaningful data on deactivation rates.

At the present time, there is not sufficient evidence to indicate that further pilot testing, even though it could be significantly reconfigured from previous testing, would yield significantly different results from that of testing already conducted at the Coyote station. Additionally, there is nothing to suggest that further testing would necessarily result in catalyst samples being made available that would allow for the measurement of deactivation rates.

SCHEDULE BASIS FOR MINNKOTA'S DECISION NOT TO CONDUCT PILOT SCR TESTING

The CD requires that compliance with the "30-day Rolling Average NO_x Emission Rate" established as BACT in accordance with the CD be achieved for Unit 2 at MRYS not later than December 31, 2010. For the hypothetical case in which an SCR pilot test were conducted to potentially establish the technical basis for SCR application to the Units at MRYS, the following tasks would need to be completed prior to this date:

1. Design the SCR pilot test protocol and obtain concurrence of NDDH and EPA
2. Design, procure and install the pilot SCR
3. Conduct the SCR pilot testing and evaluate the results
4. Conduct a technical feasibility analysis of the boiler modifications that would be necessary for Units 1 and 2 to allow reduction of flue gas temperatures (which are currently well above the required range for SCR operation, as previously documented in Minnkota's submittals to NDDH) while maintaining the ability to dry the lignite as required for combustion.
5. Revise the BACT analysis based on the results of Steps 3 and 4 (hypothetically assuming that they concluded it was technically possible to install SCR) to establish the revised "30-day Rolling Average NO_x Emission Rate" based on the hypothetical use of SCR.

6. Receive the final determination from NDDH regarding the "30-day Rolling Average NO_x Emission Rate" representing BACT in accordance with the CD.
7. Incorporate the results of steps 3 through 6 (hypothetically assuming that they concluded it was technically possible to install SCR and established an SCR-based value for the "30-day Rolling Average NO_x Emission Rate") into a procurement specification for the SCR system in accordance with RUS requirements.
8. Procure the SCR system on a "furnish and erect" basis, obtaining a vendor guarantee that assured compliance with the BACT emission limit as set forth in Step 6.
9. Design, fabricate, and erect the SCR systems and the necessary boiler modifications, using the Contractor selected in Step 8.
10. Start-up and commission the SCR system for Unit 2 and achieve stable performance to allow continuous compliance with the BACT emission limit as set forth in Step 6.

Based on Burns & McDonnell's evaluation, the time required to complete these tasks would be approximately 65 months from initiation of Task 1. Thus it would not be possible to comply with the CD date certain of December 31, 2010 for compliance with the "30-day Rolling Average NO_x Emission Rate" established as BACT in accordance with the CD.

The estimate of 65 months duration to complete this process is based on the following assumptions for the duration of the individual steps:

Step 1 is assumed to require two months. It should be noted that the EPA and its consultants have claimed that the previous SCR pilot testing at Coyote was fundamentally flawed. Thus it is essential that this step be thoroughly and carefully conducted and documented in order to assure the "buy in" of the interested parties.

Step 2 is estimated to require six months.

Step 3 is estimated to require 24 months. It is believed that the collection of 18 months of data will be necessary to properly evaluate the technical feasibility of SCR at MRYS. Due to the operating characteristics of the Units and based on prior experience with pilot testing, it is believed that the duration of pilot testing needed to acquire 18 months of data will be 24 months.

Step 4 is estimated to require six months, based on consultation with the boiler OEM. It should be noted that although Step 4 is assumed to be performed concurrently with Steps 1 through 3, all other steps must be conducted sequentially. Also, it should be noted that the subsequent sequence is based on the hypothetical assumption that the results of Steps 3 and 4 are favorable to the technical feasibility of SCR.

Steps 5 and 6 are estimated to require two months each. Because no SCR vendor has experience with SCR operation on North Dakota lignite, the determination of an emission rate corresponding to the hypothetical use of SCR will require the dissemination of the pilot test results from the catalyst vendors (which are assumed to be active participants in the pilot SCR program) to the SCR system suppliers. This is because the establishment of a NO_x emission rate representing BACT will require at least a preliminary indication from the system suppliers that such a level can be guaranteed. It is assumed that the system suppliers will guarantee the emission rate established in Step 6, and will otherwise respond favorably to the procurement process in Step 8.

The development of the technical specifications for the SCR procurement contract (Step 7) is estimated to require two months. The specifications must incorporate not only the results of the pilot SCR testing from Step 3 but the boiler modifications identified in the study conducted in Step 4. Again, the sequence assumes that it will be possible to find a feasible way of modifying the boilers to simultaneously achieve the flue gas temperature range required for SCR operation while continuing to achieve proper pre-drying of the lignite.

The period for bidding and award of the SCR contract (Step 8) is estimated to be four months. Typical bid period for a complex "furnish and erect" SCR retrofit contract such as this will be three months. One month is assumed for evaluation and negotiation.

For Step 9 it has been assumed that the period from award of the SCR contract to the completion of erection and tie-in will be 20 months. It is anticipated that the duration of construction of an SCR system in North Dakota will require somewhat longer than would be expected for other parts of the country due to the severity of the winter. Also, depending upon the complexity of the required boiler modifications, the construction period can be expected to be extended compared to a "typical" SCR project schedule which does not include the need for extensive boiler modifications.

The startup, commissioning and tuning of the SCR system (Step 10) has been estimated to require three months. It should be noted that concerns with the characteristics of the fly ash are anticipated to extend the time that would routinely be required for this step. Also, unlike most retrofit SCR projects completed to date in the U.S., this installation would be subject to a "not to exceed" emission limitation on a 30-day rolling average. Assurance that the limit could be continuously met would require more than the usual extent of operational tuning.

Minnkota Power Cooperative, Inc., et al
U.S. District Court for the District of ND
Civil Action No. 1:06-CV-034

Dear Mr. O'Clair:

Enclosed, please find a report on vendor responses you recently requested from Minnkota. This report, which was prepared by Burns & McDonnell, also includes recent additions and clarifications from vendors. As the report indicates, vendors are not able to make viable guarantees. Additionally, the vendors generally indicate that additional testing would need to be done prior to any design of an SCR for use on a North Dakota lignite-fired cyclone unit.

Should you have any questions, please contact me at jgraves@minnkota.com or 701-795-4221.

Should you have any questions concerning this submittal, please contact me at (701) 795-4221.

Sincerely yours,

MINNKOTA POWER COOPERATIVE, INC.

ADDITIONAL INFORMATION AND DISCUSSION OF VENDOR RESPONSES ON SCR TECHNICAL FEASIBILITY NORTH DAKOTA'S NOx BACT DETERMINATION for MILTON R. YOUNG STATION UNITS 1 & 2

May 8, 2008

In order to address the issue of vendor guarantees in the NSR Workshop Manual, Burns & McDonnell and Energy & Environmental Research Center (EERC) developed an SCR Vendor Query[1] which was emailed by Burns & McDonnell on April 18, 2007 to selective catalytic reduction (SCR) technology system suppliers and catalyst suppliers. The query requested information from these vendors pertaining to their willingness to offer guarantees for high-dust SCRs and catalyst with respect to NO_x emissions reduction performance at North Dakota lignite-fired Units 1 and 2 at Minnkota's Milton R. Young Station (MRYS) near Center, North Dakota. Burns & McDonnell described the unit-specific SCR system design conditions and site-specific technical challenges in this query document and its attachments.

This query document (without vendor responses) was originally submitted to the NDDH and EPA as part of an April 18, 2007 response[2] to NDDH's request for information (RFI)[3] regarding their review of the two BACT Analysis Study reports for control of NO_X emissions from existing Unit 1 and Unit 2 at MRYS required by the Consent Decree[4] that were originally submitted to the agencies in October 2006. Additional comments from Region 8 of U.S. EPA[5] were also attached to the NDDH's RFI. A summary of vendor initial responses was initially presented at a meeting of the NDDH, EPA Region 8, and Minnkota on May 23, 2007, in Bismarck by Burns & McDonnell[6].

[5] Ibid Reference number 3.
[6] See Reference number 5, May 23, 2007.

In April 2008, Burns & McDonnell became aware that the record on the BACT determination issue for Unit 1 and Unit 2 at MRYS was still open. Due to the fact that one year had passed since the development of the initial SCR Vendor Query document and the vendor responses, Burns & McDonnell initiated contact with several of the vendors in order to more fully understand their initial responses, and to gather additional information.

Appendix A to this document contains emails and letter received from six of the eight SCR technology system suppliers and catalyst suppliers that responded to the referenced original SCR Vendor Query. Subsequently, followup telephone conferences have been held and emails have been exchanged with four of the six companies that responded to the original query. The following are comments pertaining to the SCR vendor's original and followup responses to the April 18, 2007 query.

SCR Vendor Query:

In the referenced April 18, 2007 SCR Vendor Query, Burns & McDonnell requested any information that the SCR system or catalyst supplier could provide regarding the following:

- Detailed information regarding the post-combustion controlled emission rates that full-scale, full-time SCR systems in lignite-fired coal-burning boiler operations have consistently achieved over a period of time, with appropriate pre-controlled baseline emission data.

  That is, Burns & McDonnell requested information that supports a level of emission reductions that could be guaranteed over the course of time, and not merely performance test or limited-duration emissions data, including the following.
    - Data of source-specific boiler and SCR design and operating parameters, along with lignite coal quality characteristics (analytical data) representative of the lignite-fired coal-burning boiler operations associated with long-term post-combustion controlled emission rates that SCR systems have achieved in practice at full-scale installations.
    - If provided, non-full scale laboratory, pilot or bench-scale exposure testing, short-term full-scale compliance or acceptance test data shall be clearly identified as such.

- Definitive statements of expected guaranteed life and control effectiveness performance for SCR catalyst when located in high-dust, hot-side applications at MRYS.

  These statements were requested to be supported by detailed descriptions of the vendor's interpretation of the technical information Burns & McDonnell provided, the vendor's awareness of proven methods of dealing with similar site-specific applications, the vendor's own qualifications and experience, and any stated or assumed design and operational requirements. That is, the guarantee must specifically reference the site-specific operating conditions at MRYS, with an SCR system calibrated to operate in that environment.
- Definitive statements regarding Burns & McDonnell's and EERC's serious concerns involving catalyst blinding and deactivation due to high sodium concentrations along with sulfate and other known components in the flue gas expected from cyclone boilers firing North Dakota lignite.

  Burns & McDonnell provided an analysis of the lignite fuel fired at MRYS, and asked that the guarantee specifically discuss the impact of this particular fuel on SCR system and catalyst performance and longevity.
- A detailed description of the vendor's approach to mitigating Minnkota's risks of failure to meet NO_X emissions control requirements and catalyst activity versus life guarantees, stating what the vendor would do to improve the probability of success prior to initial operation, and how they would respond if the emission control effectiveness and catalyst activity did not match the expectations of the guarantee.

It was understood that the vendor was expected to make certain assumptions regarding SCR system design operating conditions, because detailed development of MRYS unit-specific design schemes to deal with the high boiler outlet flue gas temperatures and other conditions resulting from operation of these cyclone boilers firing North Dakota lignite have not been confirmed. Recognizing that such SCR design details were not currently available, SCR system and catalyst vendors were requested to review the technical information Burns & McDonnell provided. This data was offered as a supplement to the vendors' own technical knowledge, commercial experience, and proprietary data to aid in the understanding of technical feasibility of installing and successfully operating and maintaining currently-available coal-fired SCR system technology on the referenced North Dakota lignite-fired cyclone boilers.

The SCR vendors were also advised of the background of the Consent Decree and BACT Analysis that included Selective Catalytic Reduction (SCR) technology for the Milton R. Young Station. They were made aware that the EPA had issued comments regarding the agency's reviews of the NO_X BACT Analyses. A basic issue to be resolved in order to address the EPA's comments was stated as:

- Would continuous exposure of available high-dust SCR catalyst to current flue gas temperatures and flyash with high sodium concentrations along with sulfate and other known components in the flue gas expected from MRYS cyclone boilers cause severe catalyst fouling, deactivation, and degradation resulting in unacceptable long-term NO_X emission control effectiveness, catalyst life, and cost-effectiveness?

The SCR system and catalyst vendors were asked to consider the current operating conditions and identify solutions to address boiler outlet flue gas temperatures and other conditions resulting from operation of these cyclone boilers firing North Dakota lignite. Vendor responses also needed to consider historic MRYS boiler outlet flue gas temperature data provided with the query that showed wide variations with boiler fireside cleanliness and load.

<u>Comments on SCR Vendor Query Responses:</u>

Information requests via email were sent to four SCR system vendors and four catalyst vendors[7]. Two of the original eight SCR system vendors and catalyst vendors (Argillon and Cormetech) indicated they would provide a response but subsequently did not, even after further followup. Six of the eight vendors did provide information: Alstom Power Environment, Babcock & Wilcox, Babcock Power Environmental, Ceram, Haldor Topsoe, and Hitachi.

---

[7] See Reference number 6, April 18, 2007.

None of the vendors provided all of the information requested. The initial vendor responses that were unclear or provided information appearing to be stated without substantive basis or backup with identified source data were targeted for followup and telephone conference. The following includes comments by Burns & McDonnell (and EERC where so indicated) regarding the initial individual vendor responses from May 2007, and the subsequent supplemental responses following the late April 2008 telephone conference calls.

<u>Summary of Alstom Power's Responses and 2008 Followup</u>:

Alstom Power's initial response was provided in a letter dated May 30, 2007[8] submitted via email. Their initial comments provided information on lignite-fired boiler SCR applications, alternative tail-end SCR, predicted SCR performance, and indicative pricing and delivery for conventional SCR technology.

Alstom confirmed that there have not been any SCRs applied to boilers in the United States firing North Dakota or Texas lignites. Experience with an in-situ mini SCR reactor installed at TXU Energy's Martin Lake Unit 3, tested with two types of catalyst, was not detailed. Alstom recognized that North Dakota lignite is higher in sodium than Texas lignite, but stated that fuels high in sodium and potassium can be treated with specially selected catalyst. Wood and biomass-fired European boilers equipped with a hot-side electrostatic precipitators (ESPs) were cited as examples of dealing effectively with these catalyst poisons in such hot-side SCR applications.

Alstom expects acceptable emissions control and maintenance requirements can be achieved on North Dakota lignite service, assuming that the SCR system operates between 600-750°F. They anticipate that a modification or replacement of the economizer will be required to control boiler flue gas temperature within an acceptable range.

A Tail End SCR was mentioned as an alternative solution, with advantages and disadvantages briefly described. No plants firing fuels similar to North Dakota lignite with a Tail End SCR were identified.

---

[8] See Reference number 7, included in Appendix A, dated May 30, 2007.

Alstom predicts that a properly designed SCR (presumably on a boiler firing North Dakota lignite) should be capable of achieving up to 90% [NO_X] removal efficiency with 2 ppm ammonia slip. They acknowledge minimal field data to predict how often the catalyst would need to be replaced, with 16,000 hours between replacements as a suggested average based on lab results.

Indicative pricing for materials and labor to provide conventional SCR technology at MRYS was stated, absent detailed analysis and without potential additional scope because of unusual design requirements to deal with the boiler flue temperatures and catalyst contaminants.

Alstom's April 28, 2008 Telephone Conference Call and Followup Response:

Alstom could not offer any new or different information that agrees with or refutes information presented in the October 2005 EERC report of slipstream catalyst testing at Coyote Unit 1 referenced in the SCR vendor query. Alstom acknowledged that "there are no known existing applications of SCR to ND lignite fired boilers, therefore there is some risk on any first [of] a kind application". Alstom's May 2008 letter also states:

> "Application of a traditional SCR to Lignite fired units will require some R&D, custom engineering, and likely a pilot testing program. This will be time consuming and expensive but will reduce the risks involved in a new application such as this one".

Alstom indicated its belief that Tail End SCR downstream of a hot-side ESP would be immune to catalyst poisoning from sodium-potassium-sulfur compounds. They agree that biomass and wood-fired boiler SCR experience with low sulfur is not the same situation as cyclone boilers firing North Dakota lignite.

Based on current data, Alstom indicated that they cannot guarantee SCR system performance for MRYS boilers firing North Dakota lignite because it hasn't been installed full-scale on a boiler firing this fuel. Additional pilot-testing of at least one year would be needed.[9]

---

[9] See Reference number 8, included in Appendix A, dated May 5, 2008.

Comments on Alstom Power's Responses and April 28, 2008 Telephone Conference Call: Alstom did not provide detailed information completely responsive to all aspects of the subject raised in the original SCR Vendor query. Sources of field and laboratory test results of catalyst were cited but not substantiated with actual technical references or submittal of data.
An Alstom representative involved with Alstom's initial and followup responses (John Buschmann) acknowledged familiarity with the October 2005 EERC report of the SCR catalyst pilot testing at Coyote station.

Alstom did not appear to fully recognize how the method of firing the fuel in a cyclone boiler alters the character and composition of the flyash exhausted from the boiler, and that such contaminants pass through high-efficiency air cleaning equipment and create deposits that can blind and plug catalyst. The temperature of cyclone firing is higher and causes more vaporization of sodium and potassium in the lignite ash than occurs with a wood-fired boiler system. The wood-fired boiler systems have lower flame temperatures and thus less vaporization of alkali elements. This is evident based on the abundance of sodium and potassium-rich particles in the small ash size fraction found in the Coyote pilot SCR test catalyst and the particulate filter described in the referenced SCR vendor query. The sodium and potassium-rich materials combine with sulfur species to form sulfates that are significantly different and more problematic in their impacts on catalyst than Alstom's wood-fired boiler SCR experience indicates.

Alstom's wood-fired boiler SCR experience is not closely comparable to North Dakota lignite firing in cyclone boilers at MRYS. In general, alkali content of fly ash from wood firing is similar to the alkali content in the fly ash from the cyclones firing Center lignite. However, the form of the alkali in fly ash from the lignite-fired cyclone is likely in the oxide/hydroxide and partially sulfated forms; in wood fly ash, it will take another form, such as a chloride, if available. The lignite cyclone combustion derived alkali species are highly reactive with sulfur oxides resulting in the formation of a cohesive ash that produce stronger bonds and fill and coat catalyst pores and surfaces.

Alstom appeared to be unfamiliar with the unique high temperature air and flue gas requirements associated with the lignite drying systems on these MRYS boilers. Their expectation that a boiler economizer modification or replacement would resolve the low load-clean boiler-low flue gas temperature and high load-dirty boiler-high flue gas temperature situation appears to be a gross assumption based on an incomplete understanding of the thermodynamics of the flue gas, air, and fuel treatment systems employed at this facility[10].

No offer of any kind of SCR performance or service life guarantee was made by Alstom. The 16,000 hours between replacements, suggested as an average based on lab results[11], is not a guarantee or warranty, and was stated without the source data of the laboratory tests.

Summary of Argillon's Responses:

Argillon acknowledged the initial emailed query but failed to provide an actual initial response via phone call or email.[12]

Summary of Babcock & Wilcox's Responses:

Babcock & Wilcox did not provide detailed information completely responsive to all aspects of the subject raised in the original SCR Vendor query. Babcock & Wilcox's initial response via email[13] confirmed that there is not any full-scale operational experience with SCR systems retrofit to boilers firing North Dakota lignite or any other type of lignite in the United States. Therefore, neither B&W nor any other SCR system supplier can "provide detailed information regarding the post-combustion controlled emissions rates that full-scale, full-time SCR systems in lignite-fired coal-burning boiler operations have consistently achieved over a period of time."

B&W agrees with Burns & McDonnell that there are significant challenges associated with both boiler operation (high economizer exit gas temperature) and lignite firing (flue gas constituents) at Milton R. Young Station (MRYS). They mentioned the lack of justification and the need to invest significant dollars in research and development efforts to fully

---

[10] See Reference number 9.

[11] Ibid Reference number 7, included in Appendix A, dated May 30, 2007.

[12] See Reference number 10, included in Appendix A.

[13] See Reference number 11, included in Appendix A.

investigate and understand both technical and commercial risks involved with applying SCRs on a limited number of units firing North Dakota lignites.

B&W has not fully explored the issues presented in the SCR vendor query with catalyst suppliers to better understand and quantify these challenges, or what may be needed to identify their concerns or the lengths to which they may need to go to address them especially if catalyst guarantees must be offered.

No offer of any kind of SCR performance or service life guarantee was made by B&W.

Summary of Babcock Power's Responses and 2008 Followup:

Babcock Power Environmental's (BPE's) initial response[14] recognized that "there have been a few tests performed to ascertain the possibility of using a high dust SCR on lignite and the potential for fouling/poisoning of the catalyst has been in question". BPE also indicated an expectation that "an SCR system could be successfully utilized on a boiler fired with Northern lignite fuel", while recognizing uncertainty regarding the ability of a high dust SCR on a boiler firing North Dakota lignite because there has not been any testing or installation of an SCR reactor of any significant size on such a boiler. BPE also "identified the MY1 and MY2 boilers as a very difficult one on which a high dust SCR would be applied because of the unique configuration of the boiler and the wide temperature swings that are encountered".

BPE indicated that "several possible solutions exist with varying certainties of outcome. The SCR technology location may potentially mitigate the issues with the possible poisoning of the catalyst by constituents in the gas from the combustion of Northern lignite". Babcock Power recommended that "an engineering study be conducted to evaluate three key issues":

- Initial estimates of the actual deactivation of SCR catalyst in the high dust location by the use of coupons positioned in the hot gas stream downstream of the economizer.
- Initial estimates of the actual deactivation of SCR catalyst in other locations by the use of coupons positioned in the gas stream downstream of the airheater.

---

[14] See Reference number 12, included in Appendix A.

- Possibility of a retrofit of an SCR into the MY1 and MY2 boiler considering the wide range of temperature for the flue gas and possible boiler modifications required.

<u>Comments on Babcock Power's Responses and April 28, 2008 Telephone Conference Call</u>: Babcock Power Environmental did not provide detailed information completely responsive to all aspects of the subject raised in the original SCR Vendor query. BPE's original email statements seem to be based upon the vendor's experience with other lignite fuels not specifically identified by location or composition. Subsequent email[15] and telephone[16] followup in 2008 indicated that the use of high activity SCR catalyst coupons positioned in the hot gas stream downstream of the boiler economizer, would also include test locations downstream of the existing cold-side electrostatic precipitator (and in Unit 2's case, a wet lime/flyash scrubber). BPE considers this a kind of "fatal flaw" investigation that would be conducted first. This would allow BPE to analyze the test catalyst coupons for deactivation to see if a high-dust SCR location could work. This initial testing would be conducted without ammonia reagent being injected into the flue gas stream ahead of the test catalyst. If BPE determined that there was potential for SCR success after analyzing the test catalyst coupons, a test reactor of appropriate size would be designed and built and installed. BPE indicated that such a test SCR reactor would need to be operated for a minimum of 4000 hours.

A Babcock Power Environmental representative involved with BPE's initial and followup responses (Clay Erickson) appears to be familiar with the October 2005 EERC report of the SCR catalyst pilot testing at Coyote station. BPEI's second emailed response stated that they have not nor know of any further work on this topic since the response they previously provided via email on May 11th 2007[17].

No offer of any kind of SCR performance or service life guarantee was initially made by Babcock Power Environmental. BPE would not guarantee performance unless the catalyst vendors would provide such a guarantee[18]. Furthermore, BPE indicated that it would not

---

[15] See Reference number 13, included in Appendix A.
[16] See Reference number 14.
[17] Ibid Reference number 13, included in Appendix A.
[18] Ibid Reference number 14.

provide a guarantee of SCR performance on this fuel at these units without additional data such as that which would be derived from the test reactor described above[19].

Summary of Ceram's Responses and 2008 Followup:
Ceram reviewed the information provided by Burns & McDonnell regarding the technical feasibility of SCR on the Milton R. Young Station Units 1 and 2 firing North Dakota Lignite fuel[20]. Ceram's initial response comments acknowledged the lack of any catalyst installations currently operating with North Dakota lignite fuel. One brown coal SCR installation (not specifically identified) in Europe, and a large experience base with coals, refineries and incinerators combined with familiarity with the effects of a wide range of fuel and flue gas constituents was mentioned. They indicated that their brown coal from Europe was more like a Texas lignite ash. They indicated that sodium is a concern since it has a potential to infiltrate into the catalyst and cause deactivation especially during heat-up and cool-down. They were not familiar with cyclone firing and enhancement of sodium in the fines[21].

Ceram initially noted that North Dakota Lignite fuel and ash characteristics present certain challenges related to SCR operation and reliability. Additionally, the high flue gas temperatures needed for purposes of drying the fuel were mentioned as a challenge for SCR catalyst design, but no specific solution to this situation other than "flue gas tempering" being required was proposed.

Ceram's initial comments pertinent for this SCR application largely included items that needed to be considered or included in the SCR catalyst selection and reactor design, such as the presence of pyrosulfates (sodium, iron and sulfur) having the potential to increase the oxidation of sulfur (SO_2 to SO_3 conversion rate). Ceram could only guarantee the initial SO_2 to SO_3 conversion rate and not the end of life conversion rate.

Ceram provided a preliminary catalyst design that utilized a 7.4 mm pitch catalyst to minimize the risk of catalyst pluggage due to high concentrations of calcium and sulfates in the fuel. A

---

[19] Ibid Reference number 14.
[20] See Reference number 15, included in Appendix A.
[21] See Reference number 16.

full SCR bypass system with an air drying or dehumidification system was recommended to keep the catalyst warm and dry during lay-up periods because of the high sodium and iron concentrations. The maximum continuous operating temperature of the preliminary SCR catalyst design was 850° F, with an allowance of short periods of operation up to 900 degrees F. A high temperature reference list of Ceram's SCR catalyst installations was provided.

Ceram developed a preliminary catalyst design for each Unit (outlined in attached files) that were expected to provide 85% NOx reduction (0.08 lb/MBtu outlet) with an SO_2 to SO_3 conversion rate of 1.0% and ammonia slip of 2.0 ppm for a guarantee life of 16,000 hours.

A Ceram representative involved with Ceram's initial response (Noel Rosha) acknowledged he was unfamiliar with the October 2005 EERC report of the SCR catalyst pilot testing at Coyote station[22]. After the April 23, 2008 telephone conference call, Ceram obtained a copy of the referenced October 2005 EERC report. The Ceram representative responding to the followup request (John Cochran) after reviewing EERC's report believed it was "certainly premature to assume that there is a fatal flaw for the use of high dust SCR behind cyclones burning North Dakota lignite". Also, Ceram stated: "Certainly a number of circumstances are present that necessitate a pragmatic approach to the application of catalyst for a lignite application" and "Sodium is not a poison to catalyst at SCR operating temperatures. Significant deactivation can occur if condensed moisture transports sodium residing at the surface into the catalyst pore structure during outage or layup"[23].

Ceram's second emailed response included Ceram's reasons for why it believes the application of SCR technology on North Dakota lignite-fired cyclone boilers can be successful. Ceram also advised that "in no event would any ammonia be allowed to be injected below 530 F for any likely combination of reasonable sulfur and NOx removal parameters. The NOx reduction for a reduced MOT [minimum operating temperature] should be considered in 30-day rolling average scenarios. Minimum flue gas temperatures listed for Units 1 and 2 are well below this threshold"[24].

---

[22] Ibid Reference number 16.

[23] See Reference number 17, included in Appendix A.

[24] Ibid Reference number 17.

Ceram also included the following statement in their followup response: "based on the information provided as well as our large foundation of work related to the fuel considerations noted in the query and study CERAM can provide a commercial offering regarding this project. However, considering some of the remaining uncertainties we would recommend further testing to ensure a successful result"[25].

Comments on Ceram's Responses and April 23, 2008 Telephone Conference Call:
Ceram did not provide detailed information completely responsive to all aspects of the subject raised in the original SCR Vendor query. Their comments mentioned high sodium contents and fine fume as concerns reported by Dr. Benson and the EERC report on slipstream pilot SCR testing having "flawed pitch and resultant pluggage of the catalyst used during Coyote Station testing" as "inadequate evidence ... that this could be a fatal flaw to application of SCR"[26].

What appears to be missing from Ceram's comments are recognition that North Dakota lignite firing in cyclones promotes formation of low melting point eutectic combinations of sodium, potassium, and sulfur to form sulfates which produce extremely strong deposits that fill and plug the pores of the catalyst, regardless of the pitch. The effects of this eutectic melting and blinding was not considered, as Ceram's comments focus on the issue of significant deactivation from sodium due to mobilization of sodium if condensed moisture becomes available.

Ceram's initial response mentions a guaranteed catalyst service life of 16,000 hours and the initial SO_2 to SO_3 conversion rate, but did not actually expressly state that they would guarantee NOx reduction performance. Their willingness to provide a commercial offering is based upon recommended "further testing to ensure a successful result"[27].

Summary of Cormetech's Response:

Cormetech acknowledged the initial emailed query but failed to provide an actual initial response via phone call or email.[28]

Summary of Haldor Topsoe's Responses and 2008 Followup:

After its initial review of information and data provided by Burns & McDonnell regarding the viability of SCR technology on the Milton R. Young Station (MRYS) Units 1&2, Haldor Topsoe (HT) indicated that two separate issues exist with this application: extremely high flue gas exit temperatures (FGET) and lack of flue gas temperature control over the long term; and fuel-related issues specific to this variety of North Dakota lignite[29]. Haldor Topsoe did not address the high FGET as a unit-specific problem, presumably because they are not boiler heat transfer solution providers. HT indicated that they don't have a catalyst for coal-fired boiler applications that will survive 900°F flue gas that can be offered with a guarantee[30].

Based on the provided fuel and ash analysis of the North Dakota lignite that is burned at MRYS, Haldor Topsoe estimates that the deactivation rate of the catalyst will be high but manageable. A deactivation rate in line with wood-fired boilers which have been successfully fitted with SCR was predicted in HT's initial response; now, HT states this rate is higher than what they have seen on wood-fired boilers[31]. HT initially expected the deactivation rate to be steep initially but to flatten out considerably after about 4000 hours, and has recently (May 2008) modified this estimated time frame to 10,000 hours, where the catalyst is expected to lose about 60 percent of its initial activity during this time period. HT stated that the revised deactivation rate number is based mostly on comparison of the expected catalyst service conditions compared to that of wood-fired boilers. Higher flyash loading and catalyst attrition, combined with much more sulfur that leads to blinding of the catalyst were briefly described[32].

---

[28] See Reference number 18, included in Appendix A.
[29] See Reference number 19, included in Appendix A.
[30] See Reference number 20.
[31] See Reference number 21, included in Appendix A.
[32] Ibid Reference number 21, included in Appendix A.

HT originally stated that the expected catalyst poisons are mostly water soluble, therefore periodic water washing of the catalyst can be used to regain activity and to increase overall service life. This technique is used on many wood and some PRB coal-fired applications.

Besides the deactivation, Haldor Topsoe identified another catalyst impact problem: clogging[33]. Ineffective sootblower simulation in the Coyote pilot test was the primary concern/experience, which HT infers does not represent full-scale SCR installations.

HT suggests that the next step is to install a larger pilot scale experiment with cross section of catalyst on the order of 2 meters by 2 meters. This would allow better catalyst cleaning and give a better determination of the catalyst degradation over time[34].

Based on the fuel analysis provided to HT and assuming that FGET can be controlled, HT would be willing to guarantee SCR catalyst performance on these units[35]. Haldor Topsoe expects 60 percent deactivation over the first 10,000 operating hours. HT can not provide a "make good" guarantee, but is willing to warrant their catalyst performance up to the contract value[36].

A subsequent email dated May 7, 2008 from Dr. Joakim Thøgersen of Haldor Topsoe (Denmark) to Robert Blakley to address additional followup questions to Flemming Hansen's May 5, 2008 email response provided further information regarding the wood-fired boiler SCR experience versus a hypothetical North Dakota cyclone boiler SCR situation[37].

One issue was the difference in flyash loading between ND lignite-fired cyclone boilers and wood-fired boilers mentioned previously by HT. The fly ash concentration in lignite flue gas is 5-10 times higher than in wood-fired boiler flue gas. But the fraction of alkali in flyash that deposits in the catalyst is a much smaller portion of the total flyash loading in lignite flue gas than wood-fired boilers. The reason according to Dr. Thøgersen has to do with the alkali being

---

[33] Ibid Reference number 21, included in Appendix A.
[34] Ibid Reference number 21, included in Appendix A.
[35] Ibid Reference number 19, included in Appendix A.
[36] Ibid Reference number 21, included in Appendix A.
[37] See Reference number 22, included in Appendix A.

bound in coarse aluminum/silicate fly ash particles that don't contribute to the deposits in the catalyst to the same extent. When the alkali is incorporated in aluminum/silicate fly ash, the alkali also becomes inactive as a SCR poison. The lignite fly ash also has a cleaning effect by attrition of the surface that causes re-entrainment of particle deposits. Attrition is re-entrainment or cleaning of the catalyst surface by particle impaction[38].

Another issue was the much higher concentration of sulfur in ND lignite cyclone boiler flue gas compared to wood-fired boiler flue gas. Haldor Topsoe recognizes that SO_2 levels in ND lignite flue gas are 700-800 ppm whereas it is less than 10 ppm in wood flue gas. The sulfur leads to a strengthening and densification of the blinding layers that originates from deposition of calcium, sodium, and potassium aerosols[39]. The sulfur reacts with deposited sodium chloride (NaCl), calcium oxide (CaO), and potassium chloride (KCl), which means that the particles swell and the blinding layer becomes more impermeable[40].

A telephone conversation between Dr. Joakim Thøgersen and Steve Benson on May 2, 2008 indicated that the deactivation rates would be greater than that of the worst wood-fired system because of the high sodium and sulfur (greater than 60% in 10,000 hours). Dr. Thøgersen indicated that at this point, Haldor Topsoe would not be in a position to make a 100% "make good" guarantee[41]. Haldor Topsoe's predictions of SCR catalyst deactivation are somewhat semi quantitative since the predictions are based on extrapolation/interpolation from wood firing and PRB fired boilers[42].

<u>Comments on Haldor Topsoe's Responses and April 24, 2008 Telephone Conference Call</u>: Haldor Topsoe (HT) did not provide detailed information completely responsive to all aspects of the subject raised in the original SCR Vendor query. Sources of catalyst experience on wood-fired boilers were cited but not substantiated with actual technical references or submittal of data.

[39] Ibid Reference number 21, included in Appendix A.
[40] Ibid Reference number 22, included in Appendix A.
[41] See Reference number 23.
[42] Ibid Reference number 22, included in Appendix A.

The Haldor Topsoe representative involved with their initial response (Wayne Jones) acknowledged he was unfamiliar with the October 2005 EERC report of the SCR catalyst pilot testing at Coyote station[43]. Flemming Hansen provided the followup response, and was a participant in the referenced Coyote Station SCR catalyst pilot testing.

The amount and basis of HT's initial estimate of 4000 hours for rapid catalyst deactivation when exposed to North Dakota lignite-fired cyclone boiler flue gas and flyash was not provided, only that it was originally of the same magnitude as wood-fired boiler SCRs[44]. Now the expectation is stated to be worse than wood-fired boiler SCRs, with 60% deactivation over the first 10,000 operating hours[45].

Haldor Topsoe' apparent initial willingness to guarantee SCR catalyst performance on Unit 1 and Unit 2 at Milton R. Young Station firing North Dakota lignite is based largely on their experience on boilers firing wood with SCRs that have 5 to 10 times less flyash and 70 to 80 times less sulfur[46]. It also requires that the high flue gas temperatures presented in the query document are lowered and controlled, without knowing if or how this might be accomplished.

Haldor Topsoe's wood-fired boiler SCR experience is not closely comparable to North Dakota lignite firing in cyclone boilers at MRYS. In general, alkali content of fly ash from wood firing is similar to the alkali content in the fly ash from Center lignite. However, the form of the alkali in fly ash from cyclone-fired lignite is an oxide/hydroxide and sulfate; in wood fly ash, it will take another form, such as a chloride, if available. There are differences in reactivity between these forms of alkali with sulfur oxides that make the lignite flyash produce stronger bonded deposits on catalyst surfaces and in pores.

The temperature of cyclone firing is higher and causes more vaporization of alkali elements in the lignite ash than occurs with a wood-fired boiler system. The wood-fired boiler systems have lower flame temperatures and thus less vaporization of alkali elements. This is evident

---

[43] See Reference number 24.
[44] Ibid Reference number 19, included in Appendix A.
[45] Ibid Reference number 21, included in Appendix A.
[46] Ibid Reference number 21, included in Appendix A

based on the abundance of sodium and potassium-rich particles in the small ash size fraction found in the Coyote pilot SCR test catalyst and the particulate filter described in the referenced SCR vendor query. The sodium and potassium-rich materials combine with sulfur species to form sulfates are significantly different and more problematic in their impacts on catalyst than HT's wood-fired boiler SCR experience.

The pathway to the formation of bonded deposits on catalyst surfaces and pores for wood firing is different in lignite fired systems. HT suggested sodium chloride (NaCl) and potassium chloride (KCl) along with calcium oxide (CaO) are the intermediate species that become sulfated for the lignite application. It is evident that HT bases their assumptions on wood firing. In lignite, the intermediate species differ from wood because of the low levels of chlorine in the lignite coal. The reactions for sodium and potassium likely follow the path from vaporized atomic sodium and potassium in the flame to condensed sodium and potassium oxides or hydroxides. The calcium oxide (CaO) particles will form on the surface of the burning char particles and will be released as the char burns out. This resulting mixture (Na_2O/NaOH, K_2O/KOH, and CaO) of small particles (aerosols) will undergo minor sulfation during entrainment. As the particles are being transported with the bulk gas flow through the catalyst, they will deposit in the pores and on the surface of the catalyst. Once deposited, the particles will react with SO_3 to form sulfates and pyrosulfates causing the particles to swell filling pores and creating an impermeable layer. Another key point is that the rate of reaction to form sulfate is very fast in the pores because of the ability of the catalyst to convert SO_2 to SO_3.

Regarding the differences between ND lignite-fired cyclone boilers and wood-fired boilers mentioned previously by HT, loadings of ash are presumably higher for Center lignite and the potential for the scrubbing action of the silicate materials is possible. However, this scrubbing action will be unlikely for operations firing lignite with high sodium-low ash combinations supplied from the Center mine. In the low ash cases of ND lignite from the Center mine, the sulfated sodium and calcium particles are highly cohesive because of sulfate/pyrosulfate bonding that occurs between the particles. These types of bonded phases will be resistant to attrition and sulfate/pyrosulfate materials will capture the silicate particles resulting in increased growth and plugging. The scanning electron microscope (SEM) images in the October 2005 EERC paper[47] show evidence of captured aluminosilicate particles bonded in a sodium calcium sulfate matrix. The attrition effect described by Dr. Thøgersen assumes that erosion of the deposited materials will take place subsequent to particle impaction. However, if the deposit on the catalyst surface is cohesive and sticky, deposit growth will take place as described above.

Summary of Hitachi's Response:

Hitachi did not provide detailed information completely responsive to all aspects of the subject raised in the original SCR Vendor query. Hitachi's initial response via email[48] confirmed that there has been very little testing and data available on North Dakota lignite. After their initial review of information and data provided by Burns & McDonnell regarding the viability of SCR technology on the Milton R. Young Station (MRYS) Units 1&2, Hitachi expressed several concerns about the difficulty of installing and operating a hot-side, high-dust SCR:

- Without a plan to reduce the flue gas temperature, the catalyst will deactivate very quickly above 850 degrees F.
- High sodium content of the ash may cause serious deactivation of the catalyst.
- High sulfur trioxide (SO_3) content in ash may also cause faster catalyst deactivation.
- Sticky ash will cause a pluggage problem.

Because of all these unknowns, Hitachi strongly recommended that a slipstream test be performed to confirm the applicability of the catalyst for this flue gas[49].

Summary Comments on SCR System Suppliers' and Catalyst Suppliers' Responses:

The responses were mixed, with the SCR System Suppliers (boiler original equipment manufacturers) being pessimistic (B&W, Hitachi) to optimistic (Alstom, BPE) about the ability of an SCR system to be successful on these cyclone boilers burning North Dakota lignite. The SCR Catalyst Suppliers that provided technical responses (Ceram, Haldor Topsoe, and Hitachi) were mixed in their response, with Ceram and HT being more positive and Hitachi more

---

[47] See Reference number 25.
[48] See Reference number 26, included in Appendix A.
[49] Ibid Reference number 26, included in Appendix A.

negative. Of the catalyst vendors that were favorable, both indicated that their willingness to offer performance guarantees requires solving the flue gas temperature problems for which they are not responsible. Haldor Topsoe further qualified their willingness to warrant their catalyst performance was not a "make good" guarantee, but is limited to the amount of contract value of supplying the catalyst, which is a small portion of a typical full-scale full-time SCR system installation. Ceram did not specify their catalyst performance guarantee nor service life warranty limits. None of the SCR system suppliers offered any performance guarantees, not even Alstom and Babcock Power who believe that SCRs could be successfully utilized on MRYS cyclone boilers firing North Dakota lignite.

SCR suppliers and catalyst suppliers did not provide detailed information completely responsive to all aspects of the subject raised in the original SCR Vendor query. Some responses were more detailed than others; none included reference plant information or specific fuel and ash analysis data that presumably forms the basis of their opinions, estimates and predictions.

The vendors did not offer any new or different field pilot testing or laboratory/bench scale information including catalyst analysis from samples exposed to flue gas and flyash created from firing North Dakota lignite that agrees with or refutes information presented in the October 2005 EERC report of slipstream catalyst testing at Coyote Unit 1 referenced in the SCR vendor query. Several acknowledged that there are no known existing applications of full-scale, full-time SCR technology to ND lignite fired boiler, therefore there is some risk in this application. Suppliers did not provide much detail in identifying solutions to mitigate risks; mostly their comments suggested or recommended various tail-end SCR or low-dust SCR configurations to minimize flyash deposition. These responses largely ignored the evidence presented in the April 2007 query and October 2005 EERC report that fine alkali particles pass though the dust collection equipment (ESPs) that would be located ahead of these SCR reactors, which will plug pores and blind the catalyst surfaces, making the catalyst ineffective in reducing NOx emissions.

Of the SCR suppliers and catalyst suppliers providing additional responses, all recommend or favor a course of further research and pilot-scale testing before they would be confident of catalyst deactivation rates, service life, location in the gas stream for placement of the SCR reactor, and amount of catalyst required.

Conclusions on SCR Technical Feasibility for North Dakota's BACT Determination:

Minnkota has previously submitted arguments regarding the appropriateness of conducting pilot testing of selective catalytic reduction (SCR) technology at Milton R. Young Station Units 1 and 2 for use in a NOx BACT Analysis[50]. The vendor responses summarized and included herein have not altered the rationale of Minnkota's arguments that:

- Pilot-scale testing of SCR technology is specifically not required by the BACT determination procedures established by the U.S. Environmental Protection Agency (EPA).
- Previous research, including previous SCR pilot testing conducted at Coyote Station[51], indicates that there is not sufficient reason to believe that additional pilot testing suggested by SCR system suppliers and catalyst suppliers will produce results substantially different than those obtained from the prior pilot test.

Vendor responses to an SCR Vendor Query[53] did not adequately address guarantees and warranty of system performance and catalyst service life to mitigate potentially significant, long-term operational and financial risks based on the specific applications involved. This query sought information that forms the basis of the vendors' responses to the issue of guarantees, including:

- Whether such guarantees would satisfy a "make good" requirement;
- Would the vendor provide a catalyst service life guarantee and replacement warranty; and

---

[50] See Reference number 27.
[51] Ibid Reference number 25.
[53] Ibid Reference number 1, April 18, 2007.

- Whether any catalyst service life that a vendor would propose is based on the special nature of this fuel and ash composition method of firing (in a cyclone) and the location relative to gas cleaning equipment.

All vendors that responded to the query mentioned the significant challenges involved with the design considerations for applying SCR technology to these MRYS boilers. Only two vendors provided responses that included willingness to offer any guarantees on catalyst performance, with significant limitations on acceptable operating conditions which are yet to be achieved and would require solutions provided by other vendors. One of these catalyst suppliers responded that they would not be willing to offer a "make good" guarantee. The lack of suppliers' willingness to extend system and catalyst performance guarantees that satisfy "make good" requirements, as well as a lack of detail on service life warranty offers, does not support a substantial endorsement of applying SCR technology to these MRYS boilers with sufficient guarantees and certainty of results without having to perform substantial pilot testing, research and development, and specialized design as provided in the vendor responses.

Minnkota has previously presented the regulatory basis for the decision to not conduct pilot testing, as well as the reasons for technical infeasibility of SCR technology, for use in a NOx BACT Analysis[54]. The significant limitations stated by the catalyst suppliers regarding acceptable operating conditions which are yet to be attained and would require solutions provided by other vendors are significant caveats to believe that any suggested guarantees on catalyst performance or service life would be achieved with certainty. The fact that all the SCR suppliers responding to query recommend or favor pilot testing means that this technology is insufficiently developed to be considered "available" for the Unit 1 and Unit 2 boilers at MRYS burning North Dakota lignite as discussed in the EPA's NSR Manual[55].

Minnkota has provided sufficient information and documentation to NDDH and EPA, including responses to issues raised and requests made after submittal of the BACT Analysis Study reports[56] in October, 2006, to establish that SCR cannot be reasonably installed and

Subject: Request for Lignite SCR Feasibility Commercial and Technical Information

Chuck,

On behalf of Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative (Minnkota), Burns & McDonnell (B&McD) is exploring the willingness of Selective Catalytic Reduction (SCR) vendors to offer guarantees for high-dust SCRs and catalyst with respect to NO_x emissions reduction performance at Milton R. Young Station (MRYS). Minnkota's Unit 1 and Square Butte Electric Cooperative's Unit 2 each fire 100% North Dakota lignite using cyclone furnaces in subcritical boilers.

Burns & McDonnell requests Alstom to review the attached request document and respond within three weeks if possible. If Alstom's response is expected to extend beyond the timeframe requested, please advise with an estimated date when such a response could be provided.

<MRY SCR Vendor Query (4-18-07 final).doc>

We appreciate your cooperation in this matter.

Sincerely,

Robert D. Blakley, P.E.

Subject: Request For SCR Information
Milton Young Units 1&2

Dear Mr. Blakley:

As Burns and McDonnell and Minnkota Power are aware, ND Lignite does create many challenges for SCRs, but even with all of those challenges, it is possible to use ND Lignite if the system is designed properly and Minnkota Power elects to pay for the increased capital and O&M costs associated with this fuel. Alstom Power Environmental Control Systems (ECS) would like to offer Burns and McDonnell and Minnkota Power the following information in response to your request for SCR information on ND Lignite:

- Prior Applications of SCR to ND lignite fired boilers
- Alternative Tail End SCR
- Predicted SCR Performance
- Indicative Pricing and Delivery for Conventional SCR

Prior Applications of SCR to ND lignite fired boilers

Lignite coal burning units have not yet had any post combustion NOx controls installed on these units as environmental regulations have not yet required the installation of these controls. Investigative tests were performed on TXU Energy's Martin Lake Unit 3 to evaluate SCR catalyst performance on Texas-lignite-fired units. An in-situ mini SCR reactor was used for long-term tests on two types of catalyst to collect data on the effects of Texas lignite on SCR catalyst life and performance. After approximately 8000 hours of exposure to economizer outlet flue gas at typical SCR velocities of 15-20 ft./sec. (4.6-6.1 m/sec), both honeycomb and plate-type catalyst samples were shown, by field test, to have relative activities (K/K0) in the range of 0.70 to 0.75. Laboratory tests of catalyst activity performed by the catalyst vendors were consistent with these field test results. These results are expected to be representative of the first layer of a full-scale SCR reactor system. Erosion of the catalyst samples was not significant enough to affect catalyst performance. Test results further suggest that applying SCR catalyst technology (using even a high-dust design) to Texas-lignite-fired power generating units may be a practical approach for NOx control. (Electric Power Research Institute, December 2003, “Impacts of Texas Lignite Coal on SCR Catalyst Life and Performance: Field Data from TXU's Martin Lake Plant”)

It should be noted that North Dakota lignite is higher in sodium than Texas lignite. Fuels high in sodium and potassium require special selection of catalyst, but can be treated by SCR. An example of a such an application would be wood and other biofuel fired boilers in Europe. While SCR catalyst life in ND lignite service is not expected to be as long as in bituminous coal service, it is expected that acceptable emissions control and maintenance requirements can be achieved. Based on experience with wood fired units, a hot side (600-750 deg F) ESP is effective in removing the fly ash compounds that result in catalyst poisoning.

Proper operation of the SCR generally requires that the system operate in a temperature range of 600 to 750 deg F. Per the information provided, the Milton R Young boiler flue gas temperature at the economizer outlet currently varies quite a bit outside this range. Based on this temperature information, we anticipate that modification or replacement of the economizer will be required to control the temperature within an acceptable range.

Alternative Tail End SCR

While likely more expensive, an alternative solution to the conventional SCR , is a Tail End SCR where the SCR is located just before the stack. For this application, the location of the SCR just before the stack can provide significant advantages. The economizer outlet temperature variations will have no effect on the SCR, and the fly ash constituents that can poison the catalyst will have been removed from the flue gas stream by the existing ESPs. This would mean that modification of the existing economizer and any existing ESP would not be required with the application of a Tail End SCR.

The key disadvantage of the Tail End SCR is that the flue gas stream will need to be reheated from the current stack temperature up to approximately 600 deg F. Typically the flue gas is reheated using natural gas, however high pressure steam has been used in some cases. Heat recovery can be utilized to reduce the amount of energy required, however, the heating requirement is typically in the range of tens of millions of Btu per hour.

Predicted SCR Performance

Designed properly, the SCR should be capable of up to 90% removal efficiencies with an associated ammonia slip below 2 ppm. The significant unknown is how often the catalyst itself would need to be replaced. There is minimal field data to demonstrate expected catalyst life, but lab results suggest an average up to 16,000 hours between replacements.

Indicative Pricing, Sizing and Delivery

Because of the unusual design associated with this SCR and the potential additional scope items (heat exchangers or hot ESPs) required, it is expected that the cost will be significantly higher than for a conventional bituminous coal fired SCR. Without detailed anlaysis, the material and labor pricing below is our best estimate of the cost of a conventional SCR based on the increased sizing requirements.

Milton Young 1:	$50M
Milton Young 2:	$75M
Lead Time:	32 to 36 months

This estimated pricing does not include BOP costs, costs to modify the economizer, costs to modify existing precipitators, or costs to install gas to gas heat exchangers. Obviously, depending on the path forward and the resultant equipment required, the costs could be even more than stated above.

Alstom Power ECS hopes that this information can assist you in your SCR decision for Milton Young. In summary, it is possible to design and operate an SCR on this fuel if required, but doing so is not without challenges and can be very costly depending on which approach you may choose to pursue. Should you decide to pursue an SCR for these units, Alstom would be very interested in supporting you as we consider ourselves one of the industry leaders in this technology. Please contact Chuck Nordhausen, John Buschmann or me at your convenience with any questions or clarifications regarding this discussion.

Subject: RE: Request for Lignite SCR Feasibility Commercial and Technical Information

John -

Thank you for discussing the issues of SCR feasibility involving North Dakota lignite-fired cyclone boilers.

Hopefully you've gotten a chance to revisit the April 18, 2007 query, and review results of pilot SCR testing performed at Coyote Station, on a boiler of the same size, cyclones and similar fuel as fired at Milton R. Young Station's Unit 2 boiler.

We would appreciate an email response to this followup, with discussion of the technical research and experience basis of Alstom's positions on catalyst fouling, poisoning, and blinding appropriate to high sodium, medium sulfur coal flyash and flue gas produced from these boilers, both in hot-side/high-dust and low-dust/tail end SCR applications.

We are interested in learning more about the basis of lab results mentioned in discussion of the 16,000 hours as a suggested number of operating hours between catalyst replacements. Particularly, if Alstom were asked to provide a catalyst service life guarantee and replacement warranty, whether this or any other operating time that Alstom would propose is based on the special nature of this fuel and ash composition method of firing (in a cyclone) and the location relative to gas cleaning equipment. As mentioned during our telephone conference, the April 2007 SCR vendor query contained evidence of fine sodium particles downstream of MRY Station Unit 2's cold-side ESP and wet FGD scrubber.

We are also interested in knowing more about Alstom's willingness to offer SCR performance guarantees, and what that would include from a commercial standpoint along with a catalyst warranty. Of particular interest is whether Alstom's guarantee would satisfy a "make good" requirement, require full-scale field testing of each boiler prior to catalyst selection and design, testing catalyst in a slipstream arrangement or other exposure demonstrations, and if there are any other qualifiers beyond the assumption that the high flue gas temperatures in a conventional hot-side, high-dust SCR were limited by a solution to these temperature conditions yet to be developed.

It would be beneficial to reference Alstom's previous May 30, 2007 response when sending a supplemental response addressing this subject and issues raised in today's discussion.

We realize that this is a concentrated effort that does not allow much time to review and provide such responses.

We ask that Alstom provide their email response by Monday, 5/5 12 pm (noon), so that we can review this and forward to Minnkota.

Again, thank you for your attention to this matter.

Kansas City, MO 64114

Subject: Minnkota Power Cooperative
Milton R Young SCR Inquiry

Dear Mr. Blakely:

Alstom Power Environmental Control Systems (ECS) has reviewed the information available to us regarding SCR installations on ND Lignite units and feel that our original response to Minnkota dated May 27, 2007 is still valid. The highlights of that letter are clarified / summarized below.

- There are no known existing applications of SCR to ND lignite fired boilers, therefore there is some risk on any first a a kind application
- Alstom believes that hot side SCRs can be utilized in this application if a hot ESP is used upstream for ash collection before the SCR, but would as a result be very expensive from both a capital and O&M standpoint compared to non ND lignite SCRs
- In order to provide catalyst life guarantees, it is anticipated that catalyst manufacturers would require a pilot test of at least one year
- Tail end SCRs remain an alternative, but are also very expensive from a O&M standpoint

While SCR catalyst life in ND lignite service is not expected to be as long as in bituminous coal service, it is expected that acceptable emissions control and maintenance requirements can be achieved. Based on experience with wood fired units, a hot side (600-750 deg F) ESP is effective in removing the fly ash compounds that result in catalyst poisoning.

Proper operation of the SCR generally requires that the system operate in a temperature range of 600 to 750 deg F. Per the information provided, the Milton R Young boiler flue gas temperature at the economizer outlet currently varies quite a bit outside this range. Based on this temperature information, we anticipate that modification or replacement of the economizer will be required to control the temperature within an acceptable range.

Application of a traditional SCR to Lignite fired units will require some R&D, custom engineering, and likely a pilot testing program. This will be time consuming and expensive but will reduce the risks involved in a new application such as this one.

1409 Centerpoint Blvd.
Knoxville, TN (USA) 37932-1962
Tel : 865 693-7550
Fax: 865 694-5203
www.alstomenvironmental.com

While likely more expensive, an alternative solution to the conventional SCR , is a Tail End SCR where the SCR is located just before the stack. For this application, the location of the SCR just before the stack can provide significant advantages. The economizer outlet temperature variations will have no effect on the SCR, and the fly ash constituents that can poison the catalyst will have been removed from the flue gas stream by the existing ESPs. This would mean that modification of the existing economizer and any existing ESP would not be required with the application of a Tail End SCR.

We hope this helps assist you with Minnkota on its future NOx requirements Please contact Chuck Nordhausen, John Buschmann or me at your convenience with any questions or clarifications. We look forward to having the opportunity to meet with you to discuss our proposal in detail.

Subject: RE: Request for Lignite SCR Feasibility Commercial and Technical Information

Robert,

The Babcock & Wilcox Company has reviewed your request of April 18, 2007 regarding information related to the application of SCR technology on steam generating units that fire North Dakota lignite.

As you indicate in your Information Request, there is no full scale operational experience with SCR systems that have been retrofit onto an ND lignite-fired boiler. In fact, we are aware of no SCR retrofit that to date has been done on any boiler here in the US where lignite of any type has been fired. Therefore, neither we nor any other SCR system supplier can "provide detailed information regarding the post-combustion controlled emissions rates that full-scale, full-time SCR systems in lignite-fired coal-burning boiler operations have consistently achieved over a period of time."

B&W agrees with Burns & McDonnell that there are significant challenges associated with both boiler operation (high economizer exit gas temperature) and lignite firing (flue gas constituents) at Milton R. Young Station (MRYS). We have had cursory conversations with catalyst suppliers in an attempt to better understand and quantify these challenges. However we have not been able to fully explore these issues and at this time have no knowledge of the full extent of the catalyst suppliers concerns or the lengths to which they may need to go to address them especially if catalyst guarantees must be offered. In addition, with the limited number of units firing North Dakota lignites, it would be difficult for a supplier like B&W to justify investing significant dollars in R&D efforts to fully investigate and understand both the technical and commercial risks that would be involved when installing SCRs on ND lignite fired boilers.

During our delivery of over 26,000 MW of SCR systems and our evaluation of several times that many customer inquiries, B&W has identified creative solutions to address a host of boiler-SCR system integration challenges. Some were implemented while others were necessarily abandoned as economically unfeasible. B&W would welcome the opportunity to work with Burns & McDonnell and the Minnkota Power Cooperative, Inc. to further investigate opportunities to successfully meet the NOx emission challenges at MRYS should Minnkota find it necessary to do so.

Subject: Re: Request for Lignite SCR Feasibility Commercial and Technical Information

Dear Mr. Blakely:

Babcock Power Environmental (BPE) has reviewed the information provided to us on Milton Young Units 1 & 2 lignite fired boiler and the request for information on the applicability of SCR technology these boilers and their fuel. As you are aware, there have been a few tests performed to ascertain the possibility of using a high dust SCR on lignite and the potential for fouling/poisoning of the catalyst has been in question.

BPE and its licensor have supplied >60,000 MW of SCR systems around the world, including in applications with lignite in Europe and active lignite projects in the states. We have examined the various lignite fuels from around the world and, while there are differences, we expect an SCR system could be successfully utilized on a boiler fired with Northern lignite fuel however, uncertainty exists because an SCR has yet to be tested/provided on a meaningful scale to a Northern lignite application.

Furthermore, during our review of the information provided, we have identified the MY1 and MY2 boilers as a very difficult one on which a high dust SCR would be applied because of the unique configuration of the boiler and the wide temperature swings that are encountered.

BPE is very interested in working with Burns & McDonnell and Minnkota Power to provide the optimum solution to this problem. Several possible solutions exist with varying certainties of outcome. The SCR technology location may potentially mitigate the issues with the possible poisoning of the catalyst by constituents in the gas from the combustion of Northern lignite.

We recommend an engineering study be conducted to evaluate three key issues:

Initial estimates of the actual deactivation of SCR catalyst in the high dust location by the use of coupons positioned in the hot gas stream downstream of the economizer.

Initial estimates of the actual deactivation of SCR catalyst in other locations by the use of coupons positioned in the gas stream downstream of the airheater.

Possibility of a retrofit of an SCR into the MY1 and MY2 boiler considering the wide range of temperature for the flue gas and possible boiler modifications required.

BPE would lead this effort with collaboration from Burns & McDonnell and Minnkota Power. .

BPE is planning to be in the Bismarck area during the week of June 18 and offer to visit the plant and to meet to discuss our thoughts on the program, its cost, and the sharing of those costs. Furthermore, we would like to discuss issue #3 in greater detail to better understand options in the boiler area. Please let me know the availability of Minnkota and B&Mc personnel to meet and discuss this subject. We look forward to hearing from you.

Subject: Lignite SCR Response

Robert,

Per our phone conversion concerning the application of SCR technology to Northern Lignite fired boilers, BPEI has not nor knows of any further work on this topic since the response provided below on May 11th 2007. As discussed BPEI believes the issues related to the application of SCR technology for northern lignite fired units to be addressable in design.
The EERC reports have indicated significant issues however BPEI feels further tests investigating different locations and using tests alternate methods must be performed to make a final determination. BPEI, as the worldwide leader in SCR technology, continues to offer its services for to the industry to resolve the application of SCR technology to northern lignite fired units.

If you have further questions please contact me or Joe Langone.

Clay Erickson

To: Blakley, Robert
Cc: John Cochran
Subject: Request for Lignite SCR Feasibility Commercial and Technical Information

Mr. Blakley,

CERAM has reviewed the information provided by Burns & McDonnell regarding the technical feasibility of SCR on the Milton R. Young Station Units 1 and 2 firing North Dakota Lignite fuel. Based on the information provided we have developed preliminary catalyst designs for each Unit, as outlined in the attached files. Unit 1 and Unit 2 were both designed with 85% NOx reduction (0.08 lb/MBtu outlet) with an SO_2 to SO_3 conversion rate of 1.0% and ammonia slip of 2.0 ppm for a guarantee life of 16,000 hours. We have also included for your information our high temperature reference list.

CERAM currently does not have a catalyst installation with North Dakota Lignite fuel. CERAM does have a very wide fuels experience base for coals, including one brown coal reference in Europe. We also have a large experience base with refineries and incinerators and are familiar with the affects of a wide range of fuel and flue gas constituents.

North Dakota Lignite fuel and ash characteristics present certain challenges related to SCR operation and reliability. Additionally, the high flue gas temperatures needed for purposes of drying the fuel can be a challenge for SCR catalyst design. Please note the following technical clarifications that CERAM feels are pertinent for this application:

- The presence of pyrosulfates (sodium, iron and sulfur) have the potential to increase the SO_2 to SO_3 conversion rate. Based on this, CERAM could only guarantee the initial SO_2 to SO_3 conversion rate and not the end of life conversion rate.
- CERAM has utilized a 7.4 mm pitch catalyst to minimize risk of catalyst pluggage. High concentrations of calcium and sulfates in the fuel increase the potential for catalyst pluggage.
- Due to the high sodium and iron concentrations, CERAM would recommend a full SCR bypass system be installed. During lay-up periods the catalyst would need to remain warm and dry, for instance with an air drying or dehumidification system.
- CERAM would require the maximum continuous operating temperature of the SCR be designed for 850° F. Short periods of operation up to 900° F could be allowed. Boiler outlet temperatures greater than these would require flue gas tempering prior to reaching the SCR reactor.

Please let us know if you have further questions or would like additional information.

Best regards,

Noel Rosha

Subject: RE: Request for Lignite SCR Feasibility Commercial and Technical Information

Noel -

We also would like Ceram to comment on this question: if Ceram were asked to provide a catalyst service life guarantee and replacement warranty, whether a minimum operating time that Ceram would propose would be based on the special nature of this fuel and ash composition method of firing (in a cyclone) and the location relative to gas cleaning equipment. As mentioned during our telephone conference, the April 2007 SCR vendor query contained evidence of fine sodium particles downstream of MRY Station Unit 2's cold-side ESP and wet FGD scrubber.

It would be good to note in the response to the above question whether Ceram would require additional SCR catalyst coupons or slip-stream pilot testing with laboratory analysis in order to be confident in their proposed catalyst selection, design, and performance and service life guarantees.

It would be beneficial to reference Ceram's previous May 11, 2007 response when sending a supplemental response addressing this subject and issues raised in our 4/23/08 discussion.

Subject: RE: Request for Lignite SCR Feasibility Commercial and Technical Information

Noel & John -

Thank you for discussing the issues of SCR feasibility involving North Dakota lignite-fired cyclone boilers.

Hopefully you've gotten a chance to obtain Dr. Benson's paper on the pilot SCR testing performed at Coyote Station, on a boiler of the same size, cyclones and similar fuel as fired at Milton R. Young Station's Unit 2 boiler.

We would appreciate an email response to this followup, with discussion of the technical research and experience basis of Ceram's positions on catalyst fouling, poisoning, and blinding appropriate to high sodium, medium sulfur coal flyash and flue gas produced from these boilers.

We are also interested in knowing more about Ceram's willingness to offer performance guarantees, and what that would include from a commercial standpoint along with a catalyst warranty. Of particular interest is whether Ceram's guarantee would satisfy a "make good" requirement, require full-scale field testing of each boiler prior to catalyst selection and design, testing catalyst in a slipstream arrangement or other exposure demonstrations, and if there are any other qualifiers beyond the assumption that the high flue gas temperatures in a conventional hot-side, high-dust SCR were limited by a solution developed by others.

We realize that this is a concentrated effort that does not allow much time to review and provide such responses.

We ask that Ceram provide their email response by Monday, 5/5 12 pm (noon), so that we can review this and forward to Minnkota.

Again, thank you for your attention to this matter.

Subject: RE: Request for Lignite SCR Feasibility Commercial and Technical Information

Bob,

My apologies for not being able to meet your schedule for return of a response regarding your emails dated April 28, 2008.

We have reviewed the information provided including Dr. Benson's paper. We believe that the information and test work presented indicate that it is certainly premature to assume that there is a fatal flaw for the use of high dust SCR behind cyclones burning North Dakota lignite. The concerns presented are similar in argument to those that were used 10 years ago against the application of PRB for high dust applications. The results of the cited test reactor work for Baldwin and Columbia would even seemingly indicate that the use of high dust SCR on PRB applications would be similarly difficult to an installation on a lignite application. Meanwhile, dating from 1999 starting with the New Madrid project (a 2 by 660 MW cyclone base project burning 100% PRB where I was the responsible process engineer for Black & Veatch) there has been in excess of 25,000 MW of SCR installed on PRB fueled cyclone, wall, and tangential fired units with good success. Operating results for PRB units nonetheless indicate great success. The backpass fouling cited in the vendor query document is very similar to that found at the New Madrid project where backend temperatures rise from 720 F to 800 F every 6 months dependent on cleanliness. Meanwhile the cleanliness of the catalyst has been maintained to very low levels after 8 to 9 years of SCR operation.

Certainly a number of circumstances are present that necessitate a pragmatic approach to the application of catalyst for a lignite application. CERAM has more than 20 years of experience with dealing with all variety of fuels. Of particular concern with low rank fuels such as lignite and sub-bituminous coal is proper geometric and chemical design to address the unique characteristics of the ash and flue gas. As was well illustrated by the testing, the first critical parameter to consider is the geometric design of the catalyst. CERAM has experience with the slipstream test reactor used for testing at Baldwin and can confirm that this reactor is susceptible to ash accumulation due to wall effects. Additionally, the 6 mm pitch Haldor Topsoe catalyst used for the Coyote Station testing was an inadequate choice considering the ash loading and ash characteristics. Considering this choice of catalyst pitch and use of this slipstream reactor the results cannot be assumed to be representative of a full scale application. Based on the ash loading and chemistry for Milton R. Young Units 1 and 2 we would consider that at least a 7.4 mm pitch catalyst be utilized. This is the catalyst pitch we proposed in our May 11, 2007 budgetary sizing. A more conservative approach would be to use either an 8.2 or 9.2 mm catalyst. This could have alleviated the noted test element ash pluggage issues.

Sodium is a catalyst poison. Concerns reported by Dr. Benson regarding high sodium contents and fine fume are duly noted, but inadequate evidence is presented that this could be a fatal flaw to application of SCR considering the flawed pitch and resultant pluggage of the catalyst used during Coyote Station testing. Sodium is not a poison to catalyst at SCR operating temperatures. Significant deactivation can occur if condensed moisture transports sodium residing at the surface into the catalyst pore structure during outage or layup. CERAM has experience with high sodium applications to substantiate this effect. Important to avoid deactivation from sodium is the need to protect the catalyst from going through a condensation event.

With consideration of these factors we would agree that there is good cause for further testing on a lignite fired unit to further mitigate risks and optimize design. For this testing we would propose a program utilizing our CoPilot reactor (description attached) whereas wall effects can be minimized and representative ash loading can be better assured. The CoPilot reactor would be installed directly in the flue gas stream at the economizer outlet. The CoPilot reactor has been used in a number of difficult fuel circumstances to obtain accurate results supporting full scale design. If this testing is of interest to you we could prepare a test program proposal for your review.

CERAM can certainly confirm that there are certainly challenges present regarding the application of SCR to the Milton R Young Station. The following lists design requirements necessary to assure successful application of catalyst for Units 1 or 2.

- For coal, lignite, or sub-bituminous fired applications CERAM catalyst can be used to a maximum steady-state single point temperature of 900 F. Beyond this temperature severe permanent degradation of the catalyst will occur due to sintering. System configuration and design must ensure temperatures are maintained below 900 F. A design temperature of 850 F ±20 °F would be necessary.
- Based on the fuel quality presented a catalyst pitch of 7.4 mm or greater should be used. Fly ash angles entering the catalyst should be maintained approximately within ±15° from vertical. Sootblowers are recommended in this circumstance to maintain catalyst cleanliness.
- High carbon ash would carry the risk of increasing the pluggage of catalyst and possible result in a fire within the catalyst. Unburned carbon should be limited to less than approximately 15% to minimize the chance for pluggage and fire. Any catalyst that has a fire will be permanently destroyed due to sintering.
- Large particle ash (LPA) must be controlled prior to the catalyst. LPA escaping capture will cause pluggage of the catalyst.
- Ammonia should not be injected below minimum operating temperatures (MOT). Based on the SO2 and SO3 reported the MOT would be approximately 600 F. For lower sulfur fuels and/or reduced NOx removal performance a lower MOT would be possible. Additionally, brief periods of operation below the MOT would be possible without permanent degradation. In no event would any ammonia be allowed to be injected below 530 F for any likely combination of reasonable sulfur and NOx removal parameters. The NOx reduction for a reduced MOT should be considered in 30-day rolling average scenarios. Minimum flue gas temperatures listed for Units 1 and 2 are well below this threshold.
- Due to the high sodium and iron concentrations it is recommended that a full SCR bypass system be installed. During lay-up periods the catalyst would need to remain warm and dry (above condensing conditions), for instance with an air drying or

dehumidification system. This may necessitate the use of a dehumidifier and air lock system to access the reactor.
- Molar ratio NH3/NOx distribution ± 10% absolute.
- Gas velocity distribution ± 15% absolute.

I would like to note that in CERAM's catalyst production history dating from 1985 and concerning more than 350 deliveries we have never had a guarantee or warrantee claim. We certainly want to maintain this record of success. However, based on the information provided as well as our large foundation of work related to the fuel considerations noted in the query and study CERAM can provide a commercial offering regarding this project. However, considering some of the remaining uncertainties we would recommend further testing to ensure a successful result. We agree that it would be beneficial to jointly explore common concerns to ensure that any full scale application would be a success. Please advise if we could be of help to further develop a test plan or answer any questions.

Best Regards,
John Cochran

CERAM
ENVIRONMENTAL, INC.

CoPilot® Uses and Advantages

- Allows Assessment of Process Feasibility for New Application Types
- Allows Accurate Assessment of Impacts on SCR Catalyst from Existing Fuels and Plant Operations
- Minimizes Chances for Surprises Prior to Initial Operation
    - Excessive Catalyst Deactivation
    - Large Particle Ash
    - High LOI

CERAM
ENVIRONMENTAL, INC.

Fuels Assessment

- Determine SCR Catalyst Impacts of Specific Fuels
  - Highly Erosive Ash (Catalyst Mechanical Durability, Wall Thickness)
  - High Ash Loadings (Catalyst Pitch Selection)
  - Determine Impacts of Challenging Fuels (Catalyst Deactivation and Oxidation Rates)

Year-Round Catalyst Management

- Annual Catalyst Sample Testing is Recommended
- Year-Round SCR Operation will Limit the Opportunity to Remove Catalyst Samples for Testing
- CoPilot® Provides On-line Access to Catalyst Samples Exposed to Real Flue Gas Conditions
- Will Allow "Anytime" Access to Elements for Annual Catalyst Testing for Units With 2 to 3 Year Outage Intervals

CoPilot® Installation Locations

- Preferred Location: Long Vertical Downward Section of Duct Downstream of Economizer
- Ash Exposure Important Component of Simulating SCR Application
  - Representative Pluggage Risk
  - Ash Abrasion Effect on Catalyst
  - Catalyst Absorption of Catalyst Poisons

Installation

- Required Duct Opening of Approximately 36 x 101 inches
- Lift CoPilot® Into Place and Weld Frame to Duct Wall
- Install Instrument Panel on Floor/Grating/Handrail in Vicinity of the CoPilot®
- Connect Air Supply, Eductor Air, Sootblower Air, Differential Pressure Lines, and Ammonia (if applicable)
- Install Thermocouples
- Install Catalyst Test Element and Seal to Prevent Leakage

CERAM Can Provide Full Installation Support

Subject: Request for Lignite SCR Feasibility Commercial and Technical Information

Scot,

On behalf of Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative (Minnkota), Burns & McDonnell (B&McD) is exploring the willingness of Selective Catalytic Reduction (SCR) vendors to offer guarantees for high-dust SCRs and catalyst with respect to NO_x emissions reduction performance at Milton R. Young Station (MRYS). Minnkota's Unit 1 and Square Butte Electric Cooperative's Unit 2 each fire 100% North Dakota lignite using cyclone furnaces in subcritical boilers.

Burns & McDonnell requests Cormetech to review the attached request document and respond within three weeks if possible. If Cormetech's response is expected to extend beyond the timeframe requested, please advise with an estimated date when such a response could be provided.

<MRY SCR Vendor Query (4-18-07 final).doc>

We appreciate your cooperation in this matter.

Sincerely,

Robert D. Blakley, P.E.

Subject: HTI: Comments to SCR Technology at MRYS Units 1&2

Bob,

Haldor Topsoe has reviewed in detail the information and data sent regarding the viability of SCR technology on the Milton R. Young Station (MRYS) Units 1&2. We believe that two separate issues exist with this application. First are the extremely high flue gas exit temperatures (FGET) and lack of flue gas temperature control over the long term and second are the fuel related issues specific to this variety of North Dakota lignite. Since high (FGET) is a unit specific problem we are not going to address this issue. We will however address the North Dakota lignite fuel that is burned at MRYS.

Based on the fuel and ash analysis that was provided, we estimate that the deactivation rate of the catalyst will be high but manageable. We expect a deactivation rate in line with wood fired boilers which have been successfully fitted with SCR. We also expect the deactivation rate to be steep initially but to flatten out considerably after about 4000 hours.

The expected poisons are mostly soluble, therefore periodic water washing of the catalyst can be used to regain activity and to increase overall service life. This technique is used on many wood and some PRB fired applications.

Based on the fuel analysis provided to HT and assuming that FGET can be controlled HT would be willing to guarantee SCR catalyst performance on these units.

Regards,
Wayne

Subject: RE: Comments to SCR Technology at MRYS Units 1&2

Flemming -

We would like Haldor Topsoe to comment on this question: if Haldor Topsoe were asked to provide a catalyst performance and service life guarantee and replacement warranty, whether a minimum operating time that Haldor Topsoe would propose would be based on the special nature of this fuel and ash composition method of firing (in a cyclone) and the location relative to gas cleaning equipment. As mentioned during our telephone conference, the April 2007 SCR vendor query contained evidence of fine sodium particles downstream of MRY Station Unit 2's cold-side ESP and wet FGD scrubber.

We are also interested in learning more about the basis of statements mentioned in the May 10, 2007 response of the 4,000 hours as a suggested number of operating hours for the initially steep but tapering catalyst deactivation rate. It would be good to note in the response to the above questions whether Haldor Topsoe would require additional SCR catalyst coupons or slip-stream pilot testing with laboratory analysis in order to be confident in their proposed catalyst selection, design, and performance and service life guarantees.

It would be beneficial to reference Haldor Topsoe's previous May 10, 2007 response when sending a supplemental response addressing this subject and issues raised in our 4/24/08 discussion.

Flemming -

Thank you for discussing the issues of SCR feasibility involving North Dakota lignite-fired cyclone boilers.

Hopefully you've gotten a chance to review the April 18, 2007 query, and pilot SCR testing performed at Coyote Station, on a boiler of the same size, cyclones and similar fuel as fired at Milton R. Young Station's Unit 2 boiler.

We would appreciate an email response to this followup, with discussion of the technical research and experience basis of Haldor Topsoe's positions on catalyst fouling, poisoning, and blinding appropriate to high sodium, medium sulfur coal flyash and flue gas produced from these boilers. We are interested in learning more about the experience you mentioned about washing of catalyst fouled with high sodium alkalis that was ineffective at restoring catalyst activity.

We are also interested in knowing more about Haldor Topsoe's willingness to offer performance guarantees, and what that would include from a commercial standpoint along with a catalyst warranty. Of particular interest is whether Haldor Topsoe's guarantee would satisfy a "make good" requirement, require full-scale field testing of each boiler prior to catalyst selection and design, testing catalyst in a slipstream arrangement or other exposure demonstrations, and if there are any other qualifiers beyond the assumption that the high flue gas temperatures in a conventional hot-side, high-dust SCR were limited by a solution developed by others.

We realize that this is a concentrated effort that does not allow much time to review and provide such responses.

We ask that Haldor Topsoe provide their email response by Monday, 5/5 12 pm (noon), so that we can review this and forward to Minnkota.

Again, thank you for your attention to this matter.

Subject: RE: Comments to SCR Technology at MRYS Units 1&2

Bob,

We have reviewed the design basis and experience on ND lignite.

Our general conclusion was that the deactivation rate is probably going to be at the high in the initial 10,000 hours. Somewhat longer than the 4,000 hours stated earlier. The deactivation rate will be tapering off as the catalyst ages. We expect the catalyst to loos about 60% of its initial activity over the first 10,000 operating hours. This deactivation rate is higher than what we have seen for wood fired boilers.

The number is based on the following assumptions:

1) Alkali content is at the same order as it is found in a wood fly ash.

2) The fly ash load is 5 to 10 times higher than it is seen in wood fired boilers which means that the deactivation should be 5 -10 higher with ND lignite with the assumption that the fraction of alkali aerosol that is captured in the catalyst is constant (this is not the case, cf. 3).

3) The fly ash size distribution of North Dakota lignite is broader compared to wood fly ash, which is an advantage since the attrition of the catalyst surface is higher. However, the attrition effect is not as high as in most coal fired applications since cyclone fired boilers are typically used in ND lignite fired boilers. The carry over of coarse fly ash from the furnace is much lower in cyclone fired boilers. All together we expect that the effect of fly ash distribution compensates for the higher fly ash load compared to a wood fired boiler.

3) The effect of sulfur in the flue gas adds to the deactivation rate compared to typical wood firing. SO2 levels in ND lignite flue gas are 700-800 ppm whereas it is <10 ppm in wood flue gas. The sulfur leads to a strengthening and densification of the blinding layers that originates from deposition of Ca, Na, K aerosols.

Besides the deactivation there is a clogging issue. At the Coyote station test this was the primary concern/experience. It is well known that soot blowing is difficult in pilot scale due to edge effects but also due to the dimensions of the soot blower tubes (max about 1/2"). Orifices have to be smaller compared to full scale in order to distribute the soot blower air. As a consequence the soot blower should be moved closer to the catalyst in order to obtain the same dynamic pressure at the catalyst surface which makes it difficult to actually cover the entire catalyst surface. We suggest that the next step is a larger pilot scale experiment with in the order of 2x2m of catalyst installed. We would like to participate in such an experiment. This would allow better catalyst cleaning and give a better determination of the catalyst degradation over time.

Based on our current information we expect 60% deactivation over the first 10,000 operating hours.
We can not provide a "make good" guarantee, but are willing to warrant the catalyst performance up to the contract value.

I trust the above will be helpful in your design of SCRs for this type of application.

Subject: RE: Comments to SCR Technology at MRYS Units 1&2

Flemming -

We have reviewed your response to our followup to the query, and had some clarifications:

Do we understand your meaning correctly in item 1 of your email that due to the increased flyash loading for a hot-side, high-dust SCR application at MRY Station, Haldor Topsoe thinks the deactivation rate will be 5-10 percent higher than what is typically seen in wood-fired boiler SCR applications?

The meaning of the attrition effect is not readily understood. We are not sure if you are referring to erosion or gross pluggage of the catalyst gas passages from the flyash particles.
Can you provide some additional explanation?

The expected impact of sulfur on the catalyst deactivation rate compared to wood firing was not provided, as was given for the higher flyash loading. It would seem to be a much more significant impact if it is at all related to the gross difference in sulfur concentration (70-80 times more sulfur on a volume basis).
Can you provide some additional explanation of the expected impact of sulfur on the catalyst deactivation rate compared to wood firing, especially given that the Coyote pilot SCR test catalyst pores were completely filled with sodium and potassium-sulfate compounds.

We also assume that the comments about sootblowing and clogging of catalyst with flyash relate to the impact largely as an issue of avoiding gross flow channeling or maldistribution that would make some sections of the catalyst non-effective, assuming that the pores were otherwise not blinded or plugged?

We would appreciate any immediate reply to these questions, so that we can forward these to Minnkota.

Bob,

Some answers to your questions/comments:

Do we understand your meaning correctly in item 1 of your email that due to the increased flyash loading for a hot-side, high-dust SCR application at MRY Station, Haldor Topsoe thinks the deactivation rate will be 5-10 percent higher than what is typically seen in wood-fired boiler SCR applications?

No we don't think the the deactivation is 5-10 times higher. The alkali concentration in the fly ash is similar. The fly ash concentration is 5-10 times higher i lignite flue gas. But the fraction of flue alkali alkali that deposits in the catalyst is much smaller in lignite flue gas. The reason is that part of the alkali ihe furnace is bound in coarse aluminum/silicate fly ash that don't to the same extent deposits in the catalyst. When the alkali is incorporated in aluminum/silicate fly ash the alkali also becomes inactive as a SCR poison. The lignite fly ash also has a cleaning effect by attrition of the surface that causes re-entrainment of particle deposits.

The meaning of the attrition effect is not readily understood. We are not sure if you are referring to erosion or gross pluggage of the catalyst gas passages from the flyash particles.
Can you provide some additional explanation?

Re-entrainment or cleaning of the catalyst surface by particle impaction

The expected impact of sulfur on the catalyst deactivation rate compared to wood firing was not provided, as was given for the higher flyash loading. It would seem to be a much more significant impact if it is at all related to the gross difference in sulfur concentration (70-80 times more sulfur on a volume basis).
Can you provide some additional explanation of the expected impact of sulfur on the catalyst deactivation rate compared to wood firing, especially given that the Coyote pilot SCR test catalyst pores were completely filled with sodium and potassium-sulfate compounds.

The sulfur reacts with deposited NaCl, CaO, KCl which means that the particles swell and the blinding layer becomes more impermeable.

We also assume that the comments about sootblowing and clogging of catalyst with flyash relate to the impact largely as an issue of avoiding gross flow channeling or maldistribution that would make some sections of the catalyst non-effective, assuming that the pores were otherwise not blinded or plugged? Exactly.

Our predictions are somewhat semi quantitative since the predictions are based on extrapolation/interpolation from wood firing and PRB fired boilers. I hope these clarifications are sufficient. Otherwise you can call me (+45) 22754374.

Best Regards, Joakim

Subject: Request for Lignite SCR Feasibility Commercial and Technical Information

Tony,

On behalf of Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative (Minnkota), Burns & McDonnell (B&McD) is exploring the willingness of Selective Catalytic Reduction (SCR) vendors to offer guarantees for high-dust SCRs and catalyst with respect to NO_x emissions reduction performance at Milton R. Young Station (MRYS). Minnkota's Unit 1 and Square Butte Electric Cooperative's Unit 2 each fire 100% North Dakota lignite using cyclone furnaces in subcritical boilers.

Burns & McDonnell requests Hitachi to review the attached request document and respond within three weeks if possible. If Hitachi's response is expected to extend beyond the timeframe requested, please advise with an estimated date when such a response could be provided.

<MRY SCR Vendor Query (4-18-07 final).doc>

We appreciate your cooperation in this matter.

Sincerely,

Robert D. Blakley, P.E.

Subject: RE: Request for Lignite SCR Feasibility Commercial and Technical Information

Robert,
As you know there has been very little testing and data available in North Dakota lignite. Hitachi has reviewed this data and we have the following comments:
1. Basically, it is quite difficult to install and operate the SCR at temperature over 850F. If there is no plan to reduce the flue gas temperature, the catalyst will deactivate very quickly above 850F.
2. The ash tables show the Na content as very high. It may cause serious deactivation of the catalyst.
3. Also, SO3 content in ash is very high. This means that there is Sulfur compounds in addition to the oxides. It may also cause faster catalyst deactivation.
4. There is also a concern over how sticky the ash is and if this will cause a pluggage problem.
Whit all these unknowns we strongly recommend that a slipstream test be performed to confirm the applicability of the catalyst for this flue gas.

Please advise if you have any comments,

Best Regards,

Tony Favale

ENCLOSURE 2

EPA COMMENTS ON NDDH PRELIMINARY BACT DETERMINATION

EPA COMMENTS ON NDDH PRELIMINARY BACT DETERMINATION

I. NDDH'S ANALYSIS OF TECHNICAL FEASIBILITY OF TAIL-END AND LOW-DUST SCR AT MRYS IS INCORRECT AND BASED ON INCOMPLETE INFORMATION.

In previous comment letters, EPA explained that the applicability of SCR downstream of pollution control equipment (tail-end SCR (TESCR) or low-dust SCR (LDSCR)) would effectively eliminate the catalyst plugging and deactivation problems described in the Minnkota BACT analysis and that the costs associated with plant modifications and flue gas reheat in order achieve proper catalyst operating temperatures are a matter of cost and not technical feasibility.[1] B&McD's response to EPA's comments was that the information provided by the Energy & Environmental Research Center (EERC) shows that, "effective solutions to prevent or remove micropore pluggage and blinding of SCR catalyst from sodium-sulfur compounds evident in the flue gas stream exhausted from a North Dakota lignite-fired boiler, whether installed in a conventional hot-side or cold-side application downstream of a wet scrubber, have not been developed by SCR catalyst vendors" and that, "these are credible arguments that adequately describe the reasons that preclude the successful deployment of this technology on the cyclone boilers at MRYS."[2] B&McD does not agree that an economic analysis would be required because, "[t]he extensive plant modifications anticipated to deploy SCR at Unit 1 and Unit 2 at MRYS still do not resolve the catalyst micropore plugging and blinding problems evident in the Coyote Station pilot-scale testing."[3] EERC adds that, "[t]here is evidence of sodium, potassium, calcium, and sulfur deposition downstream of the ESP as illustrated in Figure 1 presented in response to ERC Core Issue number 2."[4]

Based on these responses, it appears that the basis for Minnkota's assertion that TESCR and LDSCR are technically infeasible is solely based the perceived catalyst micropore plugging and deactivation problems extrapolated from the results of the Coyote Station pilot testing and the flue gas sampling performed on MRYS Unit 1 downstream of the electrostatic precipitator at 300° F.

The NDDH BACT determination states that the site constraint and flue gas reheat issues are a matter of economics instead of technical feasibility, but "catalyst deactivation of a low-dust or tail-gas SCR due to alkali compounds is an issue that will require extensive research, design and pilot testing to determine whether the technology can be successfully applied to units fired on North Dakota lignite. Therefore, these technologies are not

considered applicable and not technically feasible at this time."[5,6] The NDDH BACT determination cites the sampling provided in Minnkota's November 9, 2007 letter which showed weight percentages of various compounds collected downstream of the electrostatic precipitator and previous experience at the Minn-Dak Farmer's Coop. coal-fired facility, which had problems maintaining compliance with a particulate limit and subsequently had to limit their fuel sodium content.[7] As more fully set forth below, Minnkota has failed to produce sufficient evidence to show that TESCR or LDSCR would experience extreme catalyst deactivation that would preclude the successful operation at MRYS.

Coyote Station Pilot Testing

Minnkota cites the Coyote Station pilot testing results as they relate to catalyst deactivation and plugging caused by sodium compounds and other alkali compounds as evidence that MRYS would not be suitable for a TESCR or LDSCR installation. This assertion is completely unfounded for a number of reasons. First, as described in previous EPA comment letters and as supplemented by the expert opinion report of Mr. Hartenstein provided herein, the Coyote Station pilot testing was clearly flawed and does not even provide meaningful conclusions to apply to a full-scale installation of high-dust SCR (HDSCR). Furthermore, since the Coyote Station pilot testing used flue gas upstream of the pollution control equipment, there is even less reason to believe that test results (even the qualitative results expounded on by Minnkota) have any relevance to a TESCR or LDSCR application, which would have substantially less ash constituents downstream of an

---

[5] See NDDH BACT determination, pages 56-57.

[6] The NDDH has made the determination that SCR would be technically feasible in its analysis of the Westmoreland Power, Inc. Gascoyne 500 Generating Station. In its May 2007 analysis of the Gascoyne 500 project, the NDDH states, "[b]y reheating the flue gas and locating the SCR downstream of the other air pollution control devices, SCR appears to be technically feasible. However, the Department is not certain that this technology will work with a Dakota lignite-fired unit because it has not been used before. For these reasons, the Department retained, with reservations, it as a technologically feasible control option." (See pages 58-59.) This proposed project would consist of two 285 MW-gross circulating fluidized bed boilers controlled by a dry scrubber and baghouse. The SCR would be located downstream of both control devices. In this case, the applicant (Westmoreland) cited many of the same concerns stated by Minnkota and the NDDH regarding uncertainty with North Dakota lignite and the significant engineering involved in applying SCR to this facility (Westmoreland even cited the EERC report on the pilot testing at Coyote Station), but concluded low-dust SCR was still technically feasible. In their permit application, Westmoreland states, "it is likely that Westmoreland would incur significant engineering and testing to ensure the viability of a low-dust SCR control system on a lignite-fired CFB boiler. However, there does not appear to be any technical basis to exclude low-dust SCR from the BACT determination." Apparently, the NDDH agrees with Westmoreland that the significant engineering and testing does not preclude technical feasibility AND agrees with Minnkota who believes that such activities do preclude technical feasibility. Low-dust SCR was eventually eliminated from consideration for mainly economic reasons, primarily due to the low uncontrolled NOx emissions from the Gascoyne boilers. While the configuration in the Westmoreland determination is referred to as low-dust SCR, it should be considered tail-end SCR, as it is downstream of a both a particulate control device and SO_2 scrubber.

[7] See NDDH BACT determination, pages 55-56.

electrostatic precipitator (for LDSCR) and wet scrubber (TESCR). Thus, the Coyote Station pilot testing did not provide any meaningful data in terms of evaluating HDSCR and is even less useful for evaluating technical feasibility of TESCR and LDSCR.

MRYS Unit 1 Sampling

Minnkota's November 9, 2007 letter, which is cited in the NDDH BACT determination, explains that flue gas sampling of MRYS Unit 1 was conducted downstream of the electrostatic precipitator and a cross-sectional analysis of the constituents was performed. Minnkota and the EERC asserts that the sampling shows a high degree of sulfated potassium and sodium compounds similar to the compounds observed at the Coyote Station pilot test. Therefore, Minnkota believes that the electrostatic precipitator would not remove much of the vaporized sodium and potassium and implies that similar results would have been produced during the Coyote Station pilot test if conducted downstream of the electrostatic precipitator. Aside from the fact that the Coyote Station pilot testing had significant design and operational problems, the results of the flue gas sampling presented in Minnkota's November 9, 2007 letter in no way quantifies the total amount of particulate material that was collected and would be expected to exist in a LDSCR environment. The data that was presented is only in terms weight percentages and only provides evidence that there will be sodium and potassium downstream of the electrostatic precipitator. While these compounds may exist in a LDSCR environment, no attempt was made by Minnkota to quantify how these weight percentage would translate to loading to a LDSCR and how that would affect catalyst life. Therefore, using this data to show that the presence of sodium and potassium compounds downstream of the electrostatic precipitator would preclude the successful operation of a LDSCR is completely speculative and highly questionable.

The NDDH BACT determination uses this data in conjunction with an emission factor comparison presented in the NDDH analysis to reach a similar conclusion. Without knowing what the total amount of loading is downstream of the electrostatic precipitator and how these weight percentages relate to LDSCR loading and catalyst life, however, the conclusions in the NDDH BACT determination are pure speculation and highly questionable. The NDDH BACT determination also uses this data to support that conclusion that these catalyst poisons will enter a TESCR, even though the sampling was done without wet scrubbing. Using this data in any way to support the conclusion that a TESCR could not be successfully operated is completely without merit. As explained in the expert opinion report by Mr. Hartenstein provided herein, soluble compounds would almost completely be removed by a wet scrubber and the flue gas temperatures after gas reheat for either a TESCR or LDSCR system would be higher than those expected for condensation of any trace sodium or potassium compounds remaining. Therefore, the MRYS Unit 1 sampling presented does not demonstrate, to any degree, that a TESCR or LDSCR could not be successfully operated at MRYS.[8]

Minn-Dak Farmer's Coop. Experience

As explained in detail in Mr. Hartenstein's expert opinion report, using the experience at the Minn-Dak Farmer's Coop. facility to make the claim that TESCR and LDSCR is technically infeasible at MRYS is unfounded. First, the pollution control at the Minn-Dak facility is completely unlike that at MRYS. The Minn-Dak boilers are equipped with multiclones and a venturi scrubber. The lack of similarity of MRYS to other facilities that have successfully operated SCR has been used extensively elsewhere in the NDDH BACT determination to support the claim of SCR technical infeasibility, yet this fact seems to be unimportant to the NDDH in this instance. The NDDH BACT determination also makes no attempt to relate the particulate matter emissions experienced at Minn-Dak to a theoretical TESCR sodium loading rate and catalyst life at MRYS that would support the claim that the Minn-Dak situation is evidence that TESCR would not be technically feasible at MRYS. This is likely because no such case could be made. Furthermore, as explained elsewhere herein and in Hans Hartenstein's expert opinion report, stack temperature conditions (and how those temperatures relate to the physical state of catalyst poison compounds) during a particulate matter stack test (as would have been the case in the Minn-Dak situation) and the operation of a TESCR after flue gas reheat are very different. Therefore, to use the NDDH's experience with the Minn-Dak facility to support the conclusion that TESCR could not be successfully operated at MRYS is completely speculative and highly questionable.

SCR System and Catalyst Vendor Responses on TESCR

The NDDH BACT determination fails to adequately address the vendor responses provided by Minnkota in the evaluation of TESCR or LDSCR. This is likely because the B&McD SCR system and catalyst vendor query appears to have been specifically directed at only getting responses related to a HDSCR application and with no attempt made to get information about vendor opinions or guarantees related to TESCR or LDSCR.

As detailed in Mr. Hartenstein's expert opinion report, an additional query was made to the same vendors that were contacted by B&McD to get information on technical feasibility, the need for additional research, and guarantees related to TESCR.

---

[8] Although not referenced in the NDDH BACT determination, Minnkota also submitted some sampling information for Unit 2 that may have been taken downstream of the electrostatic precipitator and SO_2 scrubber (although the bypass was operating during the sampling). As explained in Mr. Hartenstein's expert opinion report, this data cannot be considered relevant for any reasonable judgment concerning the technical feasibility of a TESCR.

The responses received from SCR system suppliers (Alstom and Babcock Power) and catalyst vendors (Argillion, CERAM, and Haldor Topsoe) that have extensive experience with TESCR demonstrate that TESCR is available and applicable to MRYS without the need to do additional pilot testing. This information is very important, because these experts have actual experience with these installations. While much of this experience is outside of the United States, that should not influence the analysis of technical feasibility. Clearly, these companies will make TESCR available to Minnkota and believe the physical and chemical characteristics of the flue gas at MRYS in a TESCR environment poses no significant differences that would preclude the successful operation at MRYS.

Conclusion on TESCR Technical Feasibility

Based on the evidence outlined above, in addition to the substantial explanation provided in the expert opinion report of Mr. Hartenstein, a leading expert in SCR installations at power plants, TESCR is a technically feasible control option at MRYS and needs to be evaluated to at least step 4 of the Top-Down BACT analysis.

Conclusion on LDSCR Technical Feasibility

Since no apparent attempt was made to query vendors related to LDSCR, this analysis remains incomplete. While both Minnkota and the NDDH have made technical arguments as to why LDSCR would be technically infeasible at MRYS due to catalyst plugging and deactivation, these arguments are based on pure speculation and improper comparisons with other situations that do not quantitatively provide any evidence that LDSCR could not be successfully operated at MRYS. EPA believes LDSCR is very likely technically feasible.

II. NDDH'S TECHNICAL FEASIBILITY ANALYSIS OF HIGH-DUST SCR IS INCORRECT AND BASED UPON FLAWED DATA.

As more fully set forth below, the NDDH BACT determination's conclusion that HDSCR is technically infeasible is not supported by the record and is based upon an incorrect interpretation of EPA's NSR Manual. NDDH's BACT determination provides twelve reasons to support its decision that HDSCR is technically infeasible. These individual points are examined in detail in Mr. Hartenstein's expert opinion report and will not be expounded upon here in detail.

HDSCR Catalyst Plugging & Deactivation

- The catalyst plugging and deactivation problems cited in the NDDH's BACT determination are largely based upon the Coyote Station pilot test conducted by EERC, which was fundamentally flawed and would not be indicative of a full-scale operation.

- The NDDH BACT determination acknowledges the fundamental problems with Coyote Station pilot test and states that it provided little useful data. However, the pilot test is cited throughout the HDSCR technical feasibility analysis as a basis for supporting the position that HDSCR is technically infeasible.[9]

- The comparison of different coal-type emission factors in the NDDH BACT determination is used to support the conclusion that the differences in flue gas characteristics of sodium and total primary alkali constituents (CaO, Na_2O, MgO, and K_2O) would "preclude the successful application of existing (presumably high-dust) SCR technology to the M.R. Young Station."[10] This conclusion is complete speculation. While the NDDH BACT determination correctly points out that a linear relationship does not exist between the loading rates of alkali constituents derived from emission factors and catalyst deactivation, the NDDH BACT determination uses this comparison to draw the conclusion that the flue gas characteristics at MRYS would be sufficiently "different" than other fuel types where SCR has been successfully applied. Again, there is no clear basis for this conclusion. The comparison shows cyclone units firing North Dakota lignite to emit about six times as much NaO and about twice as much primary alkali constituents as wall-fired or tangentially-fired plants burning Wyoming Powder River Basin (PRB) subbituminous coal. The NDDH BACT determination does not attempt to relate these ratios to expected catalyst life.

- For the current coal analyses, the ratios of primary alkali loading for Center Mine cyclone units compared to Texas Lignite cyclones, Texas Lignite pulverized units, and PRB subbituminous pulverized units are 1.7, 2.0, and 2.3 respectively. There is a larger disparity between the same primary alkali constituents on units within other fuel and boiler types that have successfully demonstrated SCR use. For example, the ratio of primary alkali constituent loading between pulverized coal units burning PRB subbituminous coal versus eastern bituminous coal on a lb/MMBtu basis would be 3.0. This difference is higher than the 2.3 ratio between a Center Mine cyclone unit and the same pulverized unit burning PRB. Therefore, based on the methodology and

---

[9] For example, on pages 49-50, the NDDH BACT determination states, "[t]he pilot scale SCR plugged after only 2 months and little useful data was obtained.....Operation of an SCR system for only 2 months between catalyst replacement is not considered successful operation of SCR technology." Based on this discussion, the NDDH is strongly implying that a HDSCR at MRYS would need a catalyst replacement due to deactivation after only two months, although it is widely known that information related to catalyst plugging on a pilot scale is not applicable to full-scale installations and no activation data was obtained on the Coyote Station pilot test. The NDDH BACT determination also states the Coyote Station pilot test was "ill-designed for a unit combusting North Dakota lignite" (see page 7), which makes the use of this 2-month prediction of catalyst replacement based on pilot-scale plugging results even more baffling.

[10] See NDDH BACT determination, page 51.

rationale presented in the NDDH BACT determination, HDSCR could not have been successfully applied to pulverized coal units burning PRB subbituminous coal because there was three times as much primary alkali constituent loading in the flue gas compared to the eastern bituminous coal plants, where SCR had already been successfully operated.

- Despite the considerable and varied experience that exists worldwide with applying SCR on different source and fuel types, the NDDH BACT determination dismisses the notion that HDSCR is technically feasible at MRYS as "speculation." However, the NDDH believes a mathematical comparison showing elevated amounts of sodium and other alkali constituents in the flue gas with some unknown effect on catalyst life in a HDSCR location is "evidence" that HDSCR is technically infeasible at MRYS.

- The responses from two of the three catalyst manufacturers (CERAM and Haldor Topsoe) to the B&McD query related to HDSCR indicates that catalyst suppliers would be willing to guarantee HDSCR performance if the temperature issue unique to the units at MRYS was resolved by SCR system suppliers. The catalyst vendors expressed concern about the flue gas constituents of North Dakota lignite, but did not indicate there was a fatal flaw to operating HDSCR based on the fuel type. The issue of sodium poisoning was specifically discussed by CERAM and was not a cause of concern based on their past experience with high sodium applications. Haldor Topsoe was also made aware of the sodium issue and was able to provide an industry-standard guarantee. The catalyst suppliers were able to estimate the catalyst life of a HDSCR application at MRYS based on their previous experience.

- It is apparent that the catalyst suppliers that responded affirmatively to being able to provide performance guarantees on a HDSCR if the temperature variation issue was resolved (CERAM and Haldor Topsoe) were prompted by B&McD to issue statements that pilot testing on North Dakota lignite would be required prior to such guarantees.[11] As noted in Mr. Hartenstein's expert opinion report, catalyst vendors would always be in favor of doing HDSCR pilot testing for a new fuel type, as it minimizes their risks at little or no cost to themselves.

- CERAM responded to B&McD's follow-up by stating that "we agree that there is good cause for further testing on a lignite fired unit to further mitigate the risks and optimize design." This statement is clearly a recommendation that acknowledges testing would enhance the applicability of their catalyst in a HDSCR application to North Dakota lignite, not a requirement in order to develop its availability. In its May 11, 2007 response to the B&McD query, CERAM outlined detailed design of the

---

[11] See April 28, 2008 emails from Robert Blakley (B&McD) to Noel Rasha (CERAM) and Flemming Hansen (Haldor Topsoe).

catalyst and guaranteed a catalyst life of 16,000 hours. Contrary to statements in the NDDH BACT determination that a HDSCR could not be designed at MRYS due to uncertainties in deactivation rates of the catalyst, a very experienced and reputable catalyst vendor has expressed confidence that it could do so (if the temperature variation issue is resolved) and provided such information.

- Haldor Topsoe responded to B&McD's follow-up by stating, "[w]e suggest that the next step is a larger pilot scale experiment with in the order of 2x2m of catalyst installed. We would like to participate in such an experiment. This would allow better catalyst cleaning and give a better determination of the catalyst degradation over time. Based on our current information, we expect 60% deactivation over the first 10,000 operating hours. We can not provide a 'make good' guarantee', but are willing to warrant the catalyst performance up to the contract value." These statements are clearly a recommendation that acknowledge testing would enhance the applicability of their catalyst in a HDSCR application to North Dakota lignite, not a requirement in order to develop its availability. In fact, contrary to statements in the NDDH BACT determination that a HDSCR could not be designed at MRYS due to uncertainties in deactivation rates of the catalyst, a very experienced and reputable catalyst vendor has expressed confidence that it could do so, provided the temperature variation issue is resolved. As explained in Mr. Hartenstein's expert opinion report, the guarantee up to the contract value is a standard industry guarantee. Thus, the statements by Haldor Topsoe do not support the notion that HDSCR would require pilot testing in order for commercial availability, as outlined in the NDDH BACT determination.

- The export opinion report of Mr. Hartenstein clearly indicates that based on his extensive knowledge and experience with SCR applications under widely different flue gas conditions and discussions he had with catalyst vendors and SCR system suppliers, catalyst and plugging and deactivation would not be a fatal flaw to installing HDSCR at MRYS.

- As will be explained in more detail in a later section, the docket information for the TXU Oak Grove New Source Review permit (a proposed project that will include HDSCR and burn 100% Texas lignite) provides further evidence that, despite the challenges that exist in applying HDSCR to a new fuel type, the utility industry believes that SCR is technically feasible and any questions about the its application are a matter of cost. This is evident not only in the permit docket, but also in a letter from the Electric Power Research Institute that was originally sent to the NDDH in EPA's January 8, 2007 letter. In addition, the Texas Commission on Environmental Quality determined that the uncertainties involved with firing a new fuel type and the accelerated HDSCR catalyst plugging and deactivation that was expected from exclusively firing Texas lignite was not a reason to find that SCR would be technically infeasible. While the properties of North Dakota and Texas lignite might not be the same, the same basic principle applies that the accelerated catalyst replacement requirements are a matter of economics and not technical feasibility.

Based on the information and observations above, EPA concludes that the successful operation and technical feasibility of HDSCR at MRYS would not be precluded by the catalyst plugging and deactivation issues related to the cyclone-firing North Dakota lignite described by Minnkota and in the NDDH BACT determination. Catalyst vendors believe the challenges involved would be manageable and they would be able to design a suitable catalyst with a performance guarantee. While the vendors would prefer to conduct some testing to mitigate risks, optimize the design, and better predict catalyst life, these same vendors also appear willing to make the catalyst commercially available. Therefore, HDSCR should not be eliminated as being technically infeasible on the basis of catalyst plugging and deactivation.

MRYS Temperature Variation Issue Related to HDSCR

- The SCR system supplier responses indicate that the temperature variation issue would likely be very challenging for a HDSCR installation at MRYS (and more unique than the potential catalyst plugging and deactivation issues for cyclone-firing of North Dakota lignite). Although the B&McD query was clearly directed toward a response only on HDSCR, SCR system suppliers (Alstom and Backbock Power) suggested looking at the possibility of TESCR as a way of avoiding both the concerns with temperature variations and fuel characteristics.

- The other SCR system supplier (Babcock & Wilcox, which does not have extensive TESCR experience) certainly did not dismiss the possibility of being able to overcome the challenges presented at MRYS for SCR installation and welcomed working with Minnkota to explore “creative solutions.”

- EPA received information in response to a Clean Air Act Section 114 request pertaining to the vendor query conducted by B&McD.[12] This information is included herein. Babcock & Wilcox (B&W), who was the original manufacturer of the boilers at MRYS, indicates that modifications to the boiler likely could be made that would address the temperature problems, or that out of boiler modifications/changes (e.g. auxiliary fuel drying) would be necessary. In either case, the temperature issue appears to a resolvable technical problem, albeit at a likely high cost.

---

[12] See July 18, 2007 e-mail from Steve Moormann (Babcock & Wilcox) to Robert Blakely (Burns & McDonnell).

EPA believes that the technical issue with the temperature variation in the backpass end of the boilers at MRYS where a HDSCR would be located presents a significant challenge. However, it appears that the technical challenges with the temperature variation can be resolved. Furthermore, the issue of backpass boiler temperature variation completely goes away in the case of TESCR and LDSCR. Therefore, no matter what the implications are of resolving the temperature variation issue, there are other options for installing SCR technology that would avoid this problem altogether.

EPA's Conclusion on HDSCR

In summary, EPA believes the NDDH BACT analysis incorrectly eliminates HDSCR as technically infeasible at MRYS because pilot testing would be required on Center Mine lignite fuel before application at MRYS. The uniqueness of the fuel at MRYS (Center Mine lignite) does not appear to pose technical problems that catalyst vendors do not believe can be managed in order to provide a reasonable guarantee. The soluble sodium deactivation issue cited in the NDDH BACT determination as a fatal flaw to installing HDSCR is not supported by any useful or relevant data and is speculative. Furthermore, the opinions of catalyst suppliers and leading SCR expert Mr. Hartenstein indicate that catalyst poisoning by sodium is only an issue during periods when the catalyst is allowed to cool well below its normal operating temperature. This would be an infrequent occurrence and can be managed by isolating the catalyst during shut-downs. Additionally, catalyst regeneration is a viable option (that is currently used in practice) for restoring catalyst life by either in-situ, on-site, or off-site water washing.[13] The temperature variation problem appears to be a more significant challenge for the successful operation of HDSCR (but not TESCR or LDSCR), but the necessary modifications to resolve this problem would be a matter of cost.

III. THE NDDH BACT DETERMINATION INCORRECTLY APPLIES THE CONCEPT OF PILOT TESTING IN EPA'S NSR MANUAL TO CONCLUDE THAT SCR IS NOT TECHNICALLY FEASIBLE.

NDDH has misinterpreted EPA's NSR Manual to support a finding of technical infeasibility of SCR at MRYS because it has been suggested pilot testing and/or engineering research would be required. EPA has previously clarified for Minnkota and the NDDH that this reference in EPA's NSR Manual is only relevant to whether a control option was

---

[13] On page 46, the NDDH BACT determination states that there are "no known engineering solutions to….restore the catalytic reactions by removing particles from catalyst pores." This is simply not true and it appears that the NDDH did not investigate this possibility in any depth. As one example of actual regeneration experience, EPA is enclosing a 2007 NOx Round Table & Expo Presentation by Reinhold Environmental Ltd (February 5-6, 2007 in Cincinnati, OH) that details in-situ and on-site catalyst washing experience at the Avedore Station in Denmark.

"available." There is little question that SCR is "available" for installation at MRYS and, in fact, the Minnkota BACT analysis already conceded that SCR is "available."[14]

The NDDH BACT determination relies upon the lack of demonstrated application of SCR technology and mitigating tools used to manage ash deposition and catalyst deactivation (such as screens, baffles, soot-blowing, rejuvenation, etc.) on a cyclone boiler firing North Dakota lignite to conclude that it is necessary for the source to do additional pilot testing and engineering studies. According to NDDH's interpretation of EPA's NSR Manual, this additional step precludes the technology from being considered technically feasible.

The NDDH BACT determination states that, "[t]he fundamental question for this BACT determination is whether SCR is an available technology for North Dakota lignite-fired cyclone boilers such as Minnkota Units 1 and 2."[15] The concept of <u>availability</u> of a control technology is introduced in the NDDH BACT determination by quoting EPA's NSR Manual, which states, "[a] control technique is considered available, within the context presented above, if it has reached the licensing and commercial state of development. A source would not be required to experience extended time delays or resource penalties to allow research to be conducted on a new technique. Neither is it expected that an applicant would be required experience extended trials to learn how to apply a technology on a totally new and dissimilar source type. Consequently, technologies in the pilot scale testing stages of development would not be considered available for BACT review."[16]

The NDDH BACT determination concludes, "SCR has not reached this stage for North Dakota lignite-fired cyclone boilers, and because of the difference in the gas stream[17], the Department concludes that Minnkota need not experience extended trials to learn how to apply the technology on such a dissimilar source type."[18]

With this statement, NDDH has erroneously combined two steps which are described in EPA's NSR Manual as separate steps for determining technical feasibility of a control option,

---

[14] See EPA's October 4, 2007 letter to NDDH and Minnkota, page 31 and Minnkota BACT analysis, page A1-32, where B&McD states, "SCR technology is an available technology which has been installed on numerous powerplant facilities around the world and there are a large number of manufacturers that market the technology. The question is whether SCR technology is "applicable" for a unit firing North Dakota lignite." In its November 13, 2007, letter, Minnkota appears to have reversed course on the issue of SCR availability, and attempts to focus on the dissimilar aspects of MRYS to other facilities that have installed SCR. Notwithstanding the statements in this letter, however, there is no disputing that the Minnkota BACT analysis clearly stated that SCR is available and that the only question is whether it is applicable.

[15] See NDDH BACT Determination, page 5.

[16] See EPA's NSR Manual, page B.18.

[17] The concept of evaluating differences in the gas stream between the source under review and other sources where a control option has been applied is introduced in EPA's NSR Manual during the discussion of whether an available control option is also <u>applicable</u>.

[18] See NDDH BACT Determination, page 6.

namely, availability and applicability. A plain reading of EPA's NSR Manual shows that EPA saw the technical feasibility determination as two separate steps. First, the reviewing authority should determine whether a control option is available. As stated in the EPA NSR Manual, if a ***new*** control option is only in the early developmental stage, it is not considered (commercially) available. Therefore, under the Top-Down BACT analysis, the control option is eliminated from consideration as being technically infeasible, without any analysis on whether the control option is applicable to the source under review and does not require the same degree of technical analysis and judgment on the part of the reviewing authority. EPA's NSR Manual specifically mentions pilot testing as a component of determining availability, which is defined as the "process commonly used for bringing a control technology concept to reality as a commercial product.

- concept stage;
- research and patenting;
- bench scale or laboratory testing;
- ***pilot scale testing;*** (emphasis added)
- licensing and commercial demonstration; and
- commercial sales." [19]

For determining whether a control option is available, EPA's NSR Manual does not describe the comparison of gas stream characteristics between the source under review and other sources. Commercial availability of SCR is a plain fact, evidenced by the SCR system supplier and catalyst vendor responses garnered by B&McD and supplemented by EPA herein, the extensive applications of SCR to coal-fired power plants and other industrial sources worldwide for decades, and even as stated in the Minnkota BACT analysis. [20]

The second step of the technical feasibility analysis is to determine whether an available control option is also applicable to the source under review. As noted correctly in the NDDH BACT determination, the EPA's NSR Manual "provides that technical judgment of the review authority must be exercised in determining whether a control alternative is *applicable* to the source type under consideration"[21] (emphasis added) and cites a portion EPA's NSR Manual regarding applicability, which states, "a commercially *available* control option will be presumed to be *applicable* if it has been or is soon to be deployed (e.g. is

---

[19] See EPA's NSR Manual, page B.17.

[20] EPA also strongly disagrees with the assertion in the NDDH BACT determination that a control option can be eliminated under the Top-Down BACT process if any "engineering study" is required. This very vague and broad term could be applied to any phase of designing a piece of pollution equipment or technique. Presumably, every major piece of pollution control equipment (i.e. scrubber, SCR, baghouse, Electrostatic Precipitator, etc.) applied to a utility boiler has entailed engineering study. EPA categorically dismisses use of this term in NDDH's BACT determination and believes that this extremely narrow view of what is required in the Top-Down BACT process is particularly problematic.

[21] See NDDH BACT Determination, page 5 and EPA's NSR Manual page B.18.

specified in a permit) on the same or similar source type. Absent a showing of this type, technical feasibility would be based on examination of the physical and chemical characteristics of the pollutant-bearing gas stream and comparison of the gas stream characteristics of the source types to which the technology has been applied previously."[22] (Emphasis added.) Hence, a comparison of gas stream characteristics would only be required once it has already been established that the control option is available. Furthermore, the question of whether pilot testing and conducting additional research is necessary no longer applies to the analysis, since it is only relevant for a determination of availability, which would have already been confirmed. Contrary to EPA's NSR Manual, the NDDH BACT determination makes a determination of availability based, in part, on the comparison of gas stream characteristics.

The NDDH BACT determination states, "all responses (to the B&McD vendor query) indicated the following: 1) The need for additional testing to either determine if there were any fatal flaws or to obtain data for the design of a potentially successful SCR system."[23] Clearly, this is not the type of pilot testing that is referenced in the EPA NSR Manual for developing a new control technology from concept stage to the commercial state of development. This type of testing would instead provide more certainty to designers and likely result in a more optimum SCR system design at MRYS, as it would to any application of SCR to a new plant. In other words, this type of testing would be used to enhance the applicability of SCR at MRYS. The responses from SCR system suppliers and catalyst vendors are speaking to the advantages of doing additional testing on North Dakota lignite to enhance the applicability of (HD)SCR at MRYS, not on whether SCR is a commercially available control technology. For example, when prompted by B&McD on the prospect of doing pilot testing, CERAM stated, "we would agree that there is good cause for further testing on a lignite fired unit to *further mitigate the risks and optimize design*."[24] (Emphasis added.)

Since SCR has been so widely applied to coal-fired boilers and other industrial sources, commercial availability of SCR should be determined primarily based on whether the SCR system suppliers and catalyst suppliers are willing to commercially provide and install the technology on the source in question, not based on whether the reviewing authority believes additional testing would provide more certainty and lead to a better designed SCR. It is clear from the record that vendors are willing to do so. Many of the vendors responses from the B&McD query clearly indicate that they believe SCR can work at MRYS[25] and do not

---

[22] See EPA's NSR Manual, page B.18.

[23] See NDDH BACT Determination, pages 39-40.

[24] See May 6, 2008 email from Ceram Environmental, Inc. to B&McD.

[25] See May 30, 2007 and May 5, 2008 letters from Alstom Power to B&McD; see May 11, 2007 and May 6, 2008 emails from Babcock Power Environmental, Inc. to B&McD; see May 11, 2007 and May 6, 2008 emails from Ceram Environmental, Inc. to B&McD; see May 10, 2007 and May 5, 2008 emails from Haldor Topsoe, Inc. to B&McD. Note that these responses have been greatly supplemented by the vendor responses related to TESCR

require that pilot testing be conducted upfront to make the technology commercially available.

Lastly, the NDDH BACT Determination for LDSCR and TESCR at MRYS also concludes, "catalyst deactivation of a low-dust or tail gas SCR due to alkali compounds is an issue that will require extensive research, design and pilot testing to determine whether the technology can be successfully applied to units fired on North Dakota lignite. Therefore, these technologies are not considered applicable and not technically feasible at this time."[26] Again, this rationale is a misinterpretation of the EPA NSR Manual. The question of whether LDSCR and TESCR are in the pilot testing stage of development is only relevant in terms of whether it is an available control option. Both LDSCR and TESCR are not only available control options, but would also be applicable to MYRS. In fact, the responses from the supplemental SCR system catalyst vendor query conducted by Mr. Hartenstein, and provided in the Enclosure herein, clearly indicates that vendors would provide a TESCR at MRYS with a guarantee and do not support doing any additional pilot testing.

IV. THE NDDH BACT DETERMINATION FRUSTRATES THE TECHNOLOGY-FORCING FUNCTION OF THE BACT PROCESS THAT WAS INTENDED BY CONGRESS.

The NDDH BACT determination is not only at odds with EPA's NSR Manual, but it also frustrates the technology-forcing function of the BACT process. As described above, the NDDH BACT determination repeatedly notes a lack of actual experience with SCR on North Dakota lignite and cyclone boilers as a primary basis for concluding that "experimentation" and/or "extensive, and correspondingly expensive, engineering studies" would be necessary to determine if uncertainties could be overcome. Congress developed the case-by-case BACT process so that the best technology becomes as widespread as possible. The NDDH BACT determination takes the position that a control option is technically infeasible because no other power plant with the exact same design and fuel source has applied the control option. Under this presumption, the best technology would not become widely used, unless some independent "proof" of it working on the exact type of source and flue gas characteristics under review was provided. This application of the BACT process is contrary to the technology-forcing function of the BACT process that congress intended when enacting Clean Air Act.

---

gathered by Mr. Hartenstein.

[26] See NDDH BACT Determination, page 57.

V. OTHER COMMENTS ON THE NDDH BACT DETERMINATION

1. Page 4 of NDDH BACT Determination: "Information from Sargent and Lundy indicates that not enough information is available to determine whether SCR technology can be successfully adapted to units burning North Dakota lignite."

   EPA Response: This is not what Sargent & Lundy actually said in the May 2007 presentation to NDDH and EPA. In Sargent and Lundy's Conclusion Summary, they state, "[s]ome important unanswered questions pose significant risks for an SCR design engineer:

   An unknown catalyst deactivation rate will prevent:

   - optimum selection of a catalyst design
   - selection of an appropriate reactor size

   This could burden the operator with a long term costly maintenance requirements (sic) and unscheduled outages"

   Sargent & Lundy states that premature catalyst failure will require more frequent catalyst replacement, ammonia slip and subsequent airheater pluggage, and higher auxiliary power requirements. These conclusions suggest that Sargent & Lundy's opinion is that the lack of data specific to North Dakota lignite on SCR operation would result in a less than optimal design and as a result increased capital and operating costs. While this opinion indicates that applying SCR to North Dakota lignite without obtaining further data might not be the best engineering approach, Sargent & Lundy did not opine that SCR could not be "successful" on units firing North Dakota lignite.

2. Page 7 of the NDDH BACT determination: "The advances made in the last few years for controlling popcorn ash are not shown to be applicable to a cyclone boiler burning North Dakota lignite. Extensive engineering analyses, and likely pilot scale testing, will be necessary to determine if these advances can be applied at M.R. Young Station."

   EPA Response: This statement and conclusion is inconsistent with the discussions between NDDH, EPA, and Minnkota at the May 23, 2007 meeting held in Bismarck. During this meeting popcorn ash was discussed and EPA's consultant, Roger Christman, stated that he believed the popcorn ash problem had been dealt with successfully at many other facilities and that it would not pose a significant problem at MRYS. Mr. Christman asked Minnkota and B&McD whether they agreed that the effects of popcorn ash is solvable at MRYS and whether it could be "taken off the table" as a real issue in the discussion of HSSCR technical feasibility. Minnkota agreed that it was a solvable issue and certainly did not indicate that pilot testing would be required to address the effects of popcorn ash at MRYS. In light of these discussions, it is unclear why NDDH still believes that this is a technical barrier for the successful operation of HDSCR at MRYS.

3. Pages 13-15 of the NDDH BACT determination: In identifying all control technologies under Step 1 of the Top-Down BACT analysis, the NDDH BACT determination lists, "Fuel Switching/Blending/Cleaning." In the Step 2 analysis for this control option, the NDDH BACT determination cites experience at the Big Stone Power Plant in South Dakota with switching to PRB fuel as not lowering NO_x emissions and then references a Seventh Circuit Appeals Court decision regarding the Prairie State Generating Station PSD permit that stated fuel switching is not required for mine mouth power plants in the BACT analysis. Therefore, the NDDH BACT determination concludes that switching or blending fuels other than Center Mine lignite in order to mitigate the effects of the fuel on other control options would not be required.

   EPA Response: While the NDDH BACT determination appears to have looked at fuel switching and blending, it ignores the possibility of fuel cleaning in Step 2, although fuel cleaning was correctly listed under Step 1. Many of the technical problems described in the NDDH BACT determination for installation of other control options, such as SCR, are due to downstream conditions caused by the poor quality of the Center Mine lignite fuel (i.e. high ash, high sodium, high moisture, low heating content, the need to do fuel predrying in the cyclone boiler, etc.). Therefore, it appears that NDDH should explore potential fuel cleaning possibilities to address these effects. While EPA does not agree that fuel cleaning would be required in order for SCR to be considered technically feasible, the conclusions of the NDDH BACT determination are further flawed and incomplete without such an analysis.

4. Page 29 of the NDDH BACT determination: "Consumers Energy indicated they purchase coal from several western mines as well as eastern mines. They also indicated that none of the coal obtained from the Spring Creek Mine is fed to a unit equipped with an SCR system. Based on this information the Department is not aware of any power plant that is equipped with an SCR system and burns Spring Creek Mine coal."

   EPA Response: There is a reference to a May 13, 2008 email from Bradely Plummer of Consumers Energy to Tom Bachman of NDDH. This email was not made part of the administrative record, but appears to be information that the NDDH relied upon in making its BACT determination. This email should be made publically available and part of the administrative record for this BACT determination.

5. EPA would like to add the documents identified in Sections VI through VIII, below, to the administrative record for the NDDH to consider in its Final BACT determination.

VI. DOCKET INFORMATION FOR THE TXU OAK GROVE NSR PERMIT IS EVIDENCE THAT THE UTILITY INDUSTRY & OTHER STATE AGENCIES BELIEVE THAT SCR IS TECHNICALLY FEASIBLE & CAN BE APPLIED TO NEW FUEL TYPES & BOILER TYPES.

On July 27, 2005, Oak Grove Management Company, LLC (Oak Grove) applied to the Texas Commission on Environmental Quality (TCEQ) for a Prevention of Significant Deterioration (PSD) permit to construct a new 1,600 MW (net) pulverized coal power plant consisting of two 860 MW (gross) units. The proposed facility would be fired on 100% Texas lignite. On February 21, 2006, the TCEQ Executive Director issued a preliminary decision and draft permit that required HDSCR and a limit of 0.08 lb/MMBtu as BACT for NO_X. At Oak Grove's request, the application and determination was referred to the State Office of Administrative Hearings (SOAH) for hearing on whether it complied with all applicable statutory and regulatory requirements.

On August 23, 2006, the SOAH Administrative Law Judges (ALJs) issued a Proposal for Decision (PFD) with a finding that Oak Grove failed "prove by a preponderance of the evidence that its BACT proposal to use SCR with lignite-fired boilers can reasonably be expected to achieve a 0.08 lb/MMBtu NOx emission rate."[27] Essentially, the ALJs found that since HDSCR has not been previously proven in practice on a plant burning 100% Texas lignite, there were uncertainties with the application of, "a relatively new technology that has never been used in the United States on a commercial scale with a lignite-fired electric power plant."[28]

While Oak Grove took the position that there were uncertainties and challenges with the design of an SCR reactor for lignite coal firing, the company argued that SCR is technically feasible and that, "the PFD failed to make the distinction between 'technical practicability' and 'economic reasonableness'."[29] Oak Grove takes the position that, "[t]o the extent that there is any issue or question regarding the use SCR (sic) at the proposed facility, it is a question of cost."[30] Oak Grove's reason for pointing out the uncertainties with

---

[27] See ALJ's Proposal for Decision and Order, August 23, 2006, page 24.

[28] See ALJ's Proposal for Decision and Order, August 23, 2006, page 24.

[29] See Applicant's Exception to the Proposal for Decision, September 12, 2006 page 10.

[30] See Applicant's Exception to the Proposal for Decision, September 12, 2006, page 10.

applying SCR to a fuel type that has never been demonstrated in practice was an attempt to have the NO_x limit raised in the final permit, not to show that SCR should be considered technically infeasible.

Additionally, Babcock Power Environmental, as the Air Quality Control System supplier for Oak Grove, sent a letter to the TCEQ's Executive Director (August 30, 2006) outlining why it believes the ALJ's PFD is incorrect and SCR is technically feasible for the Oak Grove plant. Interestingly, Babcock Power cites the EERC Coyote Station pilot testing results and dismisses those problems based on moisture problems introduced by the sootblowers that caused much of the plugging during that test.

The TCED permit engineer for the Oak Grove permit, Randy Hamilton, also believed that HDSCR should not only be considered technically feasible, but Mr. Hamilton also recommended a lower NO_x limit of 0.07 lb/MMBtu to the TCEQ Environmental Director. Although the ALJs appear to have misconstrued a statement made by Mr. Hamilton in his written deposition to SOAH, where Mr. Hamilton describes the hypothetical best and worst case possibilities of SCR ash deposition on the Oak Grove units,[31] Mr. Hamilton confirmed with EPA that it was never his professional opinion that the worst case scenario he described was a real possibility, but only a rhetorical examination of two logically possible outcomes.[32]

Ultimately, the TCEQ's Final Order (June 21, 2007) rejected the arguments over technical infeasibility of SCR at Oak Grove, overturned the ALJ's PFD, and granted the PSD permit to Oak Grove with a NO_x BACT determination of SCR and a limit of 0.08 lb/MMBtu. In short, the Commission found that the ALJs "placed too much emphasis on the absence of previous applications of the proposed technologies with regard to Texas lignite."[33]

The positions taken by the TCEQ (technical staff, Executive Director, and Final Order), Oak Grove, and Babcock Power largely coincide with and support EPA's position with regard to general technical feasibility of SCR on different fuel types and whether questions of feasibility are a matter of technical feasibility or economic feasibility. EPA also generally agrees with these parties that the position taken by the ALJs (and likewise by Minnkota and the NDDH in the case of MRYS), "will remove an essential element of the air emissions permitting process as contemplated by both state and federal Clean Air Acts – the advancement of air pollution control process.....Simply stated, the ALJ's interpretation of the

---

31 See ALJ's Proposal for Decision and Order, August 23, 2006, page 15, "[t]he uncertainty with regard to ash deposition is not mathematically convertible to a NOx emission limit adjustment. The ideal outcome would be that plugging proves to be no problem at all. Under this scenario, NOx emissions could be as low as any coal-fired boiler and the BACT emission limit could have been lower. The worst outcome would be that the SCR plugs with flyash rapidly and completely and no engineering solution can be found. Under this scenario, SCR would be technically infeasible, and BACT would have to be higher, based on the next most effective technology..."

32 See April 16, 2008 email from Randy Hamilton (TCEQ) to Hans Buenning (EPA Region 8).

33 See TCEQ Final Order, June 21, 2007, page 45.

technical practicability element of the BACT analysis would categorically prevent the first-time application of new control technologies in Texas."[34] The same could be said of the state of North Dakota under the positions taken in the NDDH BACT determination.

EPA is submitting the TCEQ/SOAH Docket information for the Oak Grove permit proceeding to be entered in the administrative record and considered in NDDH's Final BACT determination (see Enclosure 3). While EPA understands that there are differences between Texas and North Dakota lignites, as well as the boiler configurations at Oak Grove and MRYS that make the technical application of SCR different, the principles illustrated in the Oak Grove permit proceeding related to the BACT process largely parallel those in the Minnkota NOx BACT determination. EPA is also submitting additional information relative to the Oak Grove permit proceeding that is not contained in the docket (also part of Enclosure 3). The docket can be accessed electronically at:

http://www7.tceq.state.tx.us/uploads/eagendas/Agendas/2007/6-13-2007/Oak%20Grove.pdf

VII. B&McD 114 RESPONSE DOCUMENTS

On June 20, 2008, EPA issued a Clean Air Act, Section 114 request for information to B&McD asking for information related to the SCR system and catalyst vendor query that was conducted by B&McD on behalf of Minnkota. EPA received B&McD's response on July 3, 2008. EPA is submitting portions of the response herein as part of Enclosure 3 for the state to include in the administrative record and consider in NDDH's Final BACT determination. To summarize some significant findings, the B&McD response indicates:

- Early draft versions of the vendor query document prepared by B&McD asked for vendor opinions of the temperature variation issue for HDSCR at MRYS and possible boiler modifications that could address this problem. At Minnkota's direction, this request was removed from the final query document.

- Based on B&McD's call notes following up with the vendors that gave more optimistic responses in early 2007 (those that were less optimistic were deemed by Minnkota as not needing follow-up), it is clear that catalyst vendors were not swayed by the arguments set forth by B&McD and EERC related to the potential severity of sodium catalyst poisoning. Also, SCR system suppliers told B&McD that they believe tail-gas SCR would resolve the problems being advanced by B&McD and EERC related to lignite fuel firing. Why B&McD did not pursue the tail-gas option with vendors after it had been suggested is unclear.

---

[34] See Applicant's Exception to the Proposal for Decision, September 12, 2006, page 8.

- In two separate documents (comments on a draft response to EPA comments dated February 6, 2007 and an email correspondence dated May 10, 2007), Robert Johnson (who was working as a consultant, but it is believed previously worked for Argillion and then B&McD) opined on many of the technical issues for an SCR at MRYS. The positions taken by Mr. Johnson largely support positions taken by EPA, namely that there is no useful underlying data that supports the claims of EERC regarding the severity of sodium catalyst poisoning (in HDSCR, LDSCR, or TESCR), the Coyote Station pilot testing "was a flawed test and the results should not be used to draw any conclusions other than that a full scale system design needs to be done very carefully", sodium is not much of a concern as a catalyst poison at SCR operating temperatures, and that TESCR is a likely candidate for MRYS.

- It appears Minnkota has conducted a cost analysis of SCR at MRYS using different expected catalyst life spans of 12,000 and 24,000 hours. This information has not been made publically available to EPA's knowledge.

VIII. DOCKET INFORMATION FOR THE CLEAN AIR INTERSTATE RULE (CAIR), BEST AVAILABLE RETROFIT TECHNOLOGY (BART) GUIDELINES, AND NEW SOURCE PERFORMANCE STANDARDS (NSPS) STATES THAT EPA DETERMINED THAT SCR IS TECHNICALLY FEASIBLE FOR LIGNITE FIRED UTILITY BOILERS.

In a January 8, 2007 letter (sent via fax), EPA provided the NDDH with docket information and references related to various rulemakings (CAIR, BART Guidelines, NSPS), where EPA determined SCR to be feasible at lignite-fired utility boilers. This information does not appear to be completely in the administrative record for the NDDH BACT determination, so EPA is providing information related to these rulemakings herein as part of Enclosure 3 for the NDDH to include in the administrative record and consider in NDDH's Final BACT determination. As mentioned in the January 8, 2007 letter, through these three rulemakings, EPA determined SCR to be technically feasible and rejected commenter's concerns that SCR would not be technically feasible for lignite units, including those fired on North Dakota lignite. EPA reiterates that the position now being taken in the NDDH BACT determination is contrary to that established by EPA in these three national rulemakings.

1. INTRODUCTION AND OVERVIEW

1.1 Information Required for the Expert Report

The following is a listing of the items provided with this report:

(1) This report contains my personal opinions, conclusions and the reasons therefore.

(2) The body of the report and **Appendix A** list the data and other information considered in forming these opinions.

(3) **Appendix B** provides a copy of the e-mail correspondence with several selective catalytic reduction (SCR) catalyst manufacturers and SCR equipment vendors concerning the technical feasibility of tail-end SCR (TESCR).

(4) **Appendix C** includes a listing of publications authored during the past ten years.

(5) Section III presents a statement of my qualifications; my resume is attached as **Appendix D**.

(6) I am being compensated for the preparation of this report and my testimony by the U.S. Department of Justice.

(7) I have provided previous testimony within the preceding four years as an expert at trial or by deposition.

1.2 Purpose of the Report

This report is written under a consulting contract and pursuant to a request from the Department of Justice (DOJ) for an analysis of whether or not the SCR technology would be a technically feasible and available technology for the reduction of nitrous oxides (NOx) for installation at the Milton R. Young Station located near Center, North Dakota.

A preliminary Best Available Control Technology (BACT) determination for control of NOx for the M.R. Young Station conducted by the Division of Air Quality of the North Dakota Department of Health[1] (the Department) concludes that the SCR technology is not

---

[1] Preliminary Best Available Control Technology Determination for Nitrogen Oxides for M.R. Young Station Units 1 and 2, Division of Air Quality ND Department of Health, 918 E. Divide Avenue, Bismarck, ND, June 2008.

technically feasible at this time. I was asked to review the information in and provided by this preliminary BACT determination and render an expert opinion concerning the technical feasibility of the SCR technology for retrofit at the M.R. Young Station.

2. SUMMARY OF CONCLUSIONS

In summary, and for the reasons described herein, I have concluded that the SCR technology is technically feasible and principally available for installation at both units at the Milton R. Young Station for NOx reduction. I have further concluded that even though the high-dust SCR (HDSCR) principle was investigated in some detail prior to the BACT determination:

- The depth of the investigation concerning the technical feasibility of HDSCR in this case by means of pilot testing conducted at the Coyote Station (Coyote Pilot Testing) was insufficient and the conclusions drawn from this pilot testing were speculative and premature.
- Virtually no investigation of the technical feasibility of low-dust SCR (LDSCR) and TESCR was conducted at all and both distinctly different SCR principles were incorrectly treated as if they would be essentially the same.
- The HDSCR Coyote Pilot Testing was ill-designed and inadequately conducted.
- The data generated by the Coyote Pilot Testing for these reasons is inconclusive and meaningless of the purpose of this determination.
- The conclusions suggested by the Department based on the data presented are not reasonably founded but premature, purely speculative and mostly incorrect.

Consequently, it is my opinion that the conclusions presented by the North Dakota Department of Health in the BACT determination[2], namely, that the SCR technology is not technically feasible at this time for both units at the M.R. Young Station, is wrong. Such a conclusion cannot be drawn correctly based on the available data. The SCR technology must be considered principally, technically feasible for Minnkota's Milton R. Young Station. This is even true for HDSCR even though not without significant but technically resolvable challenges, which may result in HDSCR not being the economically most advantageous SCR principle. However, whether HDSCR, LDSCR or TESCR is the economically most viable SCR solution for M.R. Young is beyond the scope of this report.

Finally, I have concluded that no sufficiently detailed investigation was conducted for LDSCR and/or TESCR in this case and the record of investigation provided by the

---

[2] Preliminary Best Available Control Technology Determination for Nitrogen Oxides for M.R. Young Station Units 1 and 2, Division of Air Quality ND Department of Health, 918 E. Divide Avenue, Bismarck, ND, June 2008.

Department is insufficient, inadequate and incomplete. Both of these SCR principles were incorrectly treated by the Department as being essentially the same, which is incorrect and unacceptable as the flue gas composition and characteristics entering a LDSCR are completely different from the one entering a TESCR.

The statement made by the Department that none of the various principles of the SCR technology (HDSCR, LDSCR, TESCR) can be considered applicable and technically feasible at this time is not only purely speculative but factually incorrect. As a matter of fact a quick vendor survey conducted by me confirmed that all contacted vendors consider TESCR as being unquestionably technically feasible, available and applicable for M.R. Young Station. This was not only unanimously confirmed by all leading catalyst manufacturers (Argillon, CERAM, Cormetech, Haldor Topsoe and Hitachi) but also by leading SCR equipment vendors (Alstom, Babcock Power and Babcock & Wilcox). Furthermore, these SCR equipment vendors and catalyst manufacturers confirmed my opinion by stating that they also consider LDSCR as technically feasible and probably even HDSCR, however not without significant but resolvable technical challenges such as limiting the boiler outlet temperature variations to a range tolerable for SCR catalyst and eliminating the popcorn ash problem. The temperature variations at the boiler outlets appear to be the biggest hurdle for the application of HDSCR at this time; however, this issue is considered to be technically resolvable as indicated by Babcock & Wilcox[3], who supplied both boilers at M.R. Young Station. Answering the question of whether or not the extent of modifications of existing equipment required to resolve the temperature variation issue makes HDSCR economically less attractive in comparison to LDSCR or even TESCR is beyond the scope of this report.

However, it is my opinion that the available data presented in the Department's BACT determination[4] is insufficient, inconclusive and interpreted largely incorrectly when concluding the HDSCR is technically infeasible. This conclusion cannot be supported by the available data at all. Furthermore, concluding that LDSCR and/or TESCR are not technically feasible based on the available data is incorrect, since no relevant data was presented that supports such a conclusion in any way. Based on my more than 20 years of SCR experience and my evaluation of the vendor responses, it is my opinion that the SCR technology is technically feasible and principally available for installation at both units at the Milton R. Young Station for NOx reduction. The only design engineering challenge is the proper selection of the best suitable type of SCR principle[5] to be applied and the correct SCR process and catalyst design. This, however, is neither a question of technical feasibility nor of applicability or availability of the SCR technology but simply a question of economics.

3. QUALIFICATIONS

I have been involved in the business development, proposal engineering and estimating, project management, process and design engineering, component and equipment procurement, construction, erection, commissioning and start-up and operation of air pollution control equipment for utility and industrial power plants as well as waste incinerators (municipal waste, hazardous waste, sewage sludge, medical waste etc.) in a variety of capacities for over twenty years. I began my career in the field of air pollution control in 1983 as a staff engineer working for Mercedes-Benz in automobile engine development adapting standard type European automobile engines with catalytic converters, secondary air injection systems, exhaust gas recirculation systems etc. in order to comply with more stringent emission regulations in entities such as California, the U.S. (48 states), Japan etc.

In late 1987, I accepted a position with L&C Steinmüller GmbH in Germany, which was one of the leading engineering and equipment vendors supplying power utility boilers, including the associated air pollution control equipment. Initially, my field of responsibility included business development for all environmental control technologies (air, water, waste) in Southern Germany. In 1990, I became Department Manager of the Department of Gas Cleaning for waste incineration facilities. In 1993, I became General Manager for Flue Gas Cleaning at L&C Steinmüller. Between 1988 and 1999, I was personally fully involved in the following retrofit phases in Europe:

- Retrofitting all fossil fuel fired boilers (utility and industrial) with a thermal heat input of more than 300 MW with flue gas desulfurization (FGD) systems ensuring a continuous SO_2 removal efficiency of at least 85% at all times, mostly wet limestone forced oxidation (LSFO) FGDs producing wallboard quality gypsum as a byproduct. This retrofit phase started in Western Europe in the late 1970s and ended in Eastern Europe in the late 1990s. FGD retrofits focused on Austria, Belgium, Bulgaria, Czech Republic, Denmark, Finland, Germany, Greece, Holland, Hungary, Poland, Slovenia, Slovakia, Spain, Sweden, Turkey and the U.K.

- Retrofitting all fossil fuel fired boilers with a thermal heat input of more than 300 MW with nitrous oxide removal (DeNOx) systems ensuring a NOx emission rate of less than 100 ppm[6] at all times, almost exclusively selective catalytic reduction (SCR) DeNOx systems. This retrofit phase started in Europe in the mid 1980s and is still ongoing. SCR retrofits focused on Austria, Belgium, Denmark, Finland, Germany, Holland, Italy, and Sweden.

- Retrofitting all waste incineration facilities regardless of the type of waste (municipal, industrial, hazardous, sewage sludge, medical etc.) with extensive flue gas cleaning

---

[6] At the following flue gas characteristics: NOx concentration by volume on a dry basis @ 5% O_2, 1 atm., 273 K.

> systems for the removal of acid gases (SOx, HCl, HF), NOx, particulate matter (PM), heavy metals including mercury (Hg), cadmium (Cd), lead (Pb) and numerous others as well as dioxins (PCDD) and furans (PCDF). This retrofit phase started in Europe in the early 1990s and is still ongoing. Waste incinerator retrofits focused on Austria, Denmark, Finland, France, Germany, Holland, Norway, Sweden, and the U.K.

In 1999, I became a co-founder and Managing Director of E&EC – Energy & Environmental Consultants GmbH, an international engineering consulting firm with offices in Germany and a representation in the U.S. Through E&EC I assisted a German SCR catalyst manufacturer in a concentrated effort to supply SCR catalyst and system expertise to the North American market. Also, through E&EC I assisted Babcock Borsig Power in Germany to align their German subsidiary Babcock Borsig Power Environment (former L&C Steinmüller) with their U.S. subsidiary DB Riley (today Babcock Power) in Worcester, Massachusetts in order to take full advantage of the business opportunities provided through the NOx SIP call under the Clean Air Act Amendments (CAAA) Title I Groundlevel Ozone Requirements[7].

Three months into the project, I was offered to take over the environmental business unit of DB Riley, Inc. (later renamed Babcock Borsig Power, Inc., now renamed Babcock Power, Inc.) in Worcester, Ma. After accepting this position, I was responsible for the SCR retrofits for the coal-fired units of American Electric Power (AEP), Detroit Edison (DTE), Duke Power, Louisville Gas & Electric (LG&E) and its subsidiaries Kentucky Utilities (KU) and Western Kentucky Energy (WKE), all now consolidated under E.ON-US, Northern Utilities (NU), Pennsylvania Power & Light (PP&L), Santee Cooper (SC), and Wisconsin Electric Energies (WE Energies) as well as the development of the emerging markets for FGDs and mercury-removal technologies. I left DB Riley and refocused on E&EC shortly before DB Riley's German parent company declared bankruptcy.

Through E&EC I founded SCR-Tech LLC together with a German partner and was acting president of SCR-Tech between 2001 and 2005. SCR-Tech was dedicated to providing the North American utility industry with SCR management and catalyst regeneration services.

After the sale of SCR-Tech in 2004, I left SCR-Tech in 2005 and joined Steag LLC, a wholly owned subsidiary of Steag AG in Germany. Steag AG (now renamed Evonik Steag GmbH) is part of Evonik Industries AG and dedicated to power generation and engineering. Evonik Steag GmbH owns and operates more than 10,000 MW of mostly coal-fired power plants around the world. In 2005, I accepted the position as president of Evonik Energy Services LLC (formerly Steag LLC), which has been dedicated to serve the North American utility industry with SCR design and management services since 1992 and also with catalyst regeneration services since 2007.

Through E&EC, I am also assisting the North American utility industry in their SCR and

FGD needs by fully utilizing my experience and expertise, which I developed over the past 21 years working as an engineer solely in the area of air pollution control systems for fossil fuel fired power plants and waste incineration facilities with a focus on FGDs and SCRs.

4. THE MILTON R. YOUNG STATION: BACKGROUND

The M. R Milton Station consists of two North Dakota lignite-fired steam electric generation units, with gross electric generating capacities of approximately 257 megawatts electric (MWe) (Unit 1) owned by Minnkota Power Cooperative and 477 MWe (Unit 2) owned by Square Butte Electric Cooperative. The units went into operation in 1970 (Unit 1) and 1977 (Unit 2). Both units feature cyclone-fired Babcock & Wilcox (B&W) boilers followed by tubular air pre-heaters. Air pollution control equipment consists of overfire air (OFA) systems for both units (Unit 2 OFA is scheduled in 2007 and Unit 1 OFA in 2009), a cold-side electrostatic precipitator (ESP) for particulate matter (PM) control for both units and a lime/fly ash wet scrubber for sulfur dioxide (SO_2) control for Unit 2[8]. Unit 1 will be retrofitted also with a wet lime scrubber supplied by Marsulex, which is scheduled to commence operation in April 2011[9]. Additionally, Minnkota Power Cooperative and Square Butte Electric Cooperative are committed to retrofit BACT for NOx control for both units under a Consent Decree with the United States and the State of North Dakota, dated July 27, 2006. The NOx control technology to be retrofitted must be determined by a top-down BACT Analysis, which must evaluate various technologies including SCR.

5. SCR TECHNOLOGY

The selective catalytic reduction (SCR) technology was originally developed in Japan under a government grant in the 1970s and subsequently retrofitted to most Japanese fossil fuel fired power plants[10]. SCR involves injecting gaseous ammonia generated from UREA, aqueous or anhydrous ammonia into the flue gas at a specific temperature before it reaches a catalyst. The catalyst significantly lowers the temperature required to complete the reaction of the injected ammonia with NO_x (mostly nitrogen oxide NO and nitrogen dioxide NO_2) to form nitrogen and water. Therefore the SCR reactor can be operated at a lower temperature zone at a suitable location in the flue gas path. Compared to the same reactions taking place without the presence of a catalyst, which is commonly referred to as selective non-catalytic reduction (SNCR) and requires flue gas temperatures between 1,500 F (~800 °C) and 2000 F

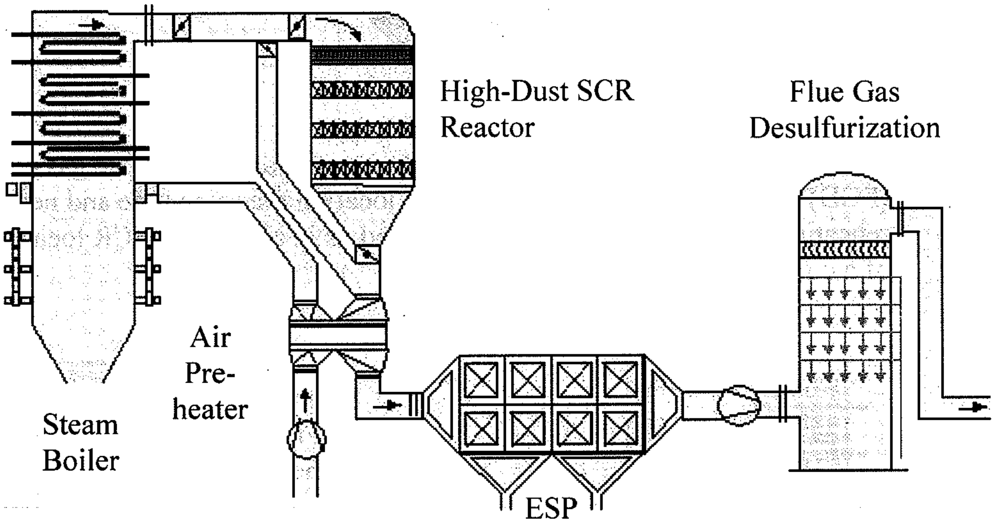
[10] Ando, Jumpei, "SO_2 and NO_x Removal for Coal Fired Boilers in Japan," presented at the Seventh Symposium on Flue Gas Desulfurization, May, 1992.

(~1,100 °C), the SCR process allows for a much higher NOx removal efficiency compared to the SNCR process while ensuring a very low (typically less than 2 ppmvd @ 3% O_2) ammonia slip. Continuous NOx removal efficiencies of well above 90% with NOx outlet concentrations well below 0.05 lbs/MMBtu[11] have been reported[12].

Various principles of the SCR technology are commonly described foremost by the SCR reactor's location within the flue gas path. Three main categories of SCR systems with one being split into two subcategories are known for fossil fuel fired utility boilers, namely:

- High-dust SCR (HDSCR) located between the boiler's economizer outlet and the air perheater inlet upstream of the ESP (pictured below). At this location typically no reheating of the flue gas is required.



- Low-dust SCR (LDSCR), which is split into two subcategories, namely:
  - Hot-side LDSCR located downstream of a hot-side ESP and upstream of the air preheater (not pictured below). At this location no reheating of the flue gas is typically required as the hot-side ESP is also upstream of the air pre-heater.
  - Cold-side LDSCR located downstream of the air preheater as well as downstream of a cold-side ESP (pictured below). At this location reheating of the flue gas is typically required as the cold-side ESP is downstream of the air preheater.

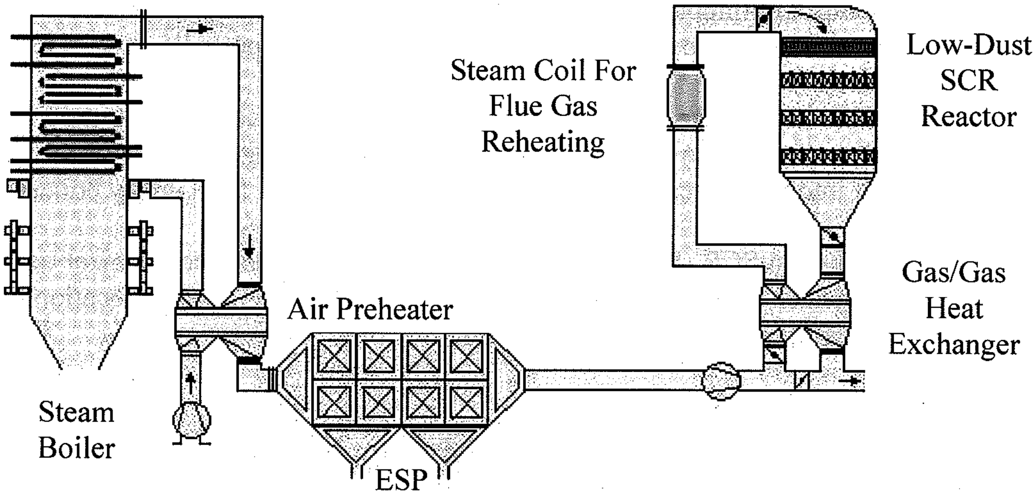
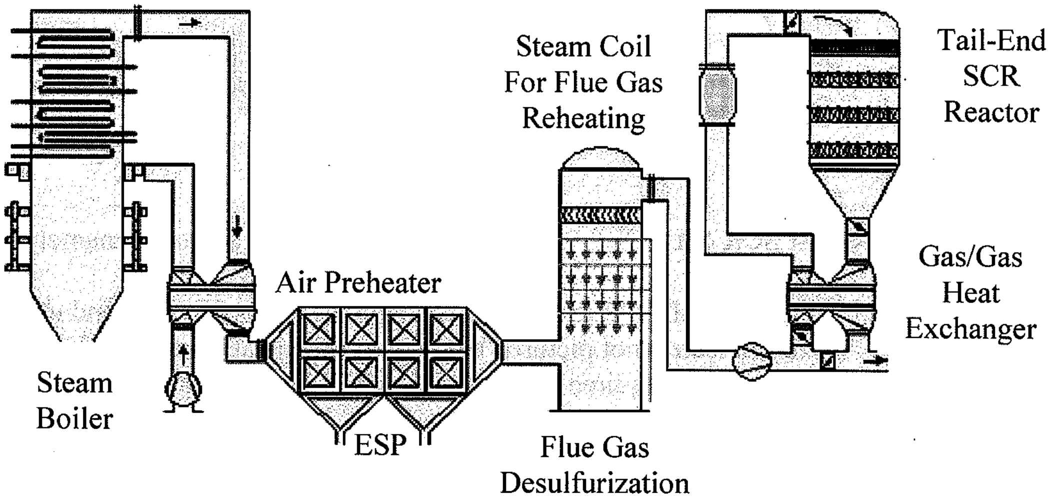
[12] Erickson, C., S. Straight, L. Hutcheson, "Coal-Fired SCR Operating Experience with High Removal Efficiency and Low-NOx Firing Systems", Babcock Power's website: www.babcockpower.com.



- Tail-end SCR (TESCR) located downstream of a dry or wet flue gas desulfurization (FGD) system (pictured below). At this location the same type and net quantity of reheating of the flue gas is always required as in case of LDSCR located downstream of a cold-side ESP pictured above.



After the technology was initially installed in Japan, SCR began to be used in Europe, mainly in Germany during the 1980s, where legislation introduced in 1983[13] required all power plants to drastically reduce the NOx emissions by the end of the decade. As a result, the first HDSCR on a coal-fired power plant in Europe went into operation in 1985 (Altbach Power

---

[13] EPA-450/3-92-004, Office of Air and Radiation, Office of Air Quality Planning and Standards, "Summary of NOx Control Technologies and their Availability and Extent of Application", February 1992.

Station Unit 5[14]), the first TESCR in Europe went into operation in 1986 (Hamburg Hafen Generating Station Unit 1[15]) and the first LDSCR went into operation in 1988 (Walsum Cogeneration Plant Unit 7[16]). By the end of the 1980s, SCRs were used in a wide variety of coal-fired power plants worldwide after Austria, Denmark, Germany, Holland and Japan had retrofitted most of their coal fired power plants with SCR systems for NOx removal. Even the first HDSCR on a lignite or brown coal fired utility boiler went into operation in Austria in 1990 (Voitsberg Power Station Unit 3[17]). By the end of the 1980s, well over 100 SCR systems had been installed in Europe on more than 30,000 MW of coal fired generating capacity with most SCRs representing retrofits of coal fired generating units[18, 19].

As reported by the Electric Power Research Institute (EPRI)[20], an institution solely funded by and dedicated to the electric utility industry, by 1989 the SCR technology was fully developed in two basic forms, namely as HDSCRs and as TESCRs. It is worth mentioning that the TESCR principle was mainly developed for the use on cyclone-fired and other wet bottom boilers because of their very high catalyst deactivation rates resulting from high arsenic levels in the flue gas in case of fly ash re-injection into the furnace for internal vitrification and no arsenic mitigation by means of limestone addition. Furthermore, TESCRs were also applied in some cases due to space constraints and/or difficult retrofit sites where the installation of a HDSCR would have caused elongated periods of downtime of the unit. In total about 40% of the SCR retrofits in Europe were TESCRs.

EPRI[21/]reports that all European SCR systems visited during a field trip in 1988 consistently met their design removal efficiencies of up to 88% in HDSCRs and TESCRs operating in coal fired units firing coals with sulfur contents up to 1.5 %wt. This overall finding was solidified by 1989 after additional years of operating experience.

EPRI reported heat rate penalties on the unit between 1 and 3% resulting from the necessity of flue gas reheating in case of cold-side LDSCR and/or TESCR. Such flue gas reheating requires the use of a gas/gas heat exchanger, in which the flue gas coming from the SCR

[21] Ibid

reactor outlet is used to reheat the flue gas going to the SCR reactor inlet similarly to an air preheater. These gas/gas heat exchangers can be designed as rotary type, tubular or plate type heat exchangers. All three types have been utilized successfully. Since a 100% efficient heat transfer from the outgoing to the incoming flue gas is physically impossible, a comparatively small amount of additional energy must be provided for reheating the flue gas downstream of the gas/gas heat exchanger to the SCR reactor inlet temperature. This additional energy, which is needed to overcome the temperature gradient of the gas/gas heat exchanger, amounts to an additional heating of the flue gas of typically between 45 degrees F (25 K) and no more than 90 degrees F (50 K) with amounts known as low as 18 degrees F (10 K). Flue gas reheating is most commonly accomplished in one of two ways, namely:

- In case of coal-fired power plants or when steam of sufficiently high pressure and temperature is available, a steam coil is used for flue gas reheating. The use of steam for flue gas reheating is generally the most economical and advantageous method as it neither increases the flue gas flow rate nor adds any additionally constituents (i.e. NOx) to the flue gas. Steam reheating is particularly economically advantageous in coal-fired power plants, which are "turbine limited" meaning the boiler can generate more high pressure steam at full load than the turbine needs for generating its maximum electrical output. In such a case, the surplus generated high pressure steam, which cannot be used for generating electricity, is ideally suitable for the use of steam reheating of the flue gas without or only minimal impact on the generating capacity of the unit. In this case, the heat rate penalty of the unit may be eliminated entirely.

- In case no steam or only steam of insufficient temperature and pressure is available as it is the case in many non-power plant applications, natural gas duct burners are typically used for flue gas reheating. Such flue gas reheating results in some additional operating cost for natural gas, which, however, can at least partially be offset by significantly prolonged catalyst life of typically well over 100,000 SCR operating hours, a smaller overall SCR reactor, less installed catalyst volume and a smaller catalyst pitch[22]. In some cases the additional operating costs can be completely offset by the elimination of extended unit downtime, which would be necessary for an HDSCR retrofit, and the availability of excess high pressure steam, thus making TESCR the most economical solution.

- EPRI[23] reported TESCR systems in Europe to achieve NOx removal efficiencies between 83 and 92% with cost between US$ 180 – 225 per kW and HDSCR systems to achieve NOx removal efficiencies between 65 and 88% with cost between US$ 65 – 200 per kW. Considering the fact that this was reported in 1989, in other words more than a decade before the SCR retrofit phase in the U.S. resulting from the

[23] Technical Feasibility and Cost of SCR NOx Control in Utility Applications, RP 1256-8 prepared by United Engineers and Constructors, Inc. for Electric Power Research Institute (EPRI), August 1989.

CAAA NOx SIP call[24] and considering the fact that the cost of almost all SCRs retrofitted in North America were within this range, it can be reasonably expected that the retrofit cost for TESCR will also fall approximately within the range determined by EPRI back in 1989.

All European and North American HDSCRs have achieved their targeted NOx emission rates without any major operational problems. Early design flaws mostly resulting from inadequate flow conditions and flue gas distribution problems were mostly corrected by about 1990. By early 2000 more than 23,000 MW of SCRs were in operation in Japan and more than 55,000 MW in Europe[25], of which about 40% are TESCRs. Currently, more than an estimated 250,000 MW of HDSCRs are successfully operating worldwide on utility boilers with an estimated more than 100,000 MW in North America. The balance can be found in Europe (Austria, Belgium, Denmark, Finland, France, Germany, Holland, Italy, Portugal, Spain, Sweden, Turkey, etc,) and Asia (China, Japan, Korea, Taiwan, etc.).

By 1989/1990 approximately 18,000 MW of TESCRs were in operation or near completion on coal-fired utility boilers in Europe. At the same time almost four years of extremely positive operating experience had been collected on the first TESCR, which went into operation in Hamburg in 1986. Today after more than 20 years of TESCR operating experience, catalyst lifetime in excess of 100,000 is considered normal[26].

As a result of this extremely positive long term operating experience with TESCR, this principle was generally adopted as a universally applicable SCR solution for all types and compositions of flue gases incompatible for HDSCR due to the catalyst deactivation characteristics. Incompatible conditions for HDSCR can be either due to:

- physical parameters of the flue gas, which are unacceptable, such as temperature, ash content, etc., or
- chemical composition of the flue gas, which may cause uneconomically rapid catalyst deactivation such as higher concentrations of gaseous arsenic, phosphorus, sodium, potassium, calcium, magnesium, chromium, barium, selenium, etc..

Consequently, TESCRs were installed for NOx control on a wide variety of high temperature combustion and other thermal processes including:

- photovoltaic cell production (2002)
- hydrogen reformers (2003)
- steel coil heat treatment facilities (2003)
- sintering plants (2003)
- steel pickling (2005)

In short, almost every high NOx producing process imaginable was successfully retrofitted with TESCR systems making the SCR technology the most widely used secondary NOx reduction technology worldwide. As a matter of fact, in many cases, HDSCRs or LDSCRs were successfully installed and operated despite the fact that original pilot testing often suggested severe, rapid catalyst deactivation and seriously questioned the technical feasibility of either one of these two SCR principles for these applications. Examples include:

- lignite or brown coal fired boilers (HDSCR, 1990)
- cyclone fired and other wet bottom boilers with fly ash re-injection (HDSCR, 1991)
- heavy fuel oil (HDSCR, 1992)
- municipal solid waste incinerators (LDSCR, 1992)
- hazardous waste incinerators (LDSCR, 1995)
- roller mills (LDSCR, 2000)
- cement kilns (HDSCR, 2003)
- biomass (HDSCR, 2006)

Two of the most recent examples of this development in the U.S. are the ongoing HDSCR retrofits on PRB-fired utility boilers as well as at several utility boilers firing Texas lignite. Once again, initial pilot testing seemed to have suggested that catalyst deactivation through fly ash pluggage and chemical poisoning may be too rapid to make HDSCR economically viable. For example, in case of PRB-fired utility boilers, HDSCR pilot testing conducted at Dynegy's Baldwin Energy Center (Baldwin Pilot Testing) yielded results that clearly suggested that PRB caused "significant accumulations of ash on the catalyst, on both macroscopic and microscopic levels. On a macroscopic level, there were significant observable accumulations that plugged the entrance as well as the exit of the catalyst sections. On a microscopic level, the ash materials filled pores in the catalyst and, in many cases, completely masked the pores within 4 months[27]."

During HDSCR pilot testing at Luminant's Sandow Generating Station Unit 4 catalyst deactivation was determined to be about 20% after approximately 2,900 hours before increasing to approximately 50% after some 3,500 hours due to catalyst plugging[28]. Based on an extrapolation of this data a HDSCR would not likely have reached 10,000 operating hours prior to catalyst needed to be added or exchanged. For comparison purposes, typical SCR catalyst design requires an addition or exchange of catalyst during an outage when the total

[28] Smith, R, J. Bennett, D. Broske, "Impacts of Texas Lignite on SCR Catalyst Life and Performance", presented at the 2007 EPRI SCR Workshop in Pensacola, Florida, November 2007.

reactor potential has reached between 60% and 75% of the original value when equipped with all new catalyst.

Yet, in both cases, at Baldwin and Sandow, HDSCR has become the NOx control method of choice. Currently, more than fifty (50) PRB-fired boilers including at least twenty two (22) cyclone-fired units have successfully operated HDSCRs without any of the problems suggested based on the Baldwin Pilot Testing results[29]. Likewise, HDSCRs are being installed at several utility units burning Texas lignite including Oak Grove 1 & 2[30], Sandow 4[31] & 5[32], Martin Lake 1, 2 & 3[33] and Limestone 3[34].

In case of a TESCR installation, the situation is dramatically less challenging resulting from the fact that the flue gas downstream of a wet scrubber, which a TESCR is exposed to, is extremely clean compared to what the catalyst is exposed to in a HDCSR upstream of the ESP. Downstream of an ESP and a wet scrubber in excess of 99% of the fly ash is removed in the ESP[35] and between 90% and 95% of SO_2 is removed in the wet scrubber[36], thus leaving very little if anything in the flue gas that is critical for catalyst deactivation.

Additionally, downstream of a wet scrubber, the flue gas has gone through its dew point after being cooled to saturation while passing through the wet scrubber. Going through the dew point of the flue gas, which is typically between 110 F (~43 °C) and 150 F (~65°C), means that all condensable catalyst poisons such as alkali and earth alkali salts, arsenic and phosphorus oxides will inevitably have condensed and, along with all other highly water soluble gaseous catalyst poisons including sodium and potassium sulfates, phosphates and carbonates, will have been mostly removed by the wet scrubber. In a wet scrubber all water soluble compounds including water soluble alkali sulfates, phosphates and carbonates as well as all residual alkali vapors are virtually quantitatively removed as a result of their extremely high water solubility.

The very small residual amounts (less than 1%) of small particles (< 5 µm) passing through the ESP consist of condensed vapors or aerosols including sulfuric acid, alkali sulfates, earth-

[36] Ibid

alkaline oxides and silicates. These small particles often act as condensation nuclei during the rapid flue gas quenching in the inlet of the wet scrubber and are largely removed by this mechanism. Thus, their already small quantity downstream of the ESP is reduced further, typically by at least 50% across a wet scrubber. This means that compared to a HDSCR, catalyst installed in a TESCR is confronted with less than 0.5% of the particulate matter and less than 5 – 10% of the acid gases, vapors and other water soluble compounds, which cause catalyst deactivation. Consequently, the experienced catalyst deactivation rate is correspondingly slower.

It must be noted that particle bound compounds add very little to the chemical catalyst poisoning causing deactivation. Only gaseous compounds or in liquid dissociated ions of salts of these compounds are chemical catalyst poisons. However, as explained earlier, these gaseous compounds are largely removed in a wet scrubber and the remaining concentrations downstream of a wet scrubber are typically so negligible that the result is and in extraordinarily slow catalyst deactivation. Furthermore, the flue gas is being reheated in a TESCR prior to entering the catalyst, which means that these very small residual concentrations of chemical catalyst poisons including alkali and earth alkali sulfates and phosphates as well as the flue gas itself are at least 400 degrees (200 K) above their respective dew points, which virtually eliminates the possibility of these residual catalyst poisons condensing in the pores of the catalyst. In general, the condensation temperature or dew point of any compound including these gaseous catalyst poisons is a function of the flue gas temperature and the compound's concentration in the flue gas. As noted above, the residual concentrations of catalyst poisons are very small in a TESCR downstream of a wet scrubber and the difference between their dew point temperature, which is the flue gas temperature at the outlet of the wet scrubber and the TESCR operating temperature is very large due to the reheating of the flue gas. Consequently, any type penetration of these chemical catalyst poisons and subsequent condensation in the catalyst pores is at least extremely unlikely if not physically impossible at the TESCR operating conditions.

The virtually negligible residual amount of gaseous catalyst poisons entering a TESCR compared to an HDSCR results directly in an almost proportionally extended catalyst life. Based on 20 years of extraordinarily successful full scale TESCR operating experience in Europe, a catalyst life of typically well more than 100,000 hours must be considered the norm rather than the exception. Several TESCRs after wet bottom utility boilers are still in operation after 20 years with the initial fill of catalyst and no replacement, exchange or addition[37].

Additionally, the minimal concentration of catalyst poisons entering a TESCR and the resulting very slow long-term catalyst deactivation (as experienced over 20 years of operation of TESCRs) led to the reduction in operating temperatures for TESCRs as shown in the graph below, which can be found on Argillon's website[38]. Argillon, who is one of the

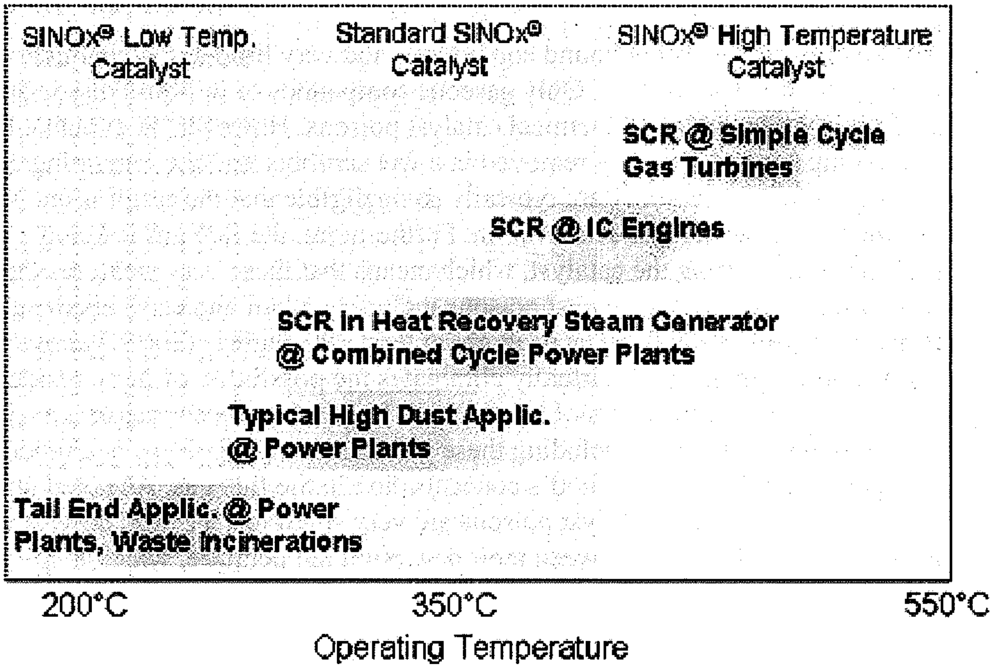
leading catalyst manufacturers of honeycomb as well as plate catalyst marketed under the trade name SINOx, has a wealth of experience in all types of SCR applications (HDSCR, LDSCR, TESCR) with more than 500 SCR installations worldwide[39]. Based on Argillon's extensive experience, Argillon promotes the use of TESCR in a temperature range between approximately 300 F (~150 °C) and no more than about 570 F (300 °C) as can be seen in the graph below.



As a matter of fact, for purely economic reasons and regardless of the fuel burned, no TESCR system in Europe operates today at a temperature greater than about 550 F (~290 °C). Today, the majority of TESCRs behind plants such as municipal and hazardous waste incinerators, which have an incomparably greater fuel variability and much higher concentrations of the entire spectrum of catalyst poisons (arsenic, barium, calcium, chromium, magnesium, phosphorus, potassium, selenium, sodium, thallium, etc.) than any coal-fired boiler will ever have, operate downstream of wet scrubbers and/or baghouses or activated carbon reactors (ACR) at temperatures as low as 300 F (~150 °C). These low temperature TESCR operations have been extremely successful for over a decade now with minimal to no catalyst deactivation experienced.

CERAM is another leading manufacturer of honeycomb SCR catalyst and with well over 500 SCR installations worldwide, more than 100 of which are LDSCR and TESCR installations. CERAM, arguably one of the most experienced suppliers of TESCR catalyst, fully confirms this concept of lowering the TESCR temperature. CERAM sees no need for a TESCR operating temperature of more than about 554 F (290 °C) even in case of a wet bottom boiler

such as a cyclone fired unit burning the most complex and difficult fuels including North Dakota lignite[40]. As a matter of fact, the only thing that dictates the minimum SCR operating temperature are the residual SO_2 and SO_3 concentrations in the flue gas, which determine the ABS reaction equilibrium[41] and thus the probability for ABS deposition on the catalyst and in the gas/gas heat exchanger. This, however, is not an irreversible catalyst poisoning issue but rather a reversible fouling problem not related to the SCR catalyst per se but simply to the reaction chemistry between H_2O, SO_3 and NH_3 in the flue gas at various temperatures.

In summary it can be stated that the SCR technology is the most widely used secondary NOx control technology in the world. It is technically feasible and applicable to a large number of thermal processes including all types of utility boilers burning any kind of fuel. In my professional experience gained over the last 20 years with the SCR technology, neither the design of the boiler or the combustion system nor the composition of the fuel burned has ever posed an irresolvable technical obstacle, which made the application of the SCR technology in one of its principles (HDCSR, LDSCR, TESCR) technically infeasible. The only challenge is the proper selection of the appropriate type of SCR principles (HDSCR, LDSCR or TESCR) and the correct SCR process and catalyst design. This selection, however, is neither a question of technical feasibility or applicability nor of availability of the SCR technology but simply a question of economics.

6. SCR EVALUATION

In June 2008, the North Dakota Department of Health's Division of Air Quality issued a "Preliminary Best Available Control Technology Determination for Control of Nitrogen Oxides for M.R. Young Station Units 1 and 2[42]", in which it determined "that SCR is not technically feasible for North Dakota lignite-fired cyclone boilers." This determination seems to rest largely on five documents provided by Minnkota Power, namely:

1. Minnkota's Best Available Control Technology Analysis Study for Milton R. Young Station Unit 1, October 2006.[43]
2. Square Butte's Best Available Control Technology Analysis Study for Milton R.

---

[40] Personal conversation with John Cochran, President of CERAM Environmental, Inc., on June 25, 2008.

[41] The reaction equilibrium between ammonium sulfate ($(NH_4)_2SO_4$) and ammonium hydrogen sulfate (NH_4HSO_4), which is often incorrectly referred to as ammonium bisulfate or ABS, in the flue gas. Both, ammonium sulfate and ammonium hydrogen sulfate are products of the inevitable reaction of gaseous sulfur trioxide (SO_3) and ammonia (NH_3) contained in the flue gas upstream of the SCR catalyst.

4. Application of SCR Technology to North Dakota Lignite Fuels, Power Point Presentation slides by Sargent and Lundy, LLC, May 2007.[46]

5. Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination for Milton R. Young Station Units 1 and 2, May 2008.[47]

These five documents are seemingly reasonably recent with the first and second document dated October 2006 and the forth and fifth documents dated May 2007 and May 2008, respectively. However, the third document even though published in 2005 was already accepted for publication in mid 2004 and the actual HDSCR catalyst pilot testing at the Coyote Station (Coyote Pilot Testing) and at the Baldwin Energy Center (Baldwin Pilot Testing) that lasted at least 6 months at each plant was conducted as early as 2000/2001[48]. This is relevant, since the Coyote Pilot Testing, which was conducted following the Baldwin Pilot Testing, used the same pilot test reactor equipped with the same Haldor Topsoe catalyst that was used at the Baldwin Pilot Testing[49]. Based on the Baldwin Pilot Test results the technical feasibility of HDSCR at Baldwin's cyclone-fired Units 1 & 2 burning 100% PRB would have been at least highly questionable and a BACT determination similarly conducted as the one by the Department for the M.R. Young Station would most likely have reached the same conclusion as was reached for the M.R. Young Station, namely that the SCR is technically infeasible for retrofit at the Baldwin Energy Center. However, the full scale HDSCRs at Baldwin Units 1 & 2 were commissioned in 2002 and 2003 and have since been in service for more than 45,000 hours without any of the problems indicated during the Baldwin Pilot Testing.

At Associated Electric's New Madrid Station Units 1 & 2, both cyclone-fired units burning 100% PRB, HDSCRs were commissioned in 1999/2000 already and have been in operation successfully since then. Numerous other cyclone-fired units burning 100% PRB were retrofitted with HDSCRs and have also been operating successfully[50, 51]. This clearly proves that the results obtained during the Baldwin Pilot Testing with this particular SCR catalyst and this particular pilot test reactor design cannot be considered representative for a full scale HDSCR installation at the same unit. Baldwin Units 1 & 2 don't use the type of Haldor Topsoe catalyst used in the Baldwin and Coyote Pilot Testing but instead use Argillon plate catalyst. New Madrid Units 1 & 2 also don't use the type of Haldor Topsoe catalyst used in the Baldwin and Coyote Pilot Testing but instead use Cormetech honeycomb catalyst. Also, the HDSCR reactors at Baldwin and New Madrid were properly designed and are adequate to meet the challenges of this application and not as ill-designed and fundamentally flawed as the Baldwin and Coyote Pilot Testing reactor and catalyst design. This fact along with the conclusion that the Coyote Pilot Testing[52] didn't provide much useful data was pointed out clearly by the Department.

Furthermore, CERAM in one of their responses explicitly stated their belief that "the information and test work presented indicate that it is certainly premature to assume that there is a fatal flaw for the use of high duct SCR behind cyclones burning North Dakota lignite. The concerns presented are similar in argument to those that where used 10 years ago against the application of PRB for high dust (SCR) applications[53]". CERAM continues stating that "concerns reported by Dr. Benson[54] regarding high sodium contents and fine fume are duly noted, but inadequate evidence is presented that this could be a fatal flaw to application of (HD)SCR considering the flawed pitch and resultant pluggage of the (Haldor Topsoe) catalyst (used) during (the) Coyote Station testing[55]". This view of CERAM was further discussed in a personal conversation with Mr. Kurt Orehovsky, Product Manager of

CERAM's SCR Catalyst Division[56]. Mr. Orehovsky clearly stated that CERAM reviewed all available data carefully and thoroughly and sees currently no reason why HDSCR would be technically infeasible at M.R. Young Station, however, only after resolving the temperature variation problem. He pointed out that CERAM would not expect any extraordinarily high catalyst deactivation or pluggage at a cyclone-fired unit burning North Dakota lignite if in fact an HDSCR system would be properly designed and operated. CERAM's extensive experience with lignite and biomass fired units equipped with HDSCR support this position.

Despite that clear statement and despite the ongoing proof in form of the success of the HDSCRs at New Madrid, Baldwin and many other cyclone-fired units burning 100% PRB, the only field data the Department relied upon concerning the expected catalyst deactivation and pluggage of an HDCSR installed at M.R. Young Units 1 and 2 is the data obtained from the ill-designed and fundamentally flawed Coyote Pilot Testing.

Admittedly, the Coyote Pilot Testing results seem to indicate worse pluggage than the Baldwin Pilot Testing results. However, it must be noted that the same pilot test reactor and the same catalyst, which had been already used (and plugged) at Baldwin was subsequently used at Coyote. The well known fact that catalyst that had been plugged and only mechanically cleaned is more likely to quickly plug again than new, unused catalyst was simply ignored. Furthermore, it is more than reasonable to expect that lignite fired units will cause a higher rate of catalyst deactivation in an HDSCR than a PRB fired unit. This fact was also proven during the Sandow 4 pilot testing[57] but is no reason for considering the SCR technology in general as technically infeasible. In case of Sandow 4 and other units burning Texas lignite HDSCR was even considered to be more economically viable than LDSCR or TESCR with the technical feasibility not even being a question.

Given the fact that the same pilot test reactor and catalyst were used for the Baldwin and subsequently for the Coyote Pilot Testing, it can be clearly stated that the reason for the pilot testing results at Coyote being worse than at Baldwin was because of the pilot test reactor and catalyst designs and the execution of the pilot testing, all of which were already inadequate for the Baldwin application but disastrous for the Coyote application. Yet, the unanswered question remains, why is it unreasonable to assume that a properly designed and operated HDSCR at M.R. Young Units 1 and 2 could be as successful as it has been and continues to be at New Madrid, Baldwin and the many other cyclone-fired units burning 100% PRB despite the fact that the results of the Baldwin Pilot Testing seemed to indicate the exact opposite? Based on this clear and indisputable evidence would not every reasonable engineer first suspect that the reason for the failure of the Coyote Pilot Testing was the ill-designed test pilot reactor and catalyst and the flawed execution of the pilot testing just as it was the case at Baldwin? However, instead of trying to answer these most important questions objectively and correctly, the Department jumped to the highly premature and speculative conclusion that the SCR technology regardless of the selected principle (HDSCR,

---

[56] Personal conversation with Mr. Kurt Orehovsky in Vienna, Austria, on July 7, 2008.

[57] Smith, R, J. Bennett, D. Broske, "Impacts of Texas Lignite on SCR Catalyst Life and Performance", presented at the 2007 EPRI SCR Workshop in Pensacola, Florida, November 2007.

LDSCR or TESCR) cannot be applied successful at the M.R. Young Station.

The Department lists the following twelve (12) conclusions that result in the Department's largely speculative and unsubstantiated determination "that high dust SCR is not technically feasible at this time for both units at the M.R. Young Station", the validity of which are discussed in detail in the following sections.

6.1 Variability of Fuel Composition

Lignite from the Center Mine is highly variable in heat and ash contents and in the constituents that make up ash, which will affect SCR design and operation. This is an undisputed fact, however, not only true for lignite from the Center Mine but for all coals regardless whether it is anthracite, bituminous, sub-bituminous, lignite, brown coal etc. As a matter of fact, these listed classifications are nothing but the result of the extremely high variability of the various types of coal. Each class in itself has a high variability again, which unquestionably affects SCR design and operation. This high variability includes also the compounds sodium and potassium (as further discussed in several subsequent sections) as well as all other catalyst poisons. Bituminous and sub-bituminous coals, which are considered relatively unproblematic for HDSCR design and operation, may serve as an example for this typical variability. Bituminous and sub-bituminous coal-fired boilers constitute the vast majority of HDSCRs in the world even though the:

- The heating value ranges from less than 8,000 Btu/lb to more than 13,000 Btu/lb.
- The ash content can vary by one order of magnitude from as low as 4 %wt. to as high as 40 %wt.
- Sulfur contents also vary easily by one order of magnitude from less than 0.5%wt. in sub-bituminous to more than 5%wt in bituminous coal.
- Likewise arsenic content range over an order of magnitude from less than 3 ppm to more than 40 ppm.

The list of similarly wide ranges of concentrations and/or variability for individual constituents of bituminous and sub-bituminous coals could be extended for almost every element of the Periodic Table. However, I am not aware of one single case where this high variability of the heat and ash contents of the coals and/or of the constituents that make up the ash precluded one of the principles of the SCR technology (HDSCR, LDSCR, TESCR) from being technically feasible and applicable.

Thus, it remains unexplained why the Department's conclusion that "lignite from the Center Mine is extremely variable in heat content, ash content and in the constituents that make up the ash", leads to the determination that the SCR technology is not technically feasible. Even though the statement that "this variability will affect the design and operation of an SCR system", is only correct with respect to a HDSCR and maybe partially to a LDSCR, it is most definitely not plausible for a TESCR. In case of TESCR the preceding air pollution control equipment (ESP and wet FGD) as well as the flue gas reheating system of a TESCR, which typically includes a gas-gas heat exchanger and steam coil upstream of the SCR reactor, virtually eliminate even the most extreme variability in the fuel and its resulting flue gas composition upstream of the SCR catalyst. It is intuitively obvious that the coal's variability in heat and ash content and in the constituents that make up the ash is no longer of any relevance in case of a TESCR system after more than 99% of the ash has been removed in the upstream air pollution control equipment[58].

6.2 Results of the Coyote Pilot Testing

The Department correctly states that "the only pilot testing that has ever been conducted on a unit firing North Dakota lignite was at the Coyote Station[59]. The pilot scale SCR was plugged after 2 months and little useful data was obtained". The Department further alludes to the fact that "the pilot testing at the Coyote Station did not provide much useful data, and in hind-sight, was ill-designed for a unit combusting North Dakota lignite". Yet despite the Department's indisputably correct and valid recognition of this as well as the facts that:

- no deactivation data exists and no conclusions should be drawn from this ill-designed and highly flawed Coyote Pilot Testing;
- several SCR equipment suppliers (Alstom, Babcock Power) clearly stated that , an "(HD)SCR system could be successfully utilized on a boiler fired with Northern lignite"[60];
- several catalyst manufacturers (CERAM, Haldor Topsoe) clearly stated and that concerns reported by Dr. Benson[61] regarding high sodium contents and fine fume are duly noted, but inadequate evidence is presented that this could be a fatal flaw to application of SCR considering the flawed pitch and resultant pluggage of the (Haldor Topsoe) catalyst during Coyote Station testing"[62];

[62] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, "Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination

- several catalyst manufacturers (CERAM, Haldor Topsoe), who have experience with high sodium and potassium containing fuels, offered industry standard type catalyst performance guarantees (NOx removal efficiency, SO_2/SO_3 conversion rate, pressure drop, NH_3 slip, catalyst lifetime)[63];

the Department still concludes that "the Coyote testing demonstrates to the Department that North Dakota lignite firing will have more severe effects (plugging and catalyst deactivation) than units firing sub-bituminous coal when the same design is employed".

This statement promotes three basic questions, namely:

a. How can the Coyote Pilot Testing demonstrate to the Department that North Dakota lignite firing will have more severe effects (plugging and catalyst deactivation) when no catalyst deactivation data exists and the pilot scale SCR reactor at the Coyote Station plugged very quickly because the reactor was ill-designed and the selected catalyst design not suitable, particularly for a unit combusting North Dakota lignite?

b. Does the Department have any additional information that may substantiate the Department's otherwise completely unfounded conclusion and that wasn't provided to the contacted vendors including Alstom, Babcock Power, CERAM and Haldor Topsoe so that they reached the essentially opposite conclusion?

c. Why does the Department imply that the same catalyst and SCR design employed for units firing sub-bituminous coal must also be used for M.R. Young Station?

As pointed out earlier, this is relevant since in the early 2000s, when the Coyote Pilot Testing[64] was conducted, the results of which provide the only catalyst relevant field data for the Department's conclusion concerning the rapid pluggage and deactivation of catalyst in a HDSCR, no long term full scale HDCSR operating experience was available from Associated Electric's New Madrid Station, which was the first one to install HDSCR on a cyclone-fired unit burning PRB. Yet, as pointed out by Burns & McDonnell, today a significant number of cyclone-fired units in the U.S. burning PRB successfully operate HDSCRs[65, 66, 67].

[65] NOx Best Available Control Technology Analysis Study for Milton R. Young Station Unit 1 Minnkota Power Cooperative, Inc., Revised Final Report, October 2006, 311777.

[66] NOx Best Available Control Technology Analysis Study for Milton R. Young Station Unit 2 Minnkota Power Cooperative, Inc. Operating Agent for Square Butte Electric Cooperative, Owner. Revised Final Report, October 2006, 311777.

The Department further states that "besides catalyst deactivation, it is likely that a high-dust SCR would experience plugging problems (deposition on the catalyst surface) due primarily to the carryover of popcorn ash from the boiler". This statement is also quite puzzling, since the formation of popcorn ash is a commonly known phenomenon that has first caused catalyst pluggage in Germany in the mid 1990s[68] and is also a well known problem in the U.S. since the early 2000s. However, it has been solved successfully[69] by the use of properly designed popcorn ash removal systems[70].

The Department's statement that "the advances made in the last few years for controlling popcorn ash are not shown to be applicable to a cyclone boiler burning North Dakota lignite" is not only purely speculative but defies all common engineering sense. Various designs and types of popcorn ash screens have been installed in a wide variety of units in the U.S. and are operating successfully. I believe that no engineering company with SCR experience including Sargent and Lundy and Burns & McDonnell would seriously argue the fact that properly designed popcorn ash screens could be successfully installed at M.R. Young Station's Units 1 and 2 without additional pilot scale testing. Needless to add that in case of a LDSCR or TESCR any concern over popcorn ash would be considered absurd simply by virtue of the location of the LDSCR or TESCR in the flue gas path downstream of the ESP (LSDCR) and wet scrubber (TESCR).

Furthermore, the Department's statement that "operation of an SCR system for only 2 months between catalyst replacements is not considered successful operation of SCR technology," implies that the catalyst in a properly designed full scale HDSCR at the M.R. Young Station would have to be replaced every two (2) months. Again, no deactivation data was ever determined during or after the Coyote Pilot Testing to substantiate this claim. This forces the conclusion that the mostly useless data obtained from the ill-designed and flawed Coyote Pilot Testing was improperly and incorrectly used by the Department to speculatively extrapolate to what may or may not happen in a properly designed HDSCR system.

This bold speculative extrapolation to a catalyst life of only two (2) months between replacements in a full scale HDSCR is particularly interesting since the Department immediately contradicts its own conclusion by postulating that "without pilot testing, the life of the catalyst cannot be predicted with any reasonable certainty." Assuming this latter statement is true and further reiterating the fact that no deactivation testing from pilot testing

is available, how can the Department assert that a properly designed full scale HDSCR system would operate for only two (2) months between catalyst replacements while stating at the same time that the life of the catalyst cannot be predicted without further pilot testing?

Furthermore, the Department's bold postulation of an expected catalyst life of only two (2) months between replacements is made despite the fact that two (2) experienced catalyst suppliers (Haldor Topsoe and CERAM) offered firm performance and lifetime guarantees[71] for their catalyst installed in an HDSCR of considerably more than the 10,000 hour threshold arbitrarily defined by the Department. Why the Department ignores all these facts and concludes that it can predict the expected catalyst life better than even the most experienced catalyst manufactures remains unknown.

6.3 Soluble Sodium

The Department concludes that "the combustion of (North Dakota) lignite produces soluble sodium compounds, which cause more severe catalyst deactivation than insoluble sodium compounds". Even though this statement may be generally correct, it remains unclear and unexplained, why soluble sodium compounds, which can only penetrate into the catalyst and deactivate the catalytically active vanadium pentoxide (V_2O_5) when in they are either in the gas phase or as sodium ions (Na^+) dissociated in a liquid, would be present in the gas phase or in a liquid and therefore in a mobile form.

The argument raised by Minnkota and reiterated by the Department that the formation of low temperature sodium-calcium-magnesium sulfates and phosphates poses the most significant problem for the successful operation of SCR catalysts in a HDSCR may be true with respect to catalyst deactivation. However, the simple comparison of emission rates of these compounds with the fly ash is not a correct and appropriate way to derive any meaningful prediction concerning the expected catalyst deactivation. Even though the Department correctly states that "the catalyst deactivation rate may not be directly proportional to the emission rates of the various constituents", incorrectly continues that "it does provide a means of comparison of the flue gas characteristics". Unfortunately, the Department fails to realize what was pointed out by one of the most experienced catalyst suppliers, namely that "sodium is not a poison to catalyst at SCR operating temperatures[72]." Thus, the elaborate comparison of emission factors of sodium, potassium, calcium and magnesium emission factors with the fly ash may have some academic value but is effectively meaningless for the correct prediction of catalyst deactivation, since particle bound sodium, potassium, calcium and magnesium in the fly ash are not mobile and therefore are not catalyst poisons.

Typically, sodium and potassium sulfates, so called pyrosulfate compounds, have very high

---

[71] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, "Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination for Milton R. Young Station Units 1 & 2", May 8, 2008.

[72] Ibid

boiling points well above any possible SCR operating temperature. Thus, it is highly unlikely that any appreciable quantities of these pyrosulfates will be present in the SCR in the gas phase. This, however, would be necessary in order to cause severe and rapid catalyst deactivation. Therefore, under these conditions these compounds are not a major concern.

Alternatively, these pyrosulfate compounds would have to be present in a liquid so that their dissociated ions (i.e. Na^+, K^+) would be mobile in order to enter the catalyst pores and react with the catalyst's active sites. However, these compounds will only be present in the catalyst in a liquid form if either the SCR operating temperature is too low or during shut down when cooling the SCR reactor to temperatures below the moisture dew point. Since the melting point of most pyrosulfates is well above the typical HDSCR operating temperature of 650 – 750 F (343 – 400 °C) the intrusion of liquid pyrosulfates is no major concern with respect to a severe, rapid catalyst deactivation. Therefore, even catalyst suppliers state clearly that "sodium is not a poison to catalyst at SCR operating temperatures. Significant deactivation can occur if condensed moisture transports sodium residing at the surface into the catalyst pore structure during outage or layup[73]". Since the HDSCR operating temperature must be expected to be maintained at well above 650 F (343 °C) at all times, no liquid ever occurs during SCR operation not even in the inner pores as the temperature is too high even for capillary condensation. This well known fact is one of the main reasons why HDSCR operating temperatures are selected to be typically in the range between 600 F (315 °C) and 800 F (427 °C). Maintaining the required minimum SCR operating temperature at all times is an absolute requirement for all HDSCRs regardless of fuel type and/or boiler/burner configuration and has nothing to do with North Dakota lignite and/or cyclone-fired boilers.

As pointed out earlier, the condensation of moisture in the pores of the SCR catalyst typically occurs only during shut-down and subsequent cooling of an SCR reactor. Thus, reducing the number of shut-downs, which result in cooling the SCR catalyst to below the moisture dew-point, is always advantageous for all HDSCRs regardless of fuel- and/or firing type.

Given the fact that sixty (60) start-ups were reported for M.R. Young Unit 1[74] within a five (5) year period and sixty two (62) start-ups for the same period for M.R. Young Unit 2[75], it can be easily calculated that this equates to an average of approximately twelve (12) start-ups per year or roughly one (1) per month. However, in case of Unit 1 only six (6) and in case of Unit 2 only seventeen (17) were considered "cold" start-ups, which are defined as the boiler having been without fuel-firing for more than seventy two (72) hours[76]. During shut-downs

[74] NOx Best Available Control Technology Analysis Study for Milton R. Young Station Unit 1 Minnkota Power Cooperative, Inc., Revised Final Report, October 2006, 311777.

[75] NOx Best Available Control Technology Analysis Study for Milton R. Young Station Unit 2 Minnkota Power Cooperative, Inc. Operating Agent for Square Butte Electric Cooperative, Owner. Revised Final Report, October 2006, 311777.

[76] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, Responses to NDDH and EPA

of less than seventy two (72) hours, SCR reactors are typically "buttoned up hot", which means the SCR reactor is isolated from the flue gas path during shut down by means of putting it in a bypass mode while the SCR is still at its design operating temperature. The cooling rate of such a "buttoned up hot" SCR reactor is known to be extremely slow. Unless forced cooled with ambient air no "buttoned up hot" SCR reactor loses more than approximately 50 – 100 degrees and therefore gets nowhere near the sulfuric acid or even the moisture condensation temperature in a seventy two (72) hour period.

Therefore, catalyst deactivation by means of soluble sodium compounds in the ash being dissociated into a liquid and penetrating into the catalyst pores and reacting there with the catalytically active V_2O_5 must be expected to be rather slow. Since the actually experienced catalyst deactivation rate due to this effect has never been measured, the respective conclusion postulated by the Department cannot be considered more than an unsubstantiated speculation.

6.4 Differences in Flue Gas Composition

The Department concludes that "the flue gas generated at the M.R. Young Station is different from the flue gas at any plant where SCR technology has been applied". The absoluteness of this statement, which is not even limited to power plants, is quite amazing as it indubitably implies that the Department has complete detailed knowledge not only of the flue gas composition of every other power plant in the world equipped with an SCR system but also of every other plant in the world where the SCR technology is applied. Even though theoretically possible, the lack of any data from all these other plants strongly suggests that this may be highly questionable and largely overreaching. As a matter of fact, I am sure that I could easily present to the Department several plants where the SCR technology has been applied successfully that the Department doesn't even know that these plants existed.

Furthermore, the Department states that this absolute uniqueness is "primarily due to the high ash concentration of soluble sodium compounds and the total loading of catalyst deactivation chemicals". Again, as discussed in section 6.3 and clearly pointed out by catalyst suppliers, sodium is not a catalyst poison at SCR operating temperatures[77]. The claimed uniqueness of the flue gas generated at the M.R. Young Station appears to be highly speculative and completely unproven as comparisons were only drawn to:

- bituminous coal (specifically mentioning Pennsylvania coal);
- sub-bituminous coal (specifically mentioning Wyoming PRB);

Comments Regarding SCR Technical Feasibility and Non-SCR Concerns Milton R. Young Station Unit 1 and Unit 2 NOx BACT Analysis Study, April 18, 2007.

[77] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, "Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination for Milton R. Young Station Units 1 & 2", May 8, 2008.

- other lignites (specifically mentioning Texas lignite).

Needless to say that Pennsylvania coal is not the only bituminous coal in the world, Wyoming PRB is not the world's only sub-bituminous coal and Texas lignite is referred to as Texas lignite for the simple reason that it is somewhat unique to Texas compared to the many other types of lignites and brown coals around the world. Thus, the Department's statement in its far reaching and absolute form must either be considered extraordinarily uninformed or only correct if rigorously limited to the three specific coal types mentioned. In that sense this conclusion has little if any relevance to the question of the technical feasibility of the SCR technology to the M.R. Young Station and should be simply ignored as completely irrelevant.

6.5 Experience of Burns and McDonnell and Sargent and Lundy

The Department concludes that "both Burns and McDonnell and Sargent and Lundy have extensive experience with the design and operation of SCR systems". The fact of the matter is, however, that the SCR experience of Burns & McDonnell must be considered rather limited for a number of reasons, namely Burns & McDonnell has provided SCR related services for only seventeen (17) power plants[78]. At least ten (10) of these are not even in operation yet and only two (2) SCR projects are retrofits. Thus, Burns & McDonnell has very little experience with SCR retrofits and the only two (2) SCR retrofits, in which Burns and McDonnell was involved as Owner's Engineer, namely Hoosier Energy's Merom Station and HMPL's Henderson Station, have accumulated any appreciable long-term operating experience. However, in both of these cases, Burns & McDonnell's scope was limited to portions completely irrelevant to SCR process and catalyst design such as balance-of-plant design including foundations, electrical, controls integration, civil and contract oversight[79]. In the case of the Henderson Station, the SCR was supplied by Alstom and the catalyst by Cormetech. All process design, catalyst selection and design and all relevant process performance guarantees were provided by either Alstom or Cormetech. None were provided by Burns & McDonnell. In the case of the Merom Station, the SCR was supplied by Lurgi and the catalyst by KWH. Again, all process design, catalyst selection and design and all relevant process performance guarantees were provided by either Lurgi or KWH. None were provided by Burns & McDonnell.

Detailed design is currently being provided by Burns & McDonnell for only one (1) power plant, namely Associated Electric's Thomas Hill Units 1, 2 and 3. The SCRs are currently under construction and Burns & McDonnell lists conceptual design and studies, structural

---

[78] Summary of Responses to EPA/DOH Questions on Minnkota Power's NOx BACT Analysis for Milton R. Young Units 1 & 2, Presentation by EERC, Minnkota Power, Burns & McDonnell to NDDH and U.S. EPA, May 23, 2007.

[79] Ibid

design, balance of plant design and construction management as services provided[80]. It is worth noting that again none of these services have anything to do with the SCR process or catalyst design. The only service provided by Burns & McDonnell for this one (1) SCR retrofit project at least remotely related to SCR process design was the selection of the reagent and the catalyst manufacturer. However, reagent selection is irrelevant for catalyst deactivation and/or pluggage and the SCR catalyst itself is supplied by CERAM including the design, sizing as well as all process performance guarantees[81]. Thus, the catalyst selection performed by Burns and McDonnell was nothing more than recommending CERAM as the catalyst supplier presumably on the basis of a lowest price competitive bidding process.

In summary it is worth noting that Burns & McDonnell has neither provided SCR process design and/or SCR process performance guarantees in one single case nor ever operated any SCR system. Thus, the Department's conclusion concerning Burns & McDonnell's "extensive experience with the design and operation of SCR systems" seems to be based on a surprising lack of familiarity of the true capabilities and limitations of these architect engineering (A/E) firms. Concerning the "extensive operating experience" the Department's conclusion is plain wrong and for the remainder coarsely exaggerating as no A/E ever provides any process and/or catalyst design and/or performance guarantees.

Even though Sargent and Lundy claims significantly more SCR experience than Burns & McDonnell, Sargent and Lundy has also only acted as an A/E for SCR retrofits. Sargent and Lundy lists to have been involved in approximately 27,000 MWs of SCRs as an A/E. This represents a little more than one fifth ($^1/_5$) of the SCRs retrofitted to coal-fired units in North America[82] or less than half of the 46% claimed by Sargent and Lundy. Despite Sargent and Lundy's greater involvement in SCR retrofits as an A/E compared to Burns & McDonnell, it must be noted that Sargent and Lundy has also never provided any SCR process and/or catalyst design and/or performance guarantees and never operated any SCR systems. Thus, the Department's conclusion concerning Sargent and Lundy's "extensive experience with the design and operation of SCR systems" seems to be also based on a lack of familiarity of the true capabilities and limitations of these architect engineering (A/E) firms. Concerning the "extensive operating experience" the Department's conclusion is plain wrong and for the remainder at least highly questionable as no A/E ever provides and process and/or catalyst design and/or performance guarantees.

In general it must be noted that all services, which are critical for SCR system process design and process performance guarantees, including:

- process design;

---

[80] Summary of Responses to EPA/DOH Questions on Minnkota Power's NOx BACT Analysis for Milton R. Young Units 1 & 2, Presentation by EERC, Minnkota Power, Burns & McDonnell to NDDH and U.S. EPA, May 23, 2007.

[81] Reference list on CERAM's website: www.frauenthal.net.

[82] Sargent and Lundy LLC, "Application of SCR Technology to North Dakota Lignite Fuels", a PowerPoint Presentation, May 2007.

- catalyst sizing and design;
- flow modeling and SCR rector design;
- process performance guarantees;
- catalyst performance guarantees;

have never been and most likely will never be provided by neither Burns and McDonnell nor Sargent and Lundy. All these critical services are always either supplied by an SCR equipment supplier (Alstom, Babcock Power, Babcock & Wilcox, etc.) or by the catalyst manufacturer (Argillon, CERAM, Cormetech, Haldor Topsoe, Hitachi, etc.). As a matter of fact, all catalyst related performance guarantees (NOx removal efficiency or activity, SO_2/SO_3 conversion rate, catalyst life or deactivation rate, etc.) are never provided by anyone other than the catalyst manufacturers. Even the SCR equipment suppliers only pass through the catalyst performance guarantees obtained from the catalyst manufacturer to the end customer. And at least two (2) of these catalyst manufacturers, namely Haldor Topsoe and CERAM were clearly willing to provide industry standard type performance guarantees for their catalyst[83]. Notably, both of these catalyst manufacturers have extensive HDSCR experience with high sodium and potassium containing fuels such as biomass and/or lignite. It remains unclear why the Department didn't exploit the statements of these highly experienced catalyst manufacturers further but rather relied on the A/E's who have no SCR process and/or catalyst design experience, have never provided any SCR process and/or catalyst related performance guarantees and have absolutely no SCR operating experience.

6.6 Development Stage of High-Dust SCR

The Department states that "to design and install an SCR system for a cyclone-fired unit firing North Dakota lignite without obtaining additional data from bench scale would be experimentation". This conclusion is again in clear disagreement with the statement of catalyst manufacturers such as Haldor Topsoe and CERAM, who were willing to provide industry standard type catalyst performance guarantees even for HDSCR. This clearly indicates that both of these highly experienced catalyst manufacturers see no need for obtaining additional data from bench scale experimentation but feel to be in the position to design and install a HDSCR system at M.R. Young's Units 1 and 2.

Needless to say that no catalyst manufacturer and/or SCR system supplier will turn down the opportunity for additional bench scale and/or pilot testing if offered as it always effectively presents itself as a welcome possibility for risk free research paid by others. Also needless to say, every A/E, who typically charges billable manhours, will favor bench scale and/or pilot

---

[83] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, "Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination for Milton R. Young Station Units 1 & 2", May 8, 2008.

testing, thus extending the life of the project and therefore the amount of manhours billable.

Furthermore, even if HDSCR would not be economically viable, LDSCR or TESCR certainly would be and are indubitably technically feasible and applicable as clearly indicated by the multitude of applications of this principle of the SCR technology to a wide range of processes (see also section 5 of this report). Why the Department essentially ignores all the statements by these catalyst manufacturers and insists stubbornly that their provided SCR catalyst design[84] is experimentation, remains a mystery.

6.7 Temperature Variations

The Department correctly states that "the temperature variation of the flue gas entering the (HD)SCR will adversely affect the performance and must be resolved for successful application of this technology". However, the large temperature variations present at these units is very unusual for coal-fired units including cyclone-fired units. It is a unit specific problem related to the very unique design of the backpass of the boiler and the air preheater rather than to cyclone-fired boilers and/or North Dakota lignite. According to the boiler supplier Babcock & Wilcox only four (4) of these type boilers including the two (2) at M.R. Young Station were ever built[85], which clearly makes this the exception rather than the rule. In fact, such large temperature variations would not be tolerable for any HDSCR installed after any type of firing system (single or opposed wall-fired, tangentially-fired, turbo-fired, cyclone-fired, etc.) burning any type of fuel (bituminous, sub-bituminous, lignite, brown, etc. coal, oil, gas, biomass, etc.). Thus, the temperature variation problem, which Babcock & Wilcox indicated can be technically resolved by incorporating the appropriate and necessary measures for the modification of the boiler's backpass and possibly the lignite pre-drying system[86], is no reason to determine that the SCR technology is technically infeasible for cyclone-fired units burning North Dakota lignite. In a worst case scenario it may make HDSCR the economically less attractive alternative compared to LDSCR or TESCR due to the very unique boiler design employed at the M.R. Young Station.

6.8 Catalyst Erosion

The Department concludes that "there are unresolved issues regarding catalyst erosion from the ash generated at the M.R. Young Station". This conclusion is not substantiated by any data and at least highly disputable based on long-term SCR operating experience in Europe. Units equipped with HDSCR systems firing up to 40% ash waste coals have been in

---

[84] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, "Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination for Milton R. Young Station Units 1 & 2", May 8, 2008.

[85] E-mail from Steve Moormann (Babcock &Wilcox) to Robert Blakley (Burns & McDonnell) dated 07/18/07.

[86] Ibid

successful operation for almost two (2) decades now without any major operating problems or excessive catalyst erosion[87]. The average ash content of Center Mine North Dakota lignite, which has an average heating value of approximately 50% of bituminous coal, is less than about 8%wt[88]. Hence, approximately twice as much lignite must be burned for the same heat input compared to average bituminous coal. This, however, results still only in an equivalent average ash content of about 16%wt. of comparable bituminous coal, which is a factor of approximately 2.5 lower than the maximum ash content that HDSCRs have been exposed to successfully in Europe. As a matter of fact, bituminous coals with ash contents in the range of 12 – 15 %wt. are considered normal in Europe and pose no erosion threat to SCR catalyst whatsoever. Consequently, preventing excessive ash erosion of the catalyst is simply a matter of correct SCR design as has been proven extensively in Europe. Neither Burns & McDonnell nor Sargent and Lundy have any experience with HDSCR designs for higher ash coals or any experience with the operation of HDSCRs on high ash units.

This leads to the conclusion that the Department's concerns over seemingly unresolved issues regarding catalyst erosion appear to be the result of a simple lack of knowledge of the many HDSCRs that have been subjected to much harsher conditions for almost two (2) decades now.

6.9 Catalyst Poisoning, Blinding and Plugging

The Department correctly states that "poisoning, blinding and plugging of a catalyst are affected by the geometries and properties of the catalyst". However, subsequently, the Department concludes that "cyclone firing of Fort Union lignite and Center Mine coal results in a flue gas stream that highly accelerates poisoning, blinding and plugging (of pores) due to the rich sodium and potassium vapors, particles and ammonia sulfates (due to ammonia injection) in lignite-fired cyclone flue gas". The categorical absoluteness of this statement is impressive as it rest solely on the highly questionable results of the ill-designed Coyote Pilot Testing[89]. As already elaborated on in detail in sections 6.2 and 6.3 of this report and confirmed by the Department[90], the data of the referenced Coyote Pilot Testing is more or less useless. Despite the facts that:

- No deactivation data of the catalyst was ever determined during or after the Coyote

[89] Benson, A. J. D. Laub, C. R. Crocker, J. H. Pavlish, „SCR catalyst performance in flue gas derived from subbituminous and lignite coals", Fuel Processing Technology 86 (2005) pages 577 – 613, 2005.

[90] Page 7 of the Preliminary Best Available Control Technology Determination for Nitrogen Oxides for M.R. Young Station Units 1 and 2, Division of Air Quality ND Department of Health, 918 E. Divide Avenue, Bismarck, ND, June 2008.

Pilot Testing.

- The combination of the fatally flawed Coyote Pilot Testing reactor design, the inadequacy of the selected catalyst type and the extremely poor execution of the test runs caused the severe catalyst pluggage after only two (2) months rather than the flue gas composition and/or ash characteristics as pointed by highly experienced catalyst manufacturers including CERAM and Haldor Topsoe[91], who provided the catalyst for the Baldwin and Coyote Pilot Testing.

- The catalyst manufacturers most experienced with similar fuels (i.e. biomass, PRB, brown coal, etc.) clearly stated[92] that:

  - "the deactivation rate of the catalyst will be high but manageable" (Haldor Topsoe);

  - "the information and test work presented indicate that it is certainly premature to assume that there is a fatal flaw for the use of high dust SCR behind cyclones firing North Dakota lignite" (CERAM);

  - they "are willing to warrant the catalyst performance" based on industry standard terms (Haldor Topsoe);

  - "a commercial offering regarding this project" can be provided (CERAM);

the Department boldly decided that "the engineering solutions of a larger SCR reactor, more catalyst and larger pitch do not resolve the rapid plugging of catalyst pores". This conclusion is in sharp contrast to the statements provided not only by the catalyst manufacturers most experienced with similar types of fuels but also with the statements made by some of the most experienced SCR system suppliers (Alstom, Babcock Power), who "expect that an SCR system could be successfully utilized on a boiler fired with Northern lignite fuel[93]".

The Department continues stating that "there is no catalyst vendor solution to reduce or eliminate pore plugging. The chemical and physical process of pore plugging cannot be reversed, which dictates catalyst change out." This statement is simply incorrect as several well proven methods exist for successfully reducing and/or eliminating pore plugging and completely reversing sodium and potassium poisoning of the catalyst. For instance, Alstom in their correspondence with Burns & McDonnell points out several times[94] that as a result of

---

[92] Ibid

[93] Ibid

[94] Ibid

the highly efficient flue gas cleaning equipment upstream of a LDSCR or TESCR, the installation of a LDSCR or TESCR would eliminate these issues. Furthermore, Haldor Topsoe points out that "the expected poisons are mostly water soluble, therefore periodic water washing of the catalyst can be used to regain activity and to increase overall service life[95]". This is a clear reference towards the various in-situ[96], on-site[97] and off-site[98] catalyst washing, rejuvenation and regeneration processes that are commercially available and have been successfully used in the U.S. as well as in Europe for more than a decade now. These methods have proven beyond any doubt the possibility of regaining the catalyst's full initial activity for a fraction of the cost of new catalyst. They can also be applied multiple times to the same catalyst, particularly in case of sodium and potassium poisoning as well as fly ash pluggage, where simple washing either in-situ[99] or on site[100] has yielded excellent results. These various washing, rejuvenation and regeneration technologies have been utilized successfully by the U.S. utility industry since early 2003[101].

Why the Department ignores these facts and makes a statement in clear contradiction to all this evidence remains unknown.

6.10 Lack of Pilot Scale Testing Data

The Department states that "without pilot testing, the long term NOx reduction efficiency, the volume of the reactor, the catalyst pitch, life of the catalyst, or even type of the catalyst to be used cannot be predicted with a high degree of confidence." This statement is most interesting as is seems to be in clear contradiction to the Department's previous statements that:

- "Cyclone firing of Fort Union lignite and Center Mine coal results in a flue gas stream that highly accelerates poisoning, blinding and plugging (of pores) due to the rich sodium and potassium vapors, particles and ammonia sulfates (due to ammonia

---

[100] www.envirgy.com/en/references/catalyst_regeneration.

[101] www.ebinger-kat.com/en/referenzen.php.

injection) in lignite-fired cyclone flue gas".

- "The engineering solutions of a larger SCR reactor, more catalyst and larger pitch do not resolve the rapid plugging of catalyst pores."
- "The pilot scale (HD)SCR that was deployed at the Coyote Station was plugged and the catalyst pores deactivated after 2 months (approx. 1,430 hours)" The Department believes successful operation is considerably more than a few thousand hours of operation."

How can the Department postulate on one hand that without further pilot testing long term NOx reduction efficiency or in other words catalyst deactivation and therefore catalyst life cannot be predicted with a high degree of confidence, while claiming on the other hand with the seemingly highest degree of confidence that:

- The flue gas composition leads to highly accelerated catalyst poisoning, blinding and plugging?
- Successful operation is considerably more than a few thousand hours based on the fact that the ill-design HDSCR pilot test reactor plugged after only two (2) months?

Likewise how can the Department postulate on one hand that such fundamental HDSCR design parameters as volume of the SCR reactor, catalyst pitch and type of catalyst cannot be predicted with a high degree of confidence, while claiming on the other hand with the seemingly highest degree of confidence that no engineering solutions of a larger SCR reactor, more catalyst volume and larger pitch exist to resolve the rapid plugging of catalyst pores? Unfortunately, the Department fails to resolve these obviously diametrically contradicting statements.

Yet, it must be noted that the Department's claims concerning the rapid catalyst poisoning, blinding and plugging as well as the claim that no engineering solutions exist to mitigate these, are solely based on the highly questionable results of the ill-designed Coyote Pilot Testing. At the same time, however, the Department states that without additional pilot testing none of these necessary predictions could be made since the Coyote Pilot Testing was ill-designed and didn't provide much useful data[102]. This contradiction further nurtures the impression that the Department either solely relies upon or completely negates the Coyote Pilot Testing results depending on what ever seems to favor the particular argument against SCR at the moment.

---

[102] Preliminary Best Available Control Technology Determination for Nitrogen Oxides for M.R. Young Station Units 1 and 2, page 7, Division of Air Quality ND Department of Health, 918 E. Divide Avenue, Bismarck, ND, June 2008.

6.11 Lack of Vendor Guarantees

The Department states that "vendors cannot without further pilot testing, guarantee SCR system performance for M.R. Young Station boilers firing North Dakota lignite". This statement is simply incorrect as both CERAM and Haldor Topsoe clearly stated that they would be willing to offer industry standard type performance guarantees[103] for their catalyst for a HDSCR system installed at M.R. Young Station – see also the discussion in section 6.9 of this report.

The Department's claim that "even the most optimistic vendors don't offer true guarantees of catalyst performance", is as incorrect as the first statement. Both, Haldor Topsoe and CERAM clearly stated that they would be willing to offer industry standard type guarantees for the performance of their catalyst for a HDSCR at M.R. Young Station. The fact that the Department argues that "the guarantee is limited to the contract value" merely unveils the Department's surprising lack of familiarity with the type and extent of performance guarantees provided within the utility industry. The fact of the matter is that no equipment vendor in the utility industry ever accepts any liability for performance guarantees above and beyond the full amount of the contract value, which is exactly what was offered i.e. by Haldor Topsoe[104]. This is not only common practice in the utility industry but also a well known fact to all A/E's including Burns & McDonnell and Sargent and Lundy. If asked, none of the eight (8) participants in the SCR Vendor Query would offer an unlimited liability or even a limit of liability of more than the contract value for performance guarantees. Burns & McDonnell as well as Sargent and Lundy, who themselves never provide any type of process or system performance guarantees what so ever, are fully aware of this fact and will surely admit to it if asked.

It is worth mentioning that in case a project such as an SCR retrofit at M.R. Young Station would be carried out by an A/E such as Burns & McDonnell or Sargent and Lundy as an owner's engineer for Minnkota and/or Square Butte, the only performance guarantees the owner (in this case Minnkota and/or Square Butte) would ever receive would be the various system performance independent guarantees for the performance of the individual equipment and components supplied by the individual vendors including the one from the catalyst supplier. Each of these individual equipment and component performance guarantees would be limited to the value of and the equipment and/or component supplied by the respective vendor and simply passed through by the A/E to the owner. Thus, none of these individual performance guarantees would come even remotely close to covering the entire value of the SCR retrofit as each one would represent only a small portion of the entire project. The owner (in this case Minnkota and/or Square Butte) would have no performance guarantee for

---

[103] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, Responses to NDDH and EPA Comments Regarding SCR Technical Feasibility and Non-SCR Concerns Milton R. Young Station Unit 1 and Unit 2 NOx BACT Analysis Study, April 18, 2007.

[104] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, "Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination for Milton R. Young Station Units 1 & 2", May 8, 2008.

the entire SCR system and not even any kind of system performance guarantee from the A/E that all the individually purchased pieces of equipment and/or components fit together as intended so that the entire system performs as intended.

As a matter of fact, the type and extent of performance guarantees offered by the catalyst suppliers CERAM and Haldor Topsoe including the stated limitation of liability are most certainly exactly the same as were provided for each and every SCR project, in which Burns & McDonnell and Sargent and Lundy were ever involved.

If an owner seeks a true system performance guarantee that covers the entire scope of the project, no A/E is needed. As a matter of fact, an A/E is a hindrance in such a case as such true complete system performance guarantees are only offered by complete system suppliers such as Alstom, Babcock Power or Babcock & Wilcox. Contrary to an A/E, these true system suppliers are willing and able to provide the entire scope of a turn-key SCR retrofit including complete system performance guarantees for up to the value of the entire retrofit project, which is then again the value of the contract. Such a turn-key supply, however, eliminates the need for an owner to additionally pay an A/E, which is the simple reason why these types of contracts are not favored by the A/Es. Yet, the most successful SCR retrofits in the U.S. were done as turn-key installations without the use of an A/E.

6.12 Review Authority

The Department claims the review authority for this case. I do not comment on this.

6.13 Conclusions

In conclusion, it must be stated that the Department made numerous factually incorrect claims, conclusions and statements as outlined in detail above. The most significant ones include:

- The conclusion that HDSCR is not technically feasible based on the data obtained from the ill-designed HDSCR Coyote Pilot Testing that provided little useful data – see sections 6.2, 6.3 and 6.9.

- The conclusion that HDSCR is not technically feasible based on the lack of any meaningful pilot testing data because the HDSCR Coyote Pilot Testing was ill-designed and provided little useful date – see sections 6.4, 6.6, 6.8 6.10 and 6.11.

- The statement that Burns & McDonnell and Sargent and Lundy have extensive experience with the design and operation of SCR systems – see section 6.5.

- The claim that vendors cannot guarantee SCR system performance for M.R. Young Station – see section 6.11.

- The claim that LDSCR and TESCR are not technically feasible based on the data obtained from the ill-designed HDSCR Coyote Pilot Testing that provided little useful data and must be considered completely irrelevant altogether for an LDSCR and/or TESCR design and application.

It is worth pointing out that the Department contradicted its own statements numerous times, particularly concerning the quality of the data of the HDSCR Coyote Pilot Testing and the unavailability of any really useful data from said pilot testing. No explanation was offered why the HDSCR Coyote Pilot Testing data is condemned as inadequate in some cases, yet hailed as offering the absolute truth in some other cases. Depending on what seems to best fit the argument at the moment that HDSCR is not technically feasible for the M.R. Young Station, the Department seems to either solely rely on this essentially useless Coyote Pilot Testing data, which appears to be the case for the Department's conclusions concerning catalyst:

- poisoning, blinding and plugging;

- deactivation and lifetime;

or seems to complain that no reliable pilot testing data is available, which appears to be the case for the Department's conclusions concerning catalyst:

- erosion;

- sizing (type, pitch, volume);

- performance guarantees from the vendors.

The incorrectness of the Department's conclusions concerning the expected catalyst deactivation as well as the performance guarantees was pointed out by some of those, who know best, namely the catalyst manufacturers and SCR system suppliers[105].

The Department's arguments concerning fuel variability and ash composition are true for all coals and by no means unique to this application and thus of no relevance to this case. Likewise, the argument concerning unacceptable temperature variations and possible popcorn ash problems are also of no further relevance to this case as all these issues would have to and can be successfully resolved regardless of the type of combustion system (i.e. cyclone fired) and/or the type of fuel burned (i.e. North Dakota lignite).

Finally, the Department's conclusions against the technical feasibility of LDSCR and TESCR are completely unsubstantiated and erroneous. Not only does the Department fail to

---

[105] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, "Additional Information and Discussion of Vendor Responses on SCR Technical Feasibility, North Dakota's NOx BACT Determination for Milton R. Young Station Units 1 & 2", May 8, 2008.

correctly distinguish and separate these two (2) distinctly different types of SCR systems, it also concludes that "the (catalyst) deactivation issue for low-dust and tail-gas SCR remains as with the high-dust SCR". Deciphered in detail, this is the Department's only single argument against the application of a LDSCR or TESCR, since all other argued issues are admitted to be "not unresolvable". Unfortunately, the Department again bases its erroneous conclusion concerning LDSCR and TESCR solely on the data obtained during the ill-designed HDSCR Coyote Pilot Testing. As little if any relevance this essentially useless data may have for an HDSCR application it most certainly has absolutely no relevance for a possible LDSCR and/or TESCR application. The Department fails to recognize this.

A noticeably poor and incomplete attempt was made to provide at least some, however, not meaningful data for the flue gas and fly ash composition downstream of the ESP. This clearly suggests the lack of any meaningful data for the correct evaluation of an LDSCR. The only data provided was some sampling performed downstream of the ESP at a temperature of 300 F (149 °C), which is well below the temperature range of 650 – 750 F (343 – 400 °C) required for LDSCR operation. Therefore, the deposition data cited by the Department from Minnkota's November 9, 2007 response to comments[106] is not relevant for the flue gas conditions present in a LDSCR and even less for the flue gas conditions in a TESCR. Unquestionably, the condensation of vapors including pyrosulfates and gaseous compounds responsible for the stickiness of the ash is a function of temperature as condensation of vapors and gaseous compounds occurs progressively at lower temperatures. The Department fails to explain how data concerning the stickiness of the ash particles collected on a silicon dioxide surface at 300 F (149 °C) would have any significant relevance for the prediction of catalyst pore pluggage by ash particles at 650 – 750 F (343 – 400 °C).

Absolutely no useful data characterizing the conditions downstream of the wet FGD was provided, thus making any conclusion concerning a TESCR nothing but presumptive speculation. The only at least somewhat factual attempts to argue why catalyst deactivation downstream of a wet scrubber could be an issue is the Department's comment concerning the Minn-Dak Farmer's Coop's coal fired boilers and some convoluted data[107], which presumably obtained by means of stack testing downstream of the wet scrubber at M.R. Young Station's Unit 2.

Using the Minn-Dak boilers 7A and 7B as an example, the Department argues that "Minn-Dak had trouble complying with its particulate matter emission limit due to sodium compounds passing through the air pollution control device. In order to maintain compliance, the ash Na_2O content of the coal combusted had to be limited". The Department argues that this is sufficient support for the Department's conclusion that "alkali mineral compounds are not removed by the ESP or SO_2 scrubbing system". As a result the Department argues that "it

[106] Response letter to EPA's October 4, 2007 letter sent from Minnkota Power Cooperative, Inc. to Mr. Terry O'Clair, Director, Division of Air Quality at the North Dakota Department of Health, dated November 9, 2007.

[107] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, Responses to NDDH and EPA Comments Regarding SCR Technical Feasibility and Non-SCR Concerns Milton R. Young Station Unit 1 and Unit 2 NOx BACT Analysis Study, April 18, 2007.

appears a significant amount of sodium compounds, a catalyst poison, will enter a low-dust or tail-gas SCR system. The deactivation issue for low-dust and tail-gas SCR will remain the same as for the high-dust SCR. The research, design and pilot testing needed to develop an SCR system that will have reasonable success makes this technology also not applicable at this time."

As will be shown in detail in section 7 of this report, no research, design and/or pilot testing is needed to install a TESCR that will have complete success at M.R. Young Station. The Minn-Dak experience cited by the Department, however, is by no means of any relevance to the technical feasibility of a TESCR at M.R. Young Station, yet it seems to form the sole and only basis for the Department's reasoning that TESCR is not applicable at this time. Reviewing Minn-Dak's Air Pollution Control Title V Permit to Operate[108] and the North Dakota Department of Health's Inspection Report[109], it becomes evident that neither the particulate matter removal device nor the wet scrubber are comparable to the air pollution control equipment installed or under construction at M.R. Young Station. Minn-Dak's boilers 7A and 7B, which are two Babcock & Wilcox stoker-fired boilers burning coal, biogas and natural gas, are equipped with multi-cyclones and co-current venturi scrubbers rather than ESPs and counter-current spray towers. The coal burned was reported to be sub-bituminous coal from the Spring Creek Coal Company in Montana rather than North Dakota lignite[110]. Not only is the partitioning of the ash constituents of the coal that occurs in a cyclone-fired boiler different from that in a stoker-fired boiler[111] but also is said partitioning different for different coals. Thus, using data from a stoker-fired unit burning PRB to predict the partitioning at a cyclone-fired unit burning North Dakota lignite is simply inappropriate.

As correctly stated by the Department, Minn-Dak has a restriction on the sodium content in the coal at 2.8% Na_2O on a dry mass basis in the coal ash in order to meet the particulate emission limit of 45.5 lb/hr, which, however, equates to 0.40 lb/10^6 Btu rather than 0.10 lb/10^6 Btu as erroneously claimed by the Department. It is critically important to note that the sub-bituminous coal fired at Minn-Dak[112] has an ash content of approximately 4 – 5%, which is typical for sub-bituminous coal and not about 8 – 10% on average as North Dakota lignite. In other words, North Dakota lignite has about twice the amount of ash compared to sub-bituminous coal. Furthermore, it is important to realize that the sub-bituminous coal burned at Minn-Dak has only between 0.3% and 0.5% sulfur, which means that the uncontrolled SO_2

[110] Ibid

[111] Response letter to EPA's October 4, 2007 letter sent from Minnkota Power Cooperative, Inc. to Mr. Terry O'Clair, Director, Division of Air Quality at the North Dakota Department of Health, dated November 9, 2007.

[112] State of North Dakota, Department of Health, Division of Air Quality, Air Pollution Control Title V Permit to Operate, Permit Number T5-X78001 issued on 7/31/2006.

emissions range between 0.7 lb/10^6 Btu and 1.1 lb/10^6 Btu[113], which compares very favorably to a permitted emission limit of 3.0 lb/10^6 Btu. The measured SO_2 emission rate was reported to be around 0.1 lb/10^6 Btu at a time when the uncontrolled emission rate was theoretically and not accounting for any SO_2 being captured in the fly ash only about 0.7 lb/10^6 Btu (based on the coal data included in the report), which suggests a SO_2 removal rate of no more than at the most 70%[114]. Combining this with the fact that these stoker fired units have no ESP but are equipped with only multi-cyclones as primary particulate control devices, suggests very strongly that the co-current venturi scrubbers were never intended to remove any significant amounts of SO_2 but where designed as additional particulate removal devices.

Multi-cyclones are comparatively simple devices designed for the removal of only the coarsest fly ash particles. Therefore, multi-cyclones have not been used in utility boilers for more than 40 years anymore. Due to the fact that multi-cyclones are based on the principal of centrifugal forces removing the particles, only the largest and heaviest particles can be removed. Contrary to that, ESPs electrically charge all sizes of particles, which are then removed in an electric field as a result of their electric charge. Therefore, ESPs are much more effective removal devices for particulate matter, particularly for very small particles.

Since PRB is known to generate a comparatively large fraction of very fine ash particles and since these stoker-fired units were most likely not designed for burning PRB, it is quite conceivable why the units didn't meet their particulate emission limit while burning PRB. Not being equipped with particulate control devices suitable for the removal of fine particles, limiting the sodium content in the ash serves as means to limit the amount of very small particles formed.

Co-current venturi scrubbers are particulate removal devices, which operate on the principle of inertial impaction of smaller particles on water droplets as a result of largely different velocities. Again, only the larger particles have enough mass and therefore inertia to be removed successfully. Small particles with a small mass and therefore very little inertia follow the gas stream and successfully evade impaction. Contrary to that, counter-current spray towers designed for SO_2 removal are based on the principle of offering a large amount of finely dispersed liquid for the rapid cooling of the flue gas to its saturation temperature followed by the absorption of gaseous air pollutants such as SO_2. During the rapid cooling of the flue gas with a large excess of water, the very small particles, which provide a comparatively large surface area, act as condensation nuclei and are absorbed into the scrubbing solution. Also, the flue gas residence time in a counter-current spray tower is much longer than in a co-current venturi scrubber, which further assists removing small particles.

Suggesting that the flue gas inlet composition to a TESCR downstream of an ESP and a counter-current wet flue gas desulfurization scrubber is even similar to the flue gas composition downstream of a multi-cyclone and a co-current venturi scrubber designed for

---

[113] North Dakota Department of Health, Inspection Report, issued on 10/27/2003.

[114] Ibid

coarse particulate removal is truly creative. Yet, the fact of the matter remains that the Minn-Dak experience is not comparable to the situation at the M.R. Young Station due to the different:

- coal burned (PRB versus North Dakota lignite);
- combustion system design (stoker fired versus cyclone fired);
- primary particulate matter removal device (multi-cyclone versus ESP);
- wet scrubber design and purpose (co-current venturi for particulate removal versus counter-current spray tower for SO_2 removal).

Thus, the Minn-Dak experience must be considered completely meaningless and irrelevant for the possible application of a TESCR at the M.R. Young Station.

In Minnkota's April 18, 2007 response to question from the Department[115], Minnkota states that "stack sampling was conducted downstream of the ESP and wet FGD on Unit 2." However, it remains unclear whether the data provided represents samples taken downstream of the ESP or samples taken downstream of the wet scrubber. Furthermore, even if the data represents samples downstream of the wet scrubber, it is unknown whether the samples were taken downstream of the wet scrubber but upstream of the bypassing flue gas re-entering the flue gas stream to the stack or downstream of the bypass re-entry point. These questions are very relevant, since the flue gas stream downstream of the ESP and upstream of the wet scrubber is significantly different from the flue gas downstream of the wet scrubber. Likewise, the flue gas stream downstream of the wet scrubber but upstream of the bypass re-entry point is significantly different than the flue gas downstream of the bypassing flue gas re-entering the flue gas stream coming from the wet scrubber to the stack. An e-mail string between Minnkota and Burns & MacDonnell[116] seems to indicate that at least the sampling may have been done downstream of the wet scrubber and downstream of the bypass re-entry point of the flue gas for reheating. If this is confirmed than this data is completely useless for the correct characterization of the flue gas stream entering a TESCR as approximately 18% of the flue gas bypassed the wet scrubber at the time of sampling[117]. This means that the flue gas sampled clearly does not represent what would enter a TESCR as everything that is removed in a wet scrubber was still present in almost one fifth of the flue gas during sampling. Since the sampling was clearly not intended to characterize the flue gas composition entering a TESCR but intended to prove the particulate removal downstream of the ESP, this data cannot be considered relevant for any reasonable judgment concerning the technical feasibility of a TESCR.

---

[115] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, Responses to NDDH and EPA Comments Regarding SCR Technical Feasibility and Non-SCR Concerns Milton R. Young Station Unit 1 and Unit 2 NOx BACT Analysis Study, April 18, 2007.

[116] E-mail string from John Graves (Minnkota) to Robert Blakely (Burns & McDonnell) dated April 12, 2007.

[117] Ibid

Also, no flue gas characteristics (temperatures, velocity, composition, etc.) at the sampling point are provided. Without exact knowledge of all these important details, the provided data is useless even for any reasonable judgment concerning a LDSCR. However, even if some of this missing information would be made available, the data would still be meaningless unless the total mass flow or at least the total concentration of the various compounds in the flue gas would be provided. The provided data only offers a morphological composition analysis of the samples expressed in relative percentages of the various elements as a portion of the entire sample. No information about the absolute amount of the various compounds as well as their aggregate state was made available, which renders the data in its provided form as absolutely useless for any meaningful interpretation concerning expected catalyst deactivation rates. Why only this by itself completely useless portion of the data was provided while all information needed to make the data possibly meaningful was withheld (assuming that this information exists), remains unknown.

While the Department devotes forty (40) pages of the seventy two (72) page document to arguments why HDSCR should be considered technically not feasible, little more than two (2) pages are dedicated to LDSCR and TESCR combined. Of these two (2) pages little more than one (1) page deals with possible site constraints and flue gas reheating, both of which are correctly dismissed as being economic considerations instead of technical feasibility issues, thus leaving about only one (1) page for the combined evaluation of LDSCR and TESCR. This one (1) page states the Department's conclusion that a LDSCR and/or a TESCR are technically infeasible without presenting any relevant supporting data. The Department's conclusion rests solely on the incorrect, unsupported and unfounded claim that "the deactivation issue for low-dust and tail-gas SCR remains the same as for high-dust SCR". However, only a few paragraphs later, the Department contradicts this earlier statement by postulating that "catalyst deactivation of a low-dust or tail-gas SCR due to alkali compounds is an issue that will require extensive research, design and pilot testing to determine whether the technology can be successfully applied to units fired on North Dakota lignite". Either the Department can provide relevant supporting data for the claim that the deactivation issue in a TESCR remains the same as in a HDSCR, or such supporting data doesn't exist, in which case the claim is purely speculative and unsupported.

It is also a fact that the SCR Vendor Query conducted by Burns & McDonnell very specifically stated that it was solely directed towards HDSCR, thus ignoring LDSCR and TESCR. Why attempts by various vendors (Alstom, Babcock Power, CERAM) to also consider LDSCR and/or TESCR were seemingly ignored remains unexplained.

Thus, the final conclusion reached by the Department that HDSCR is not technically feasible is unacceptable. All the presented data, investigations, vendor information etc. most certainly don't allow the conclusion that HDSCR is not technically feasible. Concluding that HDSCR is technically infeasible is premature and unfounded.

Furthermore, the Department's conclusion that LDSCR and TESCR are both not technically feasible is clearly presumptive and speculative as this conclusion cannot be supported by any relevant data, investigation or vendor information. Additionally, it must be stated that this conclusion is wrong as the only one (1) claim of excessive catalyst deactivation made against TESCR is clearly technically not defendable.

In summary, this leads to the conclusion that the Department's statement that that SCR technology is not technically feasible for application at the M.R. Young Station's cyclone-fired units burning North Dakota lignite is incorrect. HDSCR may very well be technically feasible, LDSCR is most likely technically feasible and TESCR is most certainly technically feasible for application at the M.R. Young Station's cyclone-fired units burning North Dakota lignite. With at least one SCR principle, namely TESCR being most certainly technically feasible for the application at the M.R. Young Station, the Department's BACT analysis incorrectly eliminated the SCR technology from further consideration.

7. VENDOR QUERY TAIL-END SCR

In order to further substantiate the technical feasibility of TESCR for the M.R. Young Station, the same eight (8) vendors were contacted that also participated in the Vendor Query conducted by Burns & McDonnell[118]. Due to vacation schedules and other personal restrictions only six (6) of the eight (8) vendors contacted were able to provide written responses, while two (2) could provide only verbal responses. Also, time constraints demanded that the scope and extent of the discussion with these eight (8) vendors had to be limited to some very fundamental questions concerning TESCR.

Since catalyst deactivation seems to be the primary concern of the Department, more time was devoted to communication with the catalyst manufacturers (Argillon, CERAM, Cormetech, Haldor Tospoe, Hitachi) as they are ultimately the ones, who provide the process performance guarantees for the catalyst. Somewhat less time was devoted to the SCR equipment vendors, who ultimately also rely on the catalyst manufacturers for catalyst performance and deactivation information and guarantees. Therefore, the response of the catalyst manufacturers was considered to be most meaningful, particularly the responses of the ones with extensive TESCR experience. Again, more time was devoted to the companies with TESCR experience (Alstom, Argillon, CERAM, Babcock Power, Haldor Topsoe) compared to the ones with no TESCR experience (Babcock & Wilcox, Cormetech, Hitachi).

The following eight (8) vendors were contacted:

- SCR equipment vendors:
    - Alstom – Mr. Michael Philips was not available due to time constraints and therefore directed me to Mr. John Buschmann, SCR Product Manager at Alstom, who provided only a verbal response due to insufficient time for a

---

[118] Minnkota Power Cooperative, Inc. and Square Butte Electric Cooperative, Responses to NDDH and EPA Comments Regarding SCR Technical Feasibility and Non-SCR Concerns Milton R. Young Station Unit 1 and Unit 2 NOx BACT Analysis Study, April 18, 2007.

written response. Alstom has extensive TESCR experience.

  - Babcock Power – Dr. Clayton Erickson provided a written statement. Babcock Power has access to extensive TESCR experience and is the equipment supplier of the LDCSR downstream of a cold-side ESP under construction as WE Energies' South Oak Creek Station.

  - Babcock & Wilcox – Mr. Steve Moormann could not be reached. Instead, Mr. Donald Tonn, SCR Process Expert at Babcock & Wilcox in Barberton, OH was contacted and provided a written response. Babcock & Wilcox has no TESCR experience.

- SCR catalyst manufacturers:

  - Argillon – Mrs. Cindy Khalaf provided a written statement. Argillon has extensive TESCR experience.

  - CERAM – Mr. John Cochran provided a written statement. CERAM has extensive TESCR experience.

  - Cormetech – Mr. Scot Pritchard provided a written statement. Cormetech has no TESCR experience but some LDSCR experience.

  - Haldor Topsoe – Mr. Flemming Hansen provided a written statement. Haldor Topsoe has extensive TESCR experience.

  - Hitachi – Mr. Anthony Favale provided only a verbal response due to insufficient time for a written response. Hitachi has no TESCR experience but some LDSCR experience.

Due to the time constraints, the person named above at each of the eight (8) vendors was contacted by phone and informed about the purpose of the discussion as well as asked whether he or she would be willing to provide a brief statement in writing per e-mail. All contacted people agreed to provide a written statement. However, Messrs. John Buschmann of Alstom and Anthony Favale of Hitachi who could provide only provide a verbal response due to time constraints as the written response would have arrived after the submission of this report.

All eight (8) vendors, namely three (3) SCR system suppliers (Alstom, Babcock Power and Babcock & Wilcox) and five (5) SCR catalyst suppliers (Argillon, CERAM, Cormetech, Haldor Topsoe and Hitachi) were asked to provide answers to the following three (3) questions:

Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would <*company*>:

a. Consider a tail-end SCR technically feasible?

b. Recommend or require additional pilot testing?
c. Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

All eight (8) vendors answered the question a. with a clear "yes". None of the vendors expressed even the slightest doubts that TESCR would not be technically feasible for both units at the M.R. Young Station. All three (3) contacted SCR system suppliers and all responding five (5) SCR catalyst suppliers consider TESCR to be unquestionably technically feasible for cyclone fired units burning North Dakota lignite.

All five (5) responding catalyst manufacturers answered question b. with a clear "no", thus dismissing any need for any further pilot testing for a TESCR application at M.R. Young Station.

Likewise, the SCR system suppliers Babcock Power and Alstom also dismissed any need for any additional pilot testing for a TESCR. The only SCR system supplier, who stated that they "would require further discussion with the catalyst suppliers", was Babcock & Wilcox. This caution is simply the result of the lack of experience of Babcock & Wilcox with TESCRs. Given the fact that even though Babcock & Wilcox has a license from Hitachi for SCR catalyst but Hitachi has no experience with TESCR either, such caution is no surprise.

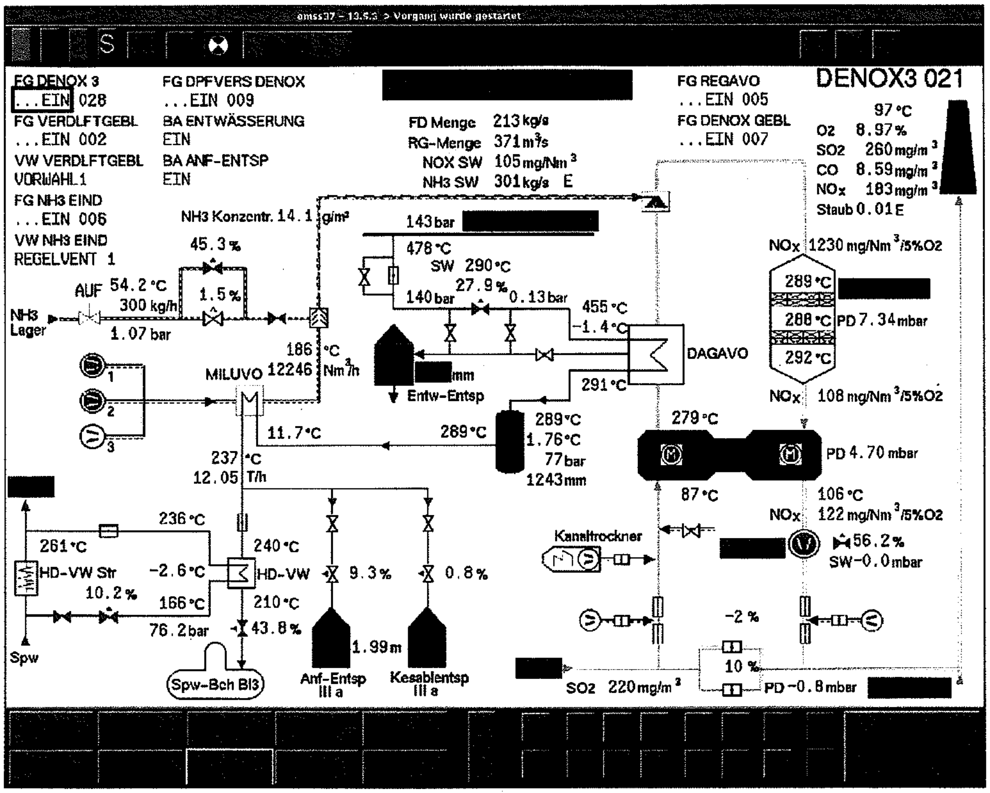
All five (5) responding catalyst suppliers and all three (3) SCR system suppliers answered question c. with a clear statement that they would provide common commercial performance guarantees. Argillon indicated 90% NOx removal efficiency at less than 2 ppmvd @ 3% O_2 NH_3 slip and greater 24,000 SCR operating hours catalyst life. Obviously, more details would have to be determined as the project would need to be defined better. Only Babcock & Wilcox stated that the commercial guarantees would have to be discussed first with the catalyst suppliers before passing them on to the buyer. Hitachi stated that they would have to see the exact flue gas composition in order to determine what commercial guarantees would be provided. Again, this can be explained by the fact that neither Babcock & Wilcox nor Hitachi has any TESCR experience and did not have time to evaluate a TESCR application for M.R. Young Station in sufficient detail.

Additionally, during the verbal discussions with all four (4) catalyst suppliers as well as all three (3) responding SCR systems suppliers, the contact persons made it very clear that their companies would not consider HDSCR as technically infeasible at this time. Particularly, all five (5) responding catalyst suppliers very adamantly stated that the existing knowledge does not support prematurely discarding HDSCR as a technically feasible possibility. All five (5) responding catalyst suppliers suggested that properly designed and executed HDSCR pilot testing would certainly be helpful to decide whether HDSCR would be more economically attractive than LDSCR or TESCR for the M.R. Young Station. The e-mail correspondence of all six (6) vendors, who responded in writing, is presented in detail in Appendix A.

8. SUMMARY

In summary, it must be concluded that TESCR is not only technically feasible but may be even the most economical SCR alternative for M.R. Young Station. As reiterated by the responding vendors, the very high removal efficiency of the ESP and wet FGD upstream of a TESCR combined with the flue gas reheating from the flue gas dew point provides flue gas conditions, which are unquestionably much more favorable for SCR catalyst than the conditions present in almost all HDSCRs. Two decades of TESCR experience in Europe have proven that TESCR can be successfully applied to the most complex processes and the most difficult flue gases. Catalyst replacement in most TESCRs has been minimal to none. Most coal-fired units equipped with TESCRs still utilize the initial catalyst fill after more than 130,000 SCR operating hours. Due to the greatly reduced mass flow of catalyst poisons to the SCR catalyst the catalyst deactivation rates in TESCRs have proven to be extremely low, in some cases barely measurable.

Additionally, minimal unit downtime for TESCR tie-in resulting in very little if any lost generation is a huge advantage for TESCRs as they can be constructed typically completely independent of and parallel to unit operation. Flue gas reheat cost is relatively low as the flue gas needs to be reheated with high pressure steam only by about 18 – 65 degrees (10 K – 35 K) and the condensate from the steam coil is typically further used for dilution air heating and subsequent feed water before returned to the condensate from the turbine.



The graph above presents a typical process flow diagram from a TESCR on a 300 MW coal-fired unit. This TESCR has operated for more than 130,000 hours for more 20 years now on the initial fill of catalyst with a continuous NOx removal efficiency in excess of 91%. As can be seen on the graph, the high pressure steam used for reheating is cooled from about 892 F (478 °C) to ultimately 410 F (210 °C) after dilution air and feedwater heating and prior to being discharged to the feedwater storage tank. Also worth noting is the small amount of only 18 degrees F (10 K) that need to be added to the flue gas by means of high pressure steam. As can be seen, the flue gas downstream of the gas-gas heat exchanger enters the steam coil with a temperature of approximately 534 F (279 °C) and enters the SCR reactor downstream of the steam coil with a temperature of only about 552 F (289 °C). This proves the high efficiency of the gas-gas heat exchanger and the small amount of high pressure steam needed for flue gas reheating, which makes this concept economically more attractive.

In the U.S. currently both 325 MW units at PSE&G's Mercer Generating Station are equipped with TESCRs with flue gas reheat downstream of the ESPs. Spray dryer absorbers followed by baghouses downstream are being added downstream of the SCRs, thus effectively converting them from TESCRs to LDSCRs. The same type SCR with flue gas reheat is currently being installed at WE Energies South Otter Creek Generating Station.

Thus, LDSCR and/or TESCR systems can neither be dismissed as being technically infeasible nor based on economic reasons. Particularly the TESCR principle was developed specifically in order to successfully adapt the SCR technology to units with the most difficult flue gas compositions and the most complex retrofit challenges. During its 22 years of extraordinarily successful operating history, the TESCR principle has not only unconditionally proven itself as one of the most viable SCR principles but certainly the most universally applicable of all SCR principles.

Appendix B: SCR Vendor Query Correspondence

1. Vendor Correspondence with SCR system suppliers

1.1 E-Mail correspondence with Clay Erickson, Babcock Power (SCR System Vendor – extensive tail-end SCR experience)

From: cerickson@babcockpower.com [mailto:cerickson@babcockpower.com]
Sent: Thursday, June 19, 2008 15:59
To: Hans Hartenstein
Cc: jlangone@babcockpower.com; tlicata@babcockpower.com
Subject: Re: Tail-end SCR

Hans,

Babcock Power has reviewed the Milton Young plant in the past, based on these reviews Babcock Power finds

- A tail-end SCR is technically and commercial feasible
- Babcock Power does not recommend or require additional pilot testing only proper flue gas characterization as with any SCR system per performed
- Will provide commercial guarantees for the SCR and catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime

Babcock Power has the largest SCR experience list in the world; from this experience we are completely confident in the application of a tail end system at Milton Young. If you have further questions please let me know.

With best regards,
Clay

Subject: Tail-end SCR

Clay,

As discussed during our phone conversation today, during which you stated that Babcock Power considers a high-dust SCR principally, technically feasible even though not without technically resolvable challenges for Minnkota's Milton R. Young Station, I would also be interested in Babcock Power's position on the technical feasibility of a tail-end SCR (downstream of a wet scrubber including flue gas reheat) Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Babcock Power:

- Consider a tail-end SCR technically feasible?
- Recommend or require additional pilot testing?
- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

Given the fact that tail-end SCRs in Germany including the ones built by your licensor Fisia Babcock (most of which are on wet bottom boilers) went into operation in the late 1980s and most of them still operate on the initial fill of catalyst after almost 20 years and up to 130,000 operating hours, I would assume that Babcock Power / Fisia Babcock has sufficient confidence in your tail-end SCR experience to competently respond to these questions. Please let me know if you have any additional questions. Thanks.

Best regards,
Hans Hartenstein

1.2 E-Mail Correspondence with Don Tonn, Babcock & Wilcox (SCR System Vendor – no tail-end SCR experience)

To: Tonn, Donald P
Subject: Tail-end SCR

Don,

As discussed during our phone conversation today, during which you stated that Babcock & Wilcox considers a tail-end SCR (downstream of a wet scrubber including flue gas reheat) principally technically feasible for Minnkota's Milton R. Young Station, I would be interested in Babcock & Wilcox's position on the following questions. Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Babcock & Wilcox:

- Consider a tail-end SCR technically feasible? Yes
- Recommend or require additional pilot testing? Requires further discussion with catalyst suppliers.

- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be? While B&W has considered tail-end SCR systems on other projects we have not had these commercial guarantee discussions with the catalyst suppliers for the North Dakota lignite application. Before consideration of providing these guarantees a comfort level would be required after obtaining guarantees from catalyst suppliers.

Given the fact that tail-end SCRs in Germany went into operation in the late 1980s and most of them still operate on the initial fill of catalyst after almost 20 years and up to 130,000 operating hours, I would assume that Babcock & Wilcox has sufficient confidence in tail-end SCR systems to competently respond to these questions. Please let me know if you have any additional questions. Thanks.

Best regards,
Hans Hartenstein

To: Hans Hartenstein
Cc: Khalaf Cindy R
Subject: Argillon Tail-end SCR
Importance: High

On behalf of Cindy Khalaf -

Hans,

Further to our phone call, as far as I know, Argillon has more tail end experience than any other SCR catalyst manufacturer and, as you noted, we also have experience with high dust, German lignite SCRs. Argillon also won the first US lignite SCR catalyst project (Luminant Oak Grove 1 & 2) and provided commercial guarantees. These units are not in service yet. So, yes, we consider ourselves able to answer these questions competently.

Consider a tail-end SCR technically feasible?

Yes, we consider this configuration to be technically feasible. As you know, tail end SCRs are often used when there are significant catalyst poisons in a flue gas stream. A wet scrubber can remove most of these poisons, resulting in very low catalyst deactivation.

Recommend or require additional pilot testing?

For a high dust configuration, we would say definitely. For a tail-end configuration, we would say no. We would only like to see a flue gas analysis for conditions at the inlet to the SCR in order to predict deactivation rate.

Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

Generally speaking, yes, we would provide guarantees for DeNOx & slip as specified (not to exceed 90% or 2 ppm), 24k hours life, SO_2 conversion rate - low but value TBD, pressure drop - value TBD. Of course we would have to see the technical specifications before being more specific. In addition, tail-end SCRs perform much longer, so depending on the application specifics, customer, etc., we may decide to extend the operating life guarantees. This is a commercial decision and will be reviewed on a case-by case basis.

If you have any more questions, please let me know.

Regards,
Cindy

To: Khalaf Cindy R
Subject: Tail-end SCR

Cindy,

As discussed during our phone conversation today, during which you stated that Argillon considers a high-dust SCR principally technically, feasible based on your high-dust SCR experience with lignite fired units in Europe even though not without technically resolvable challenges for Minnkota's Milton R. Young Station, I would also be interested in Argillon's position on the technical feasibility of a tail-end SCR (downstream of a wet scrubber including flue gas reheat). Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Argillon:

- Consider a tail-end SCR technically feasible?
- Recommend or require additional pilot testing?
- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

Given the fact that tail-end SCRs in Germany including the ones equipped with Argillon catalyst went into operation in the late 1980s and most of them still operate on the initial fill of catalyst after almost 20 years and up to 130,000 operating hours, I would assume that Argillon has sufficient confidence in your tail-end SCR experience to competently respond to these questions. Please let me know if you have any additional questions. Thanks.

Best regards,
Hans Hartenstein

2.2 E-Mail Correspondence with John Cochran, CERAM Environmental (Catalyst Manufacturer – extensive tail-end SCR experience)

From: John Cochran [mailto:John.Cochran@ceram-usa.com]
Sent: Wednesday, June 25, 2008 15:14
To: Hans Hartenstein
Cc: Greg Holscher; Noel Rosha; Orehovsky Kurt
Subject: RE: Request for Information

Hans,

CERAM certainly considers the use of a tail-end SCR on applications such as the Milton R. Young Station as technically feasible provided a proper design approach is used. CERAM has the experience from more than 100 tail-end and low dust applications dating from 1988 that would substantiate our opinion. For a tail-end approach we see no need for additional pilot testing. As such, we can provide full commercial guarantees for catalyst performance (activity or lifetime, conversion rate, pressure drop, etc.).

The choice between high dust and tail-end processes certainly should consider capital costs, operating costs and process risk. Based on our experience certainly process risk would favor a tail-end approach, but albeit for most circumstances at a higher "all-in" cost. Should very high retrofit factors be present for a high dust arrangement then the relative economic factors may even favor a tail-end approach.

I hope this information is useful to your evaluation. Please advise should you have any further questions or information needs. Thanks.

Best Regards,
John Cochran

Sent: Tuesday, June 17, 2008 7:20
To: John Cochran
Subject: Request for Information

John,

As discussed during our phone conversation today, during which you stated that CERAM considers a high-dust SCR principally technically, feasible even though not without technically resolvable challenges for Minnkota's Milton R. Young Station, I would also be interested in CERAM's position on the technical feasibility of a tail-end SCR (downstream of a wet scrubber including flue gas reheat) Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would CERAM:

- Consider a tail-end SCR technically feasible?
- Recommend or require additional pilot testing?
- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be?

Given the fact that tail-end SCRs in Germany including the ones equipped with CERAM catalyst (Herne 1, 2 and 3, Voerde (West) 1 and 2, Lünen 10 and 11 – all of which are wet bottom boilers) went into operation in the late 1980s and most of them still operate on the initial fill of catalyst after almost 20 years and up to 130,000 operating hours, I would assume that CERAM has sufficient confidence in your tail-end SCR experience to competently respond to these questions. Please let me know if you have any additional questions. Thanks.

Best regards,
Hans Hartenstein

2.3 E-Mail Correspondence with Scot Pritchard, Cormetech (Catalyst Manufacturer – no tail-end SCR experience)

From: Pritchard, Scot G. [mailto:PritchardSG@Cormetech.com]
Sent: Thursday, June 19, 2008 17:41
To: Hans Hartenstein
Subject: RE: Tail-end SCR

Hans,

I was thinking of if you put a coupon in the tailend location and it showed something weird then you would have to do something more elaborate i.e. A slipstream with longer hours, etc. We do not anticipate this - in fact you could probably do without the coupon test as well since I don't see any reason why this system would be any different the primary tail end experience i.e. Unlikely any nasties make it through the lower temperature environment and scrubber process. The coupon is OK but I really don't expect to see much. Finally, we have not done any specific coupon tests (because slipstream has been the primary way to evaluate) so we would need to think through the best way to do it - i.e. holder, mounting arrangement, test method, hours of exposure, etc. If you already have something in mind please let us know.
Hope that helps with the clarification.

Scot

From: "Hans Hartenstein" <Hans.Hartenstein@Evonik-EnergyServices.us>
Sent: Thursday, 6/19/08 4:26 pm
To: "Pritchard, Scot G." <PritchardSG@Cormetech.com>
Subject: RE: Tail-end SCR

Scot,

Thanks for the input from Cormetech, which is greatly valued. One question for clarification purposes only, though. Coupon tests and/or flue gas analysis would only be performed in order to characterize the flue gas going into the tail-end SCR as is needed for the design of any APC equipment. Obviously, nobody could offer any performance guarantees concerning what's coming out of a tail-end SCR without knowing what's going into it. You state that in case coupon tests would show a significant accumulation of catalyst poisons, a subsequent slip stream test, which is unquestionably more accurate and representative of a full scale - in this case tail-end - SCR, would be recommended. Stating this, do I understand you right that you would recommend this slip stream testing mainly for the purpose of properly characterizing the flue gas composition at the inlet to the tail-end SCR in order to provide a reliable basis for correct catalyst design? Do I assume correctly, that you would not require extensive and long-term (12 - 24 months) pilot testing with a slip stream reactor because you have serious doubts about the principal technical feasibility of a tail-end SCR for this application? Please clarify. Thanks.

Best regards,
Hans Hartenstein

From: Pritchard, Scot G. [mailto:PritchardSG@Cormetech.com]
Sent: Thursday, June 19, 2008 12:15

Subject: RE: Tail-end SCR

Hans,

Please see my input below.

As discussed during our phone conversation today, during which you stated that Cormetech considers a high-dust SCR principally technically, feasible even though not without technically resolvable challenges for Minnkota's Milton R. Young Station, I would also be interested in Cormetech's position on the technical feasibility of a tail-end SCR (downstream of a wet scrubber including flue gas reheat) Given your knowledge about the plant (cyclone-fired B&W boilers, ESP, wet scrubber) and the fuel (ND lignite), would Cormetech:

- Consider a tail-end SCR technically feasible? - yes

- Recommend or require additional pilot testing? - We generally do not consider coupon testing an accurate representation of an SCR, however in order to minimize cost and provide basic screening information we would suggest the potential use of a coupon sample test. If the coupon shows significant accumulation of catalyst poisons, a subsequent slipstream type test which is more representative of a full scale SCR i.e match velocity, AVs, etc. would be recommended.
- Be willing to provide commercial guarantees for catalyst performance (activity, pressure drop and SO_2/SO_3 conversion rate) and lifetime? If so what would these be? Presuming the coupon test does not show anything unusual (which we do not expect to see anything unusual) we would be willing to provide commercial guarantees for a low dust application. Basic guarantees would be associated with life (this would not include specific Ko and K/Ko as guarantees - the guarantee would be an efficiency and slip guarantee at a certain number of operating hours), SO2 conversion, pressure loss.

As discussed, the high dust application needs additional due diligence testing (slipstream, ash testing, etc.) as well as the practicality of the applicable operating temperature to establish the commercial stance for a high dust application on North Dakota Lignite. We have done such work for Texas lignite as well as other coal sources and other fuels/applications in the past and would expect to be able to achieve the same for this application. The economics for any given application would be considered on a case by case basis.
Let me know if you have any questions. Also I would appreciate anything of the final document that you can share.

Thank you and regards,

Scot Pritchard

Flemming,

Thanks for your note. Just to make sure that I understand you correctly. Is it correct to state that Haldor Topsoe feels fully confident that a tail-end SCR is technically feasible and would not experience any accelerated catalyst deactivation? Therefore, you would be willing to guarantee catalyst performance (NOx removal efficiency, pressure drop, SO_2/SO_3 conversion rate and catalyst lifetime) without any need for further pilot testing. Please confirm. Thanks.

Best regards,
Hans Hartenstein

Subject: Re: Tail-end SCR

Hans,

Like you describe we have had very good operating experience with SCR in the clean environment after a scrubber or bag filter. There appears to be practically no catalyst deactivation and with the low amount of particulate the catalyst pitch can be small, which both leads to a compact SCR as compared to a high dust SCR.

Based on the clean flue gas after the FGD we would not require any further testing in order to guarantee a catalyst performance.

The actual guarantees would be as normally applied in a high dust installation and depend on the catalyst volume and operating conditions. At the low operating temperature expected at the tail-end position the SO_2 oxidation will be negligible.

I hope this confirmation will have your approval.

Appendix D: Resume

Hans-Ulrich Hartenstein

Title:
Managing Director E&EC

Nationality:
German

Education:

University of Stuttgart	B. Sc. in Mechanical Engineering
University of Stuttgart	M.E. in Mechanical Engineering
University of Florida	M.E. in Environmental Engineering
University of Toronto	Global Executive MBA

General Experiences:

Mr. Hartenstein has been in the environmental field for over twenty years. His experience includes project development, project management and supervision, coordination and implementation of design and building projects for municipal waste-to-energy, hazardous waste incineration, and air pollution control facilities (SCR, FGD, Hg control, PCDD/PCDF control) in the power utility industry and waste-to-energy industry.

His responsibilities included project development, process engineering and management, procurement and construction supervision, start-up and commissioning, environmental and financial analysis, permitting application procedures and regulatory interfacing.

Mr. Hartenstein has been project management director of numerous air pollution control systems, one municipal waste-to-energy project, and four hazardous waste incineration projects. He has been involved in the development of eighteen environmental projects out of which seven also included permitting procedures and process design, two also included construction and one included complete start-up and commissioning.

Mr. Hartenstein has also directed development of waste management and air pollution control segments and managed a $ 61 million turnkey contract for 80 TPD hazardous waste incineration contract including a tail-end SCR. After completion of the facility Mr. Hartenstein was responsible for the initial 2 years of operation of the plant. He was also responsible for the successful negotiations of eight turn key mass burn, waste-to-energy contracts valued in excess of $ 600 million and he has successfully negotiated several international air pollution control technology licenses (SCR and FGD) among Polish, Korean, American and Japanese companies.

He has managed and supervised feasibility analysis, conceptual engineering and design, permitting final design, technology development, and project implementation and has assisted in project financial planning including assuring financing for several projects.

Since 1999 Mr. Hartenstein has been active mainly in the U.S. in the areas of SCR and FGD retrofits to fossil fuel fired electric utility generating stations. He expanded his initial focus on the design and construction of these SCR and FGD retrofits quickly into the areas of long term operation and maintenance of air pollution control equipment. His current focus is on most cost effective long term FGD and SCR management ensuring maximum performance at the lowest possible cost.

Positions Held:

• Environmental Engineer L&C Steinmüller GmbH[1]	1987 – 1989
• Senior Environmental Engineer L&C Steinmüller GmbH[1]	1989 – 1990
• Engineering Department Manager L&C Steinmüller GmbH[1]	1990 – 1992
• Senior Engineering Director L&C Steinmüller GmbH[1]	1992 – 1995
• Project Management Director L&C Steinmüller GmbH[1]	1995 – 1997
• Plant Manager RVA Böhlen RVA Böhlen GmbH	1997 – 1999
• Senior Vice President Babcock Borsig Power, Inc.[2]	2000 – 2001
• President SCR-Tech LLC	2001 – 2005
• President Evonik Energy Services LLC[3]	2006 - present
• Managing Director E&EC GmbH	1999 – present

[1] L&C Steinmüller GmbH has been acquired and renamed to Fisia Babcock GmbH

[2] Babcock Borsig Power, Inc. has been acquired and renamed Babcok Power, Inc.

[3] Steag LLC was renamed Evonik Energy Services LLC, no change in ownership

Professional Memberships

- Member of the World Pollution Control Association (WPCA)
- Invitational member of the Scientific Technical Advisory Panel (STAP) of the United Nations Environment Programme related to POPs and PTS.

Comments and Responses to NDDH Regarding U.S. EPA Region 8's July 31, 2008 Comments and Plains Justice July 30, 2008 Comments on NDDH Preliminary NOx BACT Determination for Milton R. Young Station (MRYS)

September 22, 2008

Burns & McDonnell (B&McD), and their SCR consultant, Tackticks LLC, along with the Energy & Environmental Research Center (EERC) of the University of North Dakota, have reviewed the EPA's comments (U.S. EPA, 2008), those of the Department of Justice's commenter, Hans Hartenstein (Hartenstein, 2008), and Plains Justice (Plains Justice, 2008). These are responses regarding selective catalytic reduction (SCR) technology feasibility and non-SCR concerns pertaining to the NDDH's Preliminary NO_X BACT Determination for Nitrogen Oxides for Milton R. Young Station Units 1 and 2, dated June 2008 (NDDH, 2008). We continue to believe that the administrative record fully supports a finding by the North Dakota Department of Health ("NDDH") that separated over-fire air (SOFA) in conjunction with selective non-catalytic reduction (SNCR) technology is Best Available Control Technology for electric generating units that utilize cyclone burners firing North Dakota lignite. The following sections address specific topics mentioned in the EPA's comments and other issues in greater detail.

- General Regulatory Considerations
- Corrections, Clarification and Omissions of Hartenstein and EPA's comments
- SCR Technology Review and Update
- Variability of Lignite
- Results of Coyote Pilot Testing
- Soluble Sodium
- Differences in Flue Gas Composition
- Catalyst Poisoning, Blinding, and Plugging
- Applicability of SCR Development for Texas Lignite
- SCR Catalyst Erosion
- Pilot Testing for SCR Catalyst

- Vendor Guarantees for TESCR
- Temperature Variations for HDSCR
- Burns & McDonnell's SCR Experience
- Comments by Sargent and Lundy on SCR Experience
- Comments on Hans Hartenstein's Qualifications for SCR Expert Opinions
- Fuel Switching
- Non-SCR Controls
- Conclusions

General Regulatory Considerations

In determining BACT, the limits placed on MRYS will be required for the plant's lifetime. In order for the units to run, emission rates will need to be met. Any emissions limit exceedance can result in a violation subject to significant financial penalties, injunctive relief and possible unforeseen equipment changes or plant outages. Many of the boilers referenced in EPA's report are not subject to New Source Review but some other form of regulation such as the NOx State Implementation Plan (SIP) Call program. There is a significant difference in NOx SIP and NSR. The NOx SIP Call is a seasonal (May to October) cap and trade program. Under this program, a utility's NOx emissions are capped to a level below historic emissions. The utility has the option to apply pollution controls and/or buy offsets from other utilities. Under the NOx SIP program, a problem with the pollution control equipment can be overcome by buying allowances while continuing to operate their units. NSR requires the controls be operating continuously and properly during plant operation.

1. EPA is deviating from a case-by-case BACT analysis by casting a wide net over SCR and insisting that it will work on all fuels and boiler types. Based on their comments, and those of DOJ's expert, in essence, "any problem can be overcome, SCR has been used successfully everywhere and no long term problems exist". However, as detailed later, our experts have found many instances where SCR was not used as a reduction strategy, or was unsuccessful.

In Minnkota's case, the combustion process from cyclone boilers and the North Dakota lignite makes application of SCR infeasible. Our specific combustion issue revolves around the size and type of combustion products produced in a cyclone-fired boiler when firing a high-sodium-containing lignite. The cyclone combustion process occurs at higher temperatures and different air distributions than other boiler types. Cyclone firing combustion products are partitioned between the slag that flows out of the bottom of the furnace and the flue gas containing impurities. The flue gas impurities are enriched in alkali (sodium and potassium) species relative to other boiler types. These species are known to blind and poison the SCR catalyst. The impurities of concern are vaporized during the cyclone combustion process to form a gas and upon gas cooling these gas phase impurities will condense to form aerosols or small particles that will deposit on the surface and in the pores of SCR catalysts. Once deposited, these alkali-rich materials will react with other gas phase species and deposited particles causing blinding or can react with active sites in the catalyst causing poisoning. This is well documented by Tackticks (see Appendix A) as well as by the DOJ's expert (Hartenstein). In a TESCR system, the flue gas passes through a precipitator and scrubber prior to reaching the SCR system. Large particles can be removed from the precipitator and scrubber. However, the removal of aerosols and small particulate (less than 2 microns in diameter) is dependent on the aerosol and small particle size and composition. Sodium, potassium and alkali aerosols are not easily removed from the precipitator and scrubber and no vendors will guarantee removal rates. In a TESCR application for a high-sodium lignite fired cyclone, the TESCR catalyst is likely to be exposed to appreciable concentrations of sodium, potassium and alkali concentrations. The second part of this case-by-case BACT evaluates the fuel used. North Dakota lignite is known to have a much higher levels of catalyst poisoning constituents than other lignite types. The lethal combination of the high temperature cyclone firing combustion process and high levels of catalyst poisoning constituents present in the lignite make this specific application technically infeasible.

2. Some catalyst vendors have "guaranteed catalyst operation" for the Minnkota units, according to DOJ's expert. EPA has taken a "guarantee" as a demonstration that the SCR application for North Dakota lignite is commercial. From the discussion above, EPA would lead us to

believe that the high sodium levels and the cyclone combustion processes resulting in an abundance of SCR blinding and poisoning alkali species in the flue gas are inconsequential since a vendor will provide equipment to Minnkota. However, Minnkota has to evaluate a guarantee on the long term viability of meeting an emissions limit, including catalyst maintenance and replacement requirements, and therefore we must question the vendor on numerous issues.

- **Does the vendor look at the long term compliance obligations that Minnkota will be subject to?** The vendor guarantees and contractual language will vary from project to project. For example, a vendor could guarantee a one time performance of their product and meet their obligation. However, the end user is stuck with a product that does not provide long term compliance. Some vendor language may guarantee a product for a longer period but assumes that certain operational conditions are met during that time period. If the operating conditions deviate, the vendor is no longer responsible. It is not unusual for vendors to guarantee performance then have to settle claims or change offer. Yet, Minnkota will still need to meet emission limits for the plant's lifetime.

- **The only test data (Coyote) for a cyclone boiler burning North Dakota lignite resulted in significant catalyst blinding and plugging in a short time period. How does a vendor resolve this issue?** Burns & McDonnell and EERC contacted Haldor Topsoe (HT) about this issue (B&McD and EERC, 2007). HT participated in the Coyote test that showed catalyst blinding and plugging was so severe that they could not make catalyst reactivity measurements. HT suggested that they would increase the pitch of the catalyst but had no solution for severe blinding and plugging of the catalyst pore structure. HT indicated that there were no catalyst designs available that would alleviate the severe blinding and plugging of the pore structure due to the high levels of sodium-rich aerosols present in flue derived from the cyclone-fired combustion of ND lignite.

3. EPA has claimed the Coyote pilot-scale SCR test to be completely invalid and no conclusions can be made. The Coyote test was developed by a consortium of Cormetech (catalyst vendor), Haldor Topsoe (catalyst vendor), Hitachi (SCR system provider), EPRI (research

agency), US. DOE, Alliant Energy, Otter Tail Power, Ameren, Dynegy, and Lignite Energy Council. This pilot test was intended to evaluate the fouling potential of SCR on lignite coal. DOJ's expert claims the test was fatally flawed, yet the participants in the test included vendors that design and install SCR systems as well as end-user utilities that have applied SCR on their boilers. This team was competent and, like many pilot tests, it is meant as a learning opportunity. Certainly, further testing may change some of the testing parameters, but the intent was to evaluate the system. Minnkota believes this testing was valid for its intended purpose and from this sole test, it was determined that there are significant impediments to using SCR on MRYS. The test results showed catalyst blinding and plugging due to sodium and potassium rich species. Peer reviewed literature written by many authors have verified that sodium and potassium species are fatal to the catalyst life.

Corrections, Clarifications and Omissions of Hartenstein and EPA Comments

The EPA's SCR technology comments (U.S. EPA. 2008) rely heavily on their interpretation of information mostly repeated from earlier comments to Minnkota and opinions expressed by the Department of Justice's (DOJ) commenter (Hartenstein, 2008), Many of these comments need to be clarified for the record.

1. Hartenstein implies that lignite-fired boilers are significantly represented among the 30,000 MW of SCR systems installed in Europe. This is misleading and substantially incorrect. Very few of the many SCRs retrofit in Europe were installed on lignite-fired utility boilers. Tackticks has advised that to the best of their knowledge, they are aware of SCR being originally installed at only two plants, and neither of these plants is operational today.

2. The EPA argues that NDDH's preliminary BACT Determination does not properly compare the emissions from other coal-fired boilers with high fuel sodium content to other boilers that successfully operate SCRs firing Powder River Basin (PRB) coal with high dust SCRs in the United States and are comparable to the Young Station boilers for their flyash alkali contents. The EPA ignored the Department's supporting detailed information by EERC that explains

why SCRs are not able to tolerate the higher levels of alkali species contained in flue gas such as exhausted from the MRYS boilers as compared to the PRB coal fired boilers..

3. In addition, the EPA and Hartenstein did not provide any substantial technical information that demonstrates that effective solutions to prevent or remove pore pluggage and blinding of SCR catalyst from sodium- and potassium-rich species present in the flue gas stream exhausted from a North Dakota lignite-fired cyclone boiler, whether installed in a conventional hot-side or cold-side application downstream of a wet scrubber, have been developed by catalyst vendors.

4. Hartenstein did not demonstrate he had an understanding of Center lignite characteristics and variability issues. Specifically, he did not understand how soluble sodium is used to define the abundance of organically associated sodium in lignite and how sodium will vary because of the abundance of other ash forming components in the coal. The abundance of sodium and other ash forming components vary dramatically and uniquely in North Dakota (Fort Union region) lignite coal and result in operational challenges. Hartenstein does not understand the differences between Fort Union lignite and Texas lignite. He indicates that the installations of SCR on Powder River Basin (PRB) subbituminous coal and testing on Texas lignite indicate feasibility for SCR on ND lignite even though the levels of sodium in typical PRB coal and Texas lignites are very low (0.7 to 1.5% Na_2O) as compared to 4.4 % Na_2O for Center lignite. The amount and form of alkali species in the coal along with combustion processes influence their ability to be enriched in the aerosol and fine particle fraction of the fly ash. The size and composition of the particle along with gas velocity determines their ability to penetrate and deposit on SCR catalyst passages and in pores and cause plugging, blinding, and poisoning.

5. Hartenstein did not address the issue of the partitioning of ash-forming species between the slag and fly ash components in cyclone-fired systems that result in an enrichment of sodium and other flame-volatilized species in the flue gas. These flame-volatilized species will condense homogeneously to produce abundant sodium and potassium-rich aerosols because

of the lower level of entrained solid ash particles in cyclone combustion-derived flue gases relative to pulverized coal combustion derived flue gas.

6. Hartenstein did not address the formation of aerosols and how that can impact SCR performance. The key issue for high sodium Fort Union (North Dakota lignite) coals fired in cyclone-fired boilers is the abundance of alkali-rich aerosols in the flue gas that can penetrate into the pores of SCR catalyst, causing blinding and poisoning. This is an issue for high dust and low dust / tail-end SCR applications. He appears to not be familiar with the diffusion mechanism of transport of aerosols deep into the SCR catalysts that can cause poisoning and plugging. Hartenstein appears to confuse the importance of catalyst pitch relative to pore plugging and blinding. He incorrectly suggests that catalyst pitch will solve the pore plugging and blinding problem. Using wider pitch catalyst does not eliminate the penetration of alkali-rich aerosols deep into SCR catalyst causing pore plugging and blinding problems. The impact of such aerosols that pass through the electrostatic precipitator (ESP) on the performance of low dust SCR applications was not discussed by Hartenstein. This fine ash that escapes from the ESP is finer than the bulk flyash and has a higher catalyst plugging potential due to a higher tendency to agglomerate. In addition, Hartenstein did not consider information provided on Powerspan barrier discharge reactor pilot slipstream testing that showed alkali rich accumulations downstream of the Unit 1 ESP at the MRY station.

7. Hartenstein's knowledge of gas-solid reaction mechanisms to form sulfate and pyrosulfate phase *in situ* in SCR catalysts appears to be very limited and was not adequately addressed.

8. Hartenstein did not discuss the recent literature on catalyst poisoning studies in Europe associated with cofiring high alkali (Na and K) containing biomass. This testing has showed significant poisoning of catalysts due to alkali aerosol penetration into catalysts and the subsequent reaction with catalyst active components causing poisoning.

9. Hartenstein did not offer information that more than 20,000 MW of lignite fired units in Germany were not required to install SCR in order to comply with the national regulation, or that even new lignite-fired units being installed today in Germany are not equipped with SCR

of any type. He did not state that Germany had only one cyclone-fired boiler operating with a LDSCR (Walsum Unit 7), or that the unit burns bituminous coal; nor did he advise that Voitsberg Unit 3, a boiler in Austria firing lignite coal, only ran for a short time with a high-dust SCR and was subsequently shutdown and demolished. He states that TESCR technology was "generally adopted as a universally applicable SCR solution for all types…" but failed to mention that there has never been another TESCR built after Siersdorf, (which was finished in early 1991 and has subsequently been decommissioned), in the United States or Europe. To the best of our knowledge, there is no TESCR anywhere in the world on a lignite-fired utility boiler. He cites "Ceram's extensive experience with lignite..", but fails to report that this consists of only one plant with Ceram catalyst having operated for a short period of time on lignite and a few pilot programs, so that it is dubious to say that this vendor has extensive experience on lignite fired boiler SCR plants (see Appendix A). There are numerous other instances of missing or factually incorrect information attributed to Mr. Hartenstein discussed in Appendix A.

10. Again, the EPA fails to recognize conclusively that ash chemical and physical properties of the Texas lignite (Wilcox formation) that TXU proposes to burn at the new Oak Grove powerplant where SCR is being installed (but has not yet begun operation) do not represent what is fired in North Dakota, and therefore technical feasibility and expected performance in a Texas lignite-fired pulverized coal boiler SCR application is not transferable to North Dakota lignite-fired cyclone burner units due to the significant differences in flue gas and ash chemical and physical properties. The composition of the Texas lignite fired at Martin Lake, where SCR mini-SCR pilot testing has been conducted, is typical of the composition of lignite fired at Sandow, with sodium oxide levels in the Texas lignite ash equal to 0.7%. The levels of sodium oxide in Center lignite average 4.4% and can be as high as 13% in as-fired samples. Hartenstein (2008) does not provide information on chemical composition of any fuels that are comparable to high sodium ND lignite where SCR installation have been installed and tested or successfully operated.

11. No examples were provided of on-line cleaning methods nor catalyst that would prove resistant to damage from such methods that would be effective in removing surface blinding and pore plugging deposits such as those seen in the Coyote pilot test catalyst even with the suggested edge erosion prevention measures in place. Hans Hartenstein does not address this issue in his comments. Hartenstein implies in his report (2008), that catalyst that has been poisoned by sodium compounds can be regenerated in-situ, and that this technique is well developed. There is extremely limited experience with in-situ catalyst cleaning on coal-fired units. It has never been used for blinded or chemically poisoned catalyst, but only for mechanically plugged catalyst (see Appendix A).

The following discussion will provide information on the following topics relevant to the EPA's comments: an SCR technology review and update; the variability of lignite; results of Coyote pilot testing; soluble sodium; differences in flue gas composition; catalyst poisoning, blinding and plugging; applicability of SCR development for Texas lignite; SCR catalyst erosion and cleaning; pilot testing for SCR catalyst; vendor guarantees for TESCR; temperature variations for HDSCR; Burns & McDonnell's SCR experience; comments by Sargent and Lundy on SCR experience; comments on Hans Hartenstein's qualifications for SCR expert opinions; fuel switching/blending/cleaning; non-SCR controls; and conclusions.

SCR Technology Review and Update

The literature provided by Hartenstein in his expert report (Hartenstein, 2008) did not provide any new information that would indicate the SCR technology is feasible for NO_x reduction at the MRY plant. Much of the information Hartenstein provided was reviewed earlier by the Energy & Environmental Research Center (EERC) and Burns and McDonnell. In addition, the reports provided by Hartenstein were not peer reviewed and were derived primarily from companies who have vested interests in the SCR technology and typically do not discuss problems and challenges. The reports from EPRI provided more useful information on the characteristics of the Texas lignite.

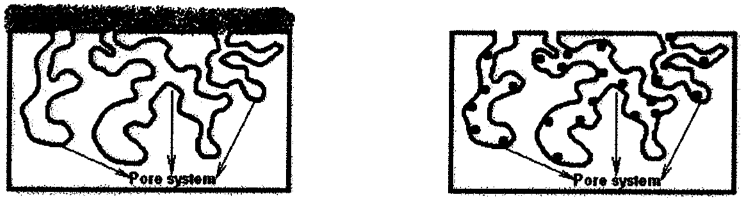
Hartenstein (2008) provided little information indicating that he is familiar with blinding and poisoning processes involving alkali (sodium and potassium). A demonstrated understanding of the blinding, plugging, and poison due to firing alkali-rich fuels is vital in determining the feasibility of SCR technologies. Much of this background information has been provided in EERC's previous comments (2007 and earlier). In addition, a significant amount of work has recently been conducted in Europe on blinding and poisoning of SCR catalysts associated with firing biomass alone and with coal. Much of the discussions are focused on the impact of alkali-rich aerosols on catalyst deactivation.

Since Hartenstein does not adequately address key mechanisms of catalyst deactivation and poisons, it is appropriate to provide a summary of the technical information. Guo (2006) who conducted testing of catalyst deactivation studies described the mechanisms of catalyst deactivation as shown in Figure 1. There are four primary types of catalyst deactivation.

- The first is channel plugging and is impacted by so called "popcorn ash" or in many cases typical of ash deposit fragments. Channel plugging is largely driven by the size of the ash materials carried back into the flue gas treatment system and can typically be controlled by the use of large particle ash screens to remove the ash, or by providing larger pitch catalyst.
- The second type is pore plugging by small fly ash particles. Small particles sometimes become lodged in the openings to the catalyst pore system and can cause plugging. These particles are typically not bonded and can be removed by various cleaning technologies.
- The third type is masking of the macrosurface by a dense phase. These phases that form are typically sulfates. The sulfates have formed as a result of in-situ sulfation of deposited alkali and alkaline earth materials.
- The fourth type is poisoning of the active sites in the catalyst. The active sites in SCR catalyst can be poisoned by the diffusion of various types of aerosols. The aerosols will diffuse into the pores and react with the active components of the catalyst.

Channel plugging: ash particles plug the monolith channel

Plugging: Microscopic blockage of catalyst pore system by small fly ash particles



Fouling/Masking: Macroscopic blockage of catalyst surface dense second-phase coating

Poisoning: Deactivation of catalyst active sites by chemical attack

Figure 1. General mechanisms of SCR catalyst deactivation (Guo, 2006).

High sodium lignites are prone to form abundant levels of aerosols when fired in a cyclone burner. Aerosols are formed as a result of the homogenous condensation of flame-volatilized species in combustion systems. During combustion of lignite, sodium, potassium, sulfur, and other components will vaporize and upon gas cooling these components will condense to form aerosols and other particles. As a result of these interactions, the resulting ash composition and mass distribution as a function of size is also shown in Figure 2. Typical ash derived from coal combustion has a bimodal to multimodal size distribution that consists of a submicron and supermicron size fraction as shown in Figure 3. The submicron component is largely a result of the condensation of flame-volatilized inorganic components. The intermediate size mode at about 2 micrometers is derived from the more refractory organically associated elements such as calcium and magnesium. The larger particles at approximately 12 to 15 μm are derived from the mineral grains present in the coal. The larger-size particles have been called the residual ash by some investigators (Sarofim and others, 1977) because these ash particles resemble, to a limited degree, the original minerals in the coal. Sodium and other flame-volatilized components are concentrated in the finer size fractions of ash as shown in Figure 4. This figure illustrates the increase in the sodium content in the finer size fractions of ash as a result of firing high sodium lignite. The sodium content of the 3rd stage (1–3 micrometer size cut) of the sampling train approached 20% Na_2O.

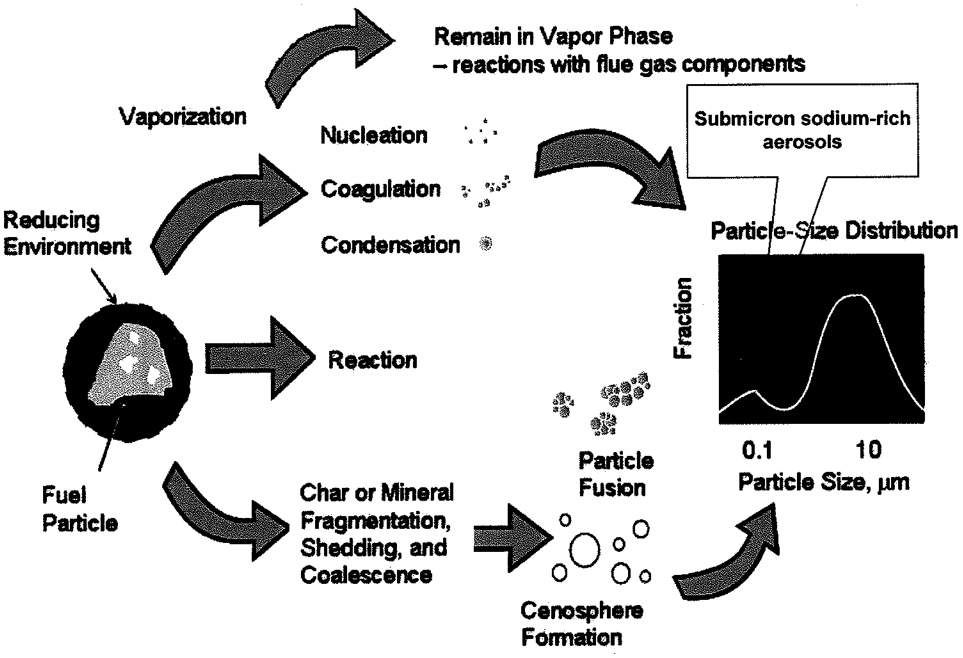


Figure 2. Transformation of inorganic components present in coal during combustion.

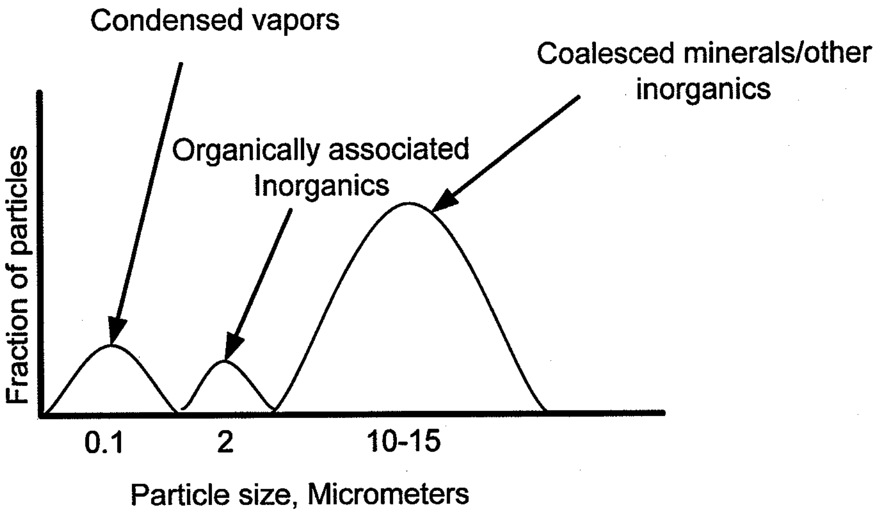

Figure 3. Final size distribution of ash particles produced upon combustion of lignitic coals (Benson and Laumb, 2007).

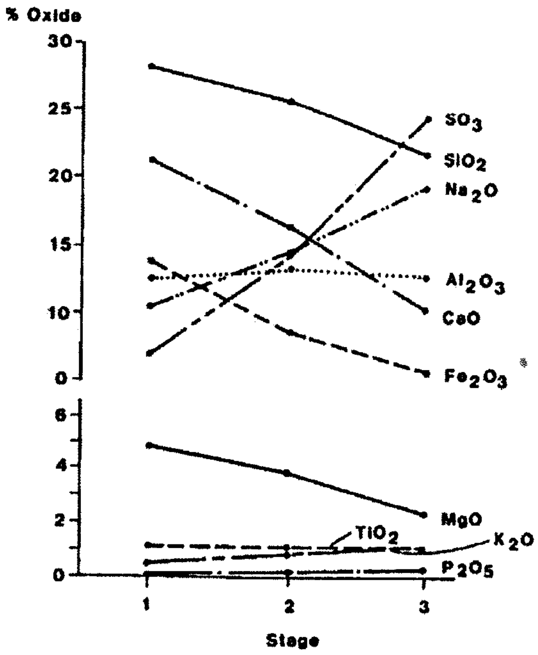

Figure 4. Composition distribution of ash particles during combustion of North Dakota Lignite (Benson and others, 1983).

The transport of intermediate ash species (i.e., inorganic vapors, liquids, and solids) is a function of the state and size of the ash species and system conditions such as gas flow patterns, gas velocity, and temperature. Several processes are involved in the transport of ash particles. These processes have been described by Raask (1985) and Rosner (1986). The primary transport mechanisms are illustrated in Figure 5. For larger particles inertial impaction and eddy impaction in turbulent regions are the dominant mechanisms. The aerosols (small particles <1 μm) and vapor-phase species are transported by the vapor phase and small particle diffusion. The inorganic materials are transported to heat-transfer and catalyst surfaces by diffusion, electrophoresis, and inertial impaction.

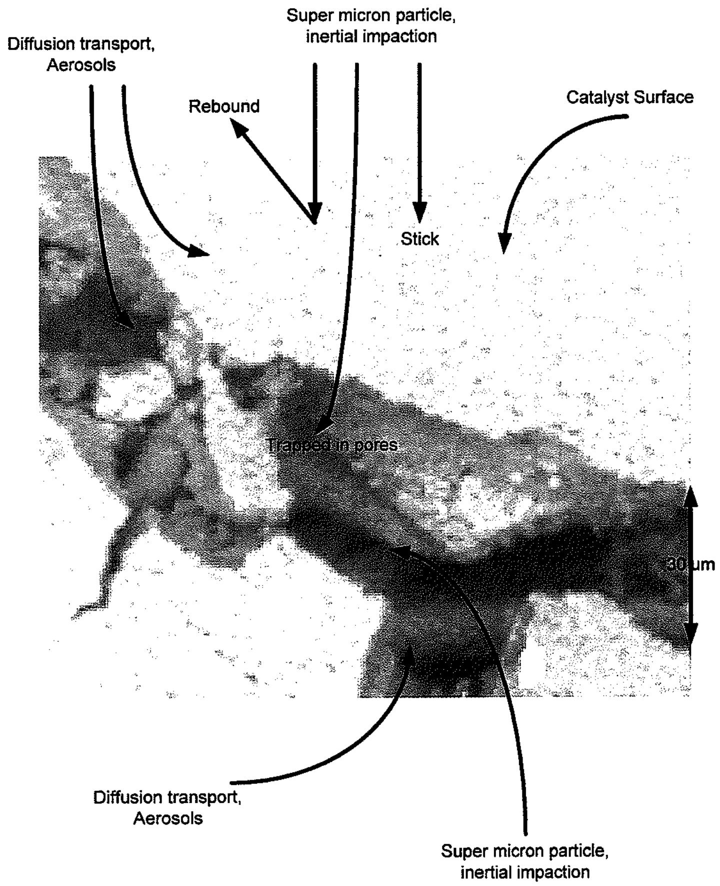

Figure 5. Scanning electron microscope secondary electron image of SCR surface structure before exposure to flue gases.

Recent work conducted by Zheng and others (2008) in a paper entitled “Deactivation of V_2O_5-WO_3-TiO_2 SCR catalyst at biomass fired power plant entitled “Elucidation of mechanisms by lab- and pilot-scale experiments” described the diffusion of aerosols and their ability to cause catalyst poisoning. Figure 6 shows a plot of the aerosol concentration as a function of size, catalyst pore size, and the diffusion coefficient with size. These result show that diffusion of the submicron aerosol is highly likely since potential for diffusion increases with the smaller size fraction of particles and that the mechanism will be active for particulate from upstream and downstream of the particulate control device such as an ESP. These efforts followed earlier studies where Zheng and others (2005) biomass-derived alkali rich aerosols caused a drop in NO_x reduction activity by 52% after about 1140 hours of operation.

b. Comparison to ESP outlet size distribution of fly ash

Figure 6. Comparison of the size distribution of the aerosol produced during combustion with the diffusion coefficient and catalyst pore size (Modified after Zheng and others (2008) with data from Linak and Wendt (1994)).

The association of alkali and alkaline earth elements in Center lignite is similar to the associations found in biomass. In both Center lignite and biomass materials the alkali and alkaline earth elements are largely organically associated. An analysis of a wood residue biomass material that is similar to lignite is shown in Table 1. The total alkali (Na_2O+K_2O)

calculated on a lb/mmBTU basis for the wood residue is 0.10. The total alkali for the average Center lignite was determined to be 0.84 lb/mmBTU. Compositions of various biomass types were compiled by Miles and others (1995) and they found the total alkali ranged from 0.06 to 1.15 lb/mmBTU. The overall chemical compositions for the biomass are listed in Tables 2 through 5 along with the water soluble alkali. Miles and others (1995) conducted chemical fractionation, a procedure that determines the abundance of alkali and other elements that is soluble (associated as soluble species and with the fuel organic fraction), on the biomass and found that the alkali were mainly organically associated.

Because of the organic association alkali species vaporize upon combustion and condense to form aerosols upon gas cooling. This vaporization of alkali during biomass combustion resulting in the formation of aerosols has been investigated by numerous researchers. One of the most recent paper is by Hindiyarti and others (2008).

Hartenstein (2008) indicated that "sodium is not a poison at SCR operating temperatures." This statement is inconsistent with Hartenstein's past claims, where he makes the following statement (Hartenstein and Licata, 1996) "…elements such as sodium and potassium, are known to cause permanent irreversible disactivation of SCR catalysts." There is literature information indicating that sodium is a poison at SCR operating temperatures. The poisoning mechanisms of alkali and alkaline earth oxides on vanadia catalysts were investigated by Chen and others (1990). Their work found that the deactivation is directly related to the basicity of the poisons. The ranking of the strengths of the poisons are listed as follows: $Cs_2O > Rb_2O > K_2O > PbO > Na_2O > LiO > CaO > P_2O_5$. Figure 7 shows the activities of the catalyst with various elements added. The testing was conducted at 300°C. In addition, Guo (2006) conducted a study on the intrinsic SCR activity for NO with NH_3 reaction and found that the additions of K, Na, and Ca greatly decrease the NO reduction activity of 1% V_2O_5 – 9% WO_3/TiO_2 as illustrated in Figure 8.

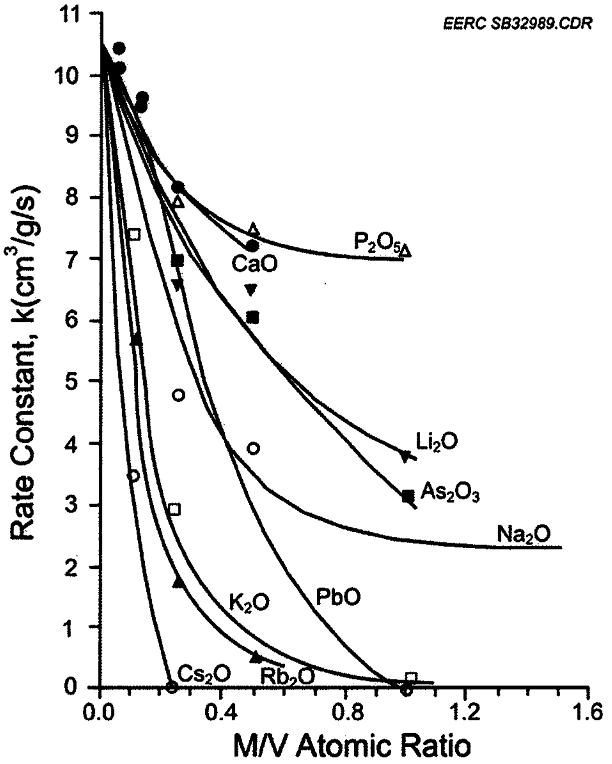

Figure 7. Rate constants for a V_2O_5/TiO_2 combined with different amount of oxide poisons (Chen and others, 1990).

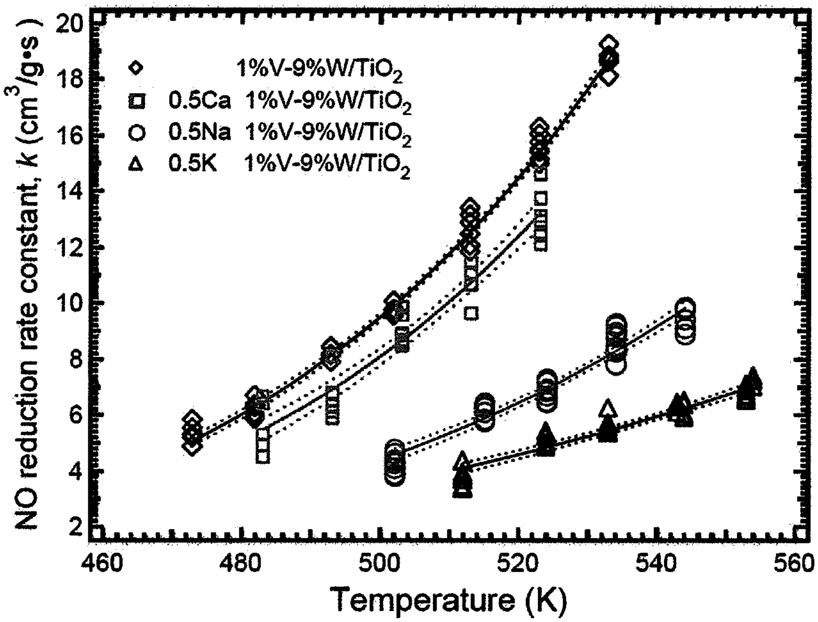

Figure 8. Impact of NO_x reduction rate constant as a result of poisoning by sodium, potassium, and calcium (Guo, 2006).

The mechanisms of catalyst deactivation due to alkali components are currently being investigated in depth. Several studies are being conducted in Europe because of poisoning of catalysts due to biomass firing and co-firing. The diffusion of alkali (Na and K) vapor has been ruled out as was correctly stated by Hartenstein (2008) because it will be in the condensed form at SCR temperatures. However, the presence of alkali aerosols does contribute to the deactivation of catalysts (Zheng and others 2008, Zheng and others 2005). The rates of deactivation in full-scale and laboratory studies were about 1% per day. They indicated that the in-situ formation of liquid potassium-vanadium-pyrosulfates could be one of the possible mechanisms. However, testing showed that the deactivation reactions also take place in the absence of SO_2 due to aerosol penetration into the catalyst.

The exact form of the alkali aerosol (hydroxide, sulfate, or other) that contributes to poisoning is not known. Zheng and others (2008) indicate the possible mechanism of deactivation occurs by the diffusion of aerosol particles rich in alkali into the catalyst pores followed by reaction with the V–OH groups producing –V–O–K (Na). These observations are consistent with the work conducted by Kling and others (2007) who investigated deactivation of SCR catalysts in three biomass and peat fired 100 MW-scale combustion systems. They found that the increased levels of sodium and potassium accumulated in the SCR catalyst was derived from the ultra fine particles (aerosols). These accumulations of aerosols resulted in decreased the NOx reduction catalytic activity as shown in Figure 9.

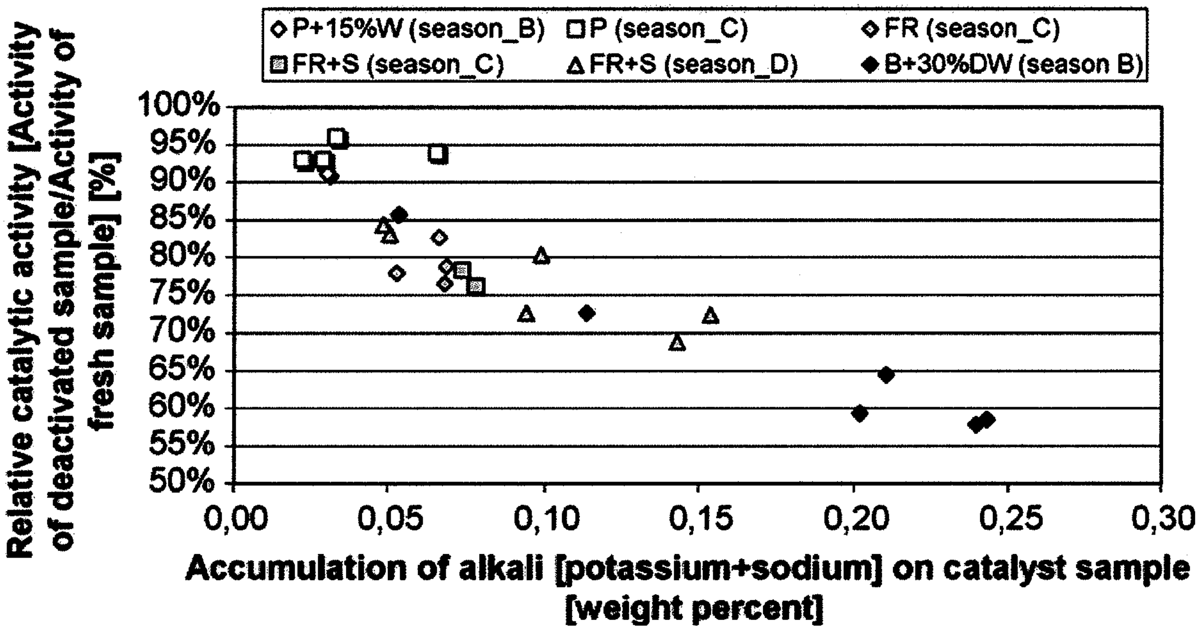

Figure 9. Reduction in catalytic activity as a function of accumulation of alkali in the catalyst (Kling and others (2007).

Recent testing conducted by Strege and others (2008) at a stoker-fired utility boiler firing a blend of biomass and Powder River Basin coal (PRB) found that the catalyst deactivation rate was about 18% per 1000 hours. The components responsible for the deactivation were sodium, potassium, and calcium sulfate-based materials. Alkali components (sodium and potassium) were found deep inside the catalyst.

Broske (2003) in an EPRI report indicated that for analysis of spent catalysts from medium sulfur bituminous (Appalachian) coal found that the concentration of sodium and potassium species accumulated to over 100 times the levels found in new catalysts. The levels reached in the catalyst were between 4000 and 6000 ppm. This is for an Appalachian coal that typically has low levels of sodium in the ash. In this particular catalyst, arsenic was found to be the primary contributor to poisoning but the alkali (sodium and potassium) also contributed.

The impact of aerosols on the performance of low dust SCR applications was not discussed by Hartenstein (2008). The impacts have been identified by Copolo and others (2003). They indicated in their paper that "The ash however, that escapes from the precipitators is finer than the ash in general ….. Although less likely to cause erosion, it does have a higher plugging potential as finer ash has been found to have a higher tendency to agglomerate." In addition, Hartenstein (2008) did not consider information provided on ash accumulations downstream of the ESP at the MRY station. Testing of Powerspan's barrier discharge reactor (Tolbert and Benson, 2008) was conducted to determine the potential application of the Powerspan technology for new power generation firing high sodium ND lignite. The barrier discharge reactor is placed downstream of particulate control systems to enable the oxidation of NO to NO_x species that will allow for capture in an ammonia-based scrubbing system. A slipstream barrier discharge reactor system was designed by Powerspan and the EERC and installed downstream of the ESP on Unit 1 at the MRY Station. The gas temperature was approximately 300°F.

The primary concern regarding the success of the Powerspan technology was that sodium-rich aerosols exiting the ESP would accumulate on the quartz rod resulting in decreased performance of the barrier discharge reactor. At two week intervals during the testing campaign, the reactor was inspected and rods were removed for analysis. The ash accumulation resulted in decreased nitrogen oxide (NO) oxidation due to accumulations of alkali and alkaline earth sulfate rich ash layer on the rods. An example of the ash accumulation on the rod after exposure to flue gases downstream of the ESP is illustrated in Figure 10. The exposed quartz rods were mounted in epoxy resin and cross-sectioned for scanning electron microscopy and x-ray microanalysis. The image in Figure 10 shows a highly bonded ash coating on the surface of the quartz rod. The red line represents the line analyzed across deposit and the quartz rod. The length of the line is 22μm. The abundance elements were determined along the red line shown in Figure 10. The levels of sodium and potassium in the bonded ash layer were greater than 10 percent.

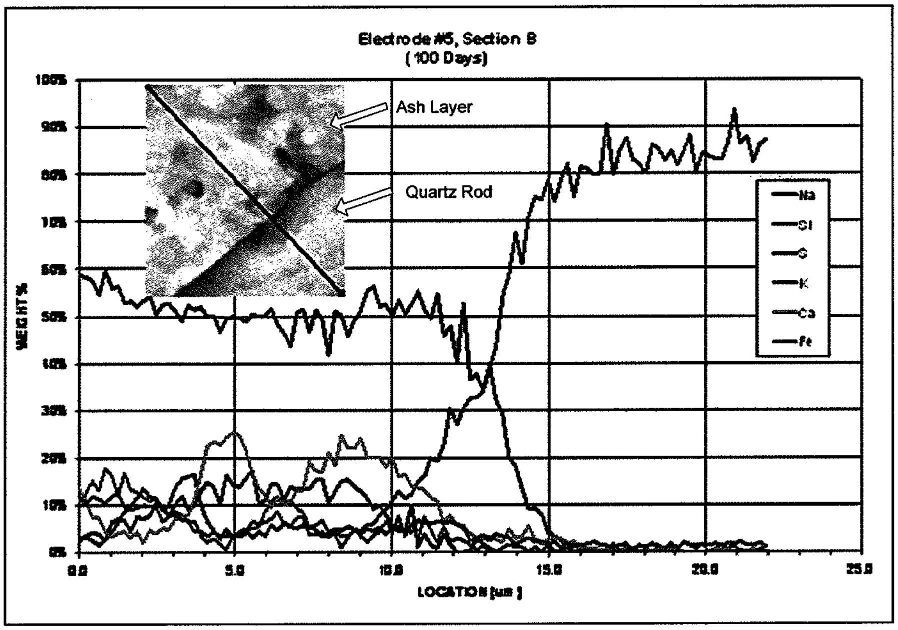

Figure 10. SEM image of quartz rod exposed to flue gas downstream of the ESP at MRY Unit 1 with element composition line scan across the deposit and quartz rod (Tolbert and Benson, 2008).

The bulk composition of ash scraped from selected quartz rods was determined by x-ray fluorescence (XRF). The rods sampled were from three electrodes that were exposed to flue gas downstream of the ESP for 20, 48, and 107 days. The bulk composition summarized in Table 6 shows significant levels of sodium, calcium, and potassium along with sulfur.

Table 6. Bulk composition of ash removed from electrode samples obtained from rod removed at 20, 48, and 107 days.

In the 1999 technical paper, Mr. Hartenstein (1999) and his co-authors reported SCR catalyst deactivation due to sodium at the RWE Staudinger plant in Germany. Specifically, it is reported on page 5 of the referenced paper that "...the fly ash from the German coal formed highly adhesive deposits, while the portion of South African coal contributed to the formation of a liquefied fly ash. The reason for this was determined by a chemical analysis of the fly ash. It can be seen that the content of the alkali sulfate, which adheres to the surface of the fly ash particles, favors the tendency to agglomerate. A phase analysis of the deposits revealed crystalline sodium aluminum sulfate and potassium aluminum sulfate ($NaAl(SO_4)_2$;$KAl(SO_4)_2$)."

This information supports the Department's opinion related to the formation of sodium–related deposits on the SCR catalyst that accelerate the deactivation of the catalysts. This information conflicts with Mr. Hartenstein's statement, on page A-28 of his expert report, that the "...the intrusion of liquid pyrosulfates is no major concern with respect to a severe, rapid catalyst deactivation."

Variability of Lignite

North Dakota lignite or lignite from the Fort Union Region of North America has very unique properties. The Fort Union lignite coals are unique because of the extraordinarily high levels of alkali and alkaline earth elements that are associated with the organic or combustible fraction of the coal. The constituents that are organically associated are considered ion exchangeable or soluble sodium. The association of the sodium in Fort Union lignites is similar to the association of sodium and potassium found in biomass. In addition, the coal contains mineral grains consisting of mixed clays, quartz, and sulfides that vary significantly in abundance. The form of the element influences their form in the flue gas. For example, organically associated sodium will vaporize during combustion and form an aerosol upon gas cooling, while mineral associated sodium (sodium in a clay) is less likely to vaporize and will be retained with the clay-derived particle. The sodium associated with the aerosol is much more reactive than sodium associated with a melted clay-derived particle.

The organically-associated elements are prone to vaporize during combustion. These organically associated elements will condense homogenously to form submicron sized aerosols or ultrafine particles. In addition, the organically associated elements will react with aluminosilicates producing low-viscosity (low melting point silicate-based liquids) phases and with sulfur-producing sulfates and pyrosulfate. These elements contribute to the formation of deposits on ceramic/refractory surfaces, cyclones, heat-transfer surfaces, SCR catalysts, and gas filters. Formation of these deposits will lead to operability problems, with the potential to shut down the system. Lignite composition is highly variable and, therefore, will contribute to a range of challenges. As a result of these challenges and efforts to identify problematic species, a significant database of selected North Dakota lignites, specifically Center lignite, has been developed to provide the basis for understanding the behavior of lignite and to project potential challenges. The variability of the Center mine lignite characteristics are summarized in Table 7.

Table 7. Center lignite composition (moisture, ash, sulfur, and heating value expressed on an as-received basis; and ash composition expressed as weight percent equivalent oxide of the ash produced at 750 °C).

* *High value may be an analysis or reporting error. Sample could not be reanalyzed to verify.*

Hartenstein (2008) indicated that "I am not aware of a single case where high variability of heat and ash contents of the coals and/or of the constituents that make up the ash preclude the principles of the SCR technology from being technically feasible and applicable." Hartenstein did not indicate how he would identify a design coal for the catalyst design for high dust SCR based on the lignite characteristic. In addition, Hartenstein incorrectly assumes that over the range of fuel properties the performance of the particulate control systems will not be impacted, thus avoiding impact on a low-dust or tail-end SCR. In cases where there is high sodium and low ash contents, the abundance of aerosol particles increases dramatically. These particles can make their way through particulate control devices and can impact the performance of low dust and tail-end SCR as discussed previously.

Hartenstein (2008) does not provide information on chemical composition of the fuels that are comparable to high sodium lignite where SCR installation have been installed and tested or successfully operated. The composition of the Texas lignite fired at Martin Lake is typical of the composition of lignite fired at Sandow and is shown in Table 8. The sodium oxide levels in the Texas lignite ash is 0.7%. The levels of sodium oxide in Center lignite average 4.4% and can be as high as 13% in as-fired samples.

It is surprising that Hartenstein did not discuss his experience with German Ruhr Brown coal as described in a paper by Hartenstein and others (1999) where they found that "... the pressure drop across the catalyst layers rapidly increased...." when they fired German Ruhr coal alone. The problem was associated with the highly "adhesive" fly ash bonded with an alkali sulfate phase. They were unable to fire 100% lignite and had to rely on blending with a South African coal to reduce the problem. He also stated that "We have also learned that we had to analyze not only for sodium (Na) and potassium (K) content of the coal but also we need to know if the Na and K compounds are water-soluble. In a water soluble form, these alkaline metals are highly mobile and will migrate throughout the catalyst material reducing active sites."

Results of the Coyote Pilot Testing

Hartenstein stated "The HDSCR Coyote pilot testing was ill-designed and fundamentally flawed." Hartenstein based this statement on his flawed interpretation of the Coyote testing. Hartenstein (2008) incorrectly interpreted the testing at Coyote Station as follows: "Admittedly, the Coyote Pilot Testing results seem to indicate worse pluggage than the Baldwin Pilot Testing results. However, it must be noted that the same pilot test reactor and the same catalyst, which had been already used (and plugged) at Baldwin was subsequently used at Coyote. The well known fact that catalyst that had been plugged and only mechanically cleaned is more likely to quickly plug again than new, unused catalyst was simply ignored."

Hartenstein (2008) described the reactor as being "ill-designed." The reactor system initial design was based on a design provided by Cormetech. The final design was reviewed and approved by the project team that included Cormetech, Haldor Topsoe, Hitachi, EPRI, US. DOE, Alliant Energy, Otter Tail Power, Ameren, Dynegy, and Lignite Energy Council. In addition, the selection of catalyst for the testing at Coyote was based on the recommendations of Haldor Topsoe. The testing protocols including the soot blowing media and frequency as well as all operating conditions were reviewed and approved by the aforementioned project team.

The following describes how the testing was conducted and is clearly described in Benson and others (2005).

1. The same reactor system used at Baldwin station was moved to the Coyote Station and installed.
2. The system was completely cleaned prior to operations at the Coyote Station.
3. Fresh catalyst was installed in reactor prior to testing at the Coyote Station.
4. At approximately two month intervals, the reactor was inspected and sections of the catalyst were removed for analysis, and fresh catalyst replaced the catalyst section that was removed.
5. The catalyst sections were analyzed for pore plugging and Haldor Topsoe was going to conduct activity measurements.
6. Haldor Topsoe indicated that the catalyst was too plugged to measure reactivity.

The slipstream reactors worked well at the Baldwin Station (cyclone PRB fired) and Columbia (pulverized coal tangential PRB fired) with minor to moderate fouling. The same reactor used at Baldwin was used at the Coyote Station. The pitch of the catalyst used at Coyote Station was 6mm as recommended by Hansen at Haldor Topsoe. A comparison of the first 500 hours with both systems using fresh catalysts is shown in Figures 11 and 12 for Baldwin and Coyote Station, respectively.

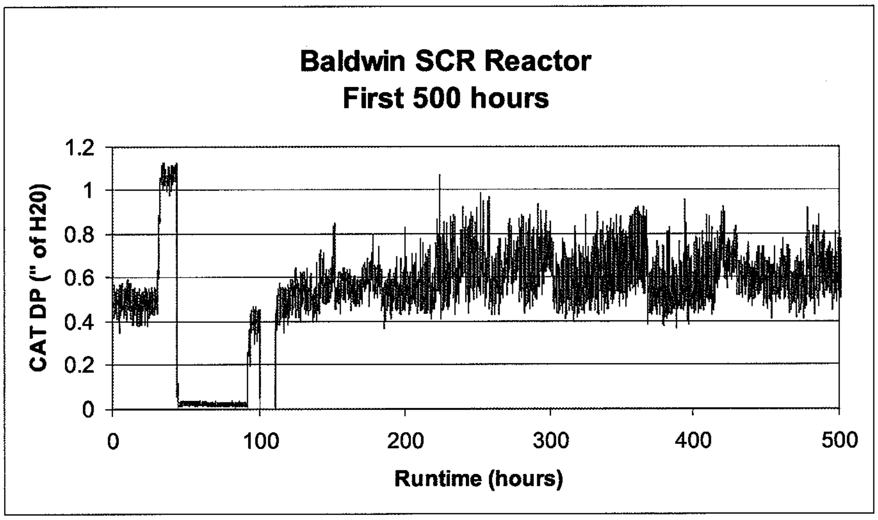

Figure 11. Pressure drop across SCR reactor during first 500 hours of testing at Baldwin

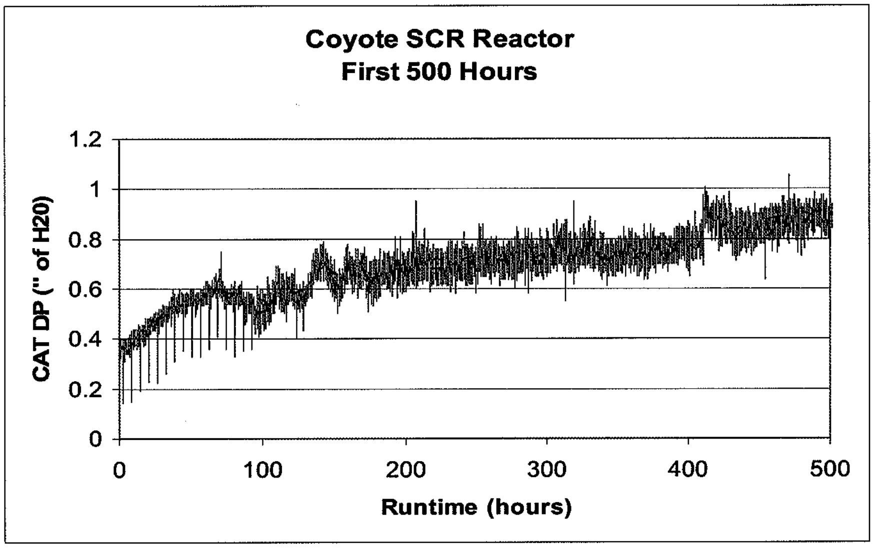

Figure 12. Pressure drop across SCR reactor during first 500 hours of testing at Coyote

Initially, at Baldwin there were some problems with start up and operation of the reactor because of plant outages. The pressure drop at the end of 500 hours averaged about 0.6 inches of water. The pressure drop for Coyote Station is shown in Figure 12, and at the end of 500 hours the pressure drop averaged about 0.85 inches of water. The plugging and blinding of the catalyst was severe.

Soluble Sodium

Soluble sodium is used to describe the form of sodium in the coal as well as forms of sodium in ash. The soluble form of sodium in coal is used to describe the abundance of sodium associated with the water soluble and organic fraction of the coal. During combustion the soluble sodium (organically associated) in the coal is much more likely to vaporize than an insoluble form. This is especially true for a cyclone-fired boiler. Upon gas cooling the alkali vapors will condense to form aerosols or sometimes called ultrafine particles. These ultrafine particles can diffuse into the pores of the catalyst and react with V-OH groups forming V-O-K(Na) rendering the site inactive (Zheng and others 2008). Hartenstein's following interpretation is inconsistent with the work by Zheng and others (2008) which is co-authored by one of the lead scientists from Haldor Topsoe.

> "Unfortunately, the Department fails to realize what was pointed out by one of the most experienced catalyst suppliers, namely that "sodium is not a poison to catalyst at SCR operating temperatures." Thus, the elaborate comparison of emission factors of sodium, potassium, calcium, and magnesium emission factors with the fly ash may have some academic value but is effectively meaningless for the correct prediction of catalyst deactivation, since particle bound sodium, potassium, calcium and magnesium in the fly ash are not mobile and therefore are not catalyst poisons."

The abundance of alkali aerosols in the flue gas as depicted by emission factor will have an impact on the rate of catalyst deactivation by the formation of aerosols that directly poison sites or produce pyrosulfates. The impact of the abundance of alkali (sodium and potassium) is clearly illustrated by the recent work conducted by (Kling and others (2007).

The formation of pyrosulfates as described earlier (EERC and Burns and McDonnell) is consistent with recent investigations of alkali poisoning of catalyst (Zheng and others 2008, Zheng and others 2005). They indicated that the in situ formation of liquid potassium-vanadium-pyrosulfates could be one of the possible mechanisms. Hartenstein (2008) states "Alternatively, these pyrosulfate compounds would have to be present in a liquid so that their dissociated ions (i.e. Na+, K+) would be mobile in order to enter the catalyst pores and react with the catalyst's active sites." He does not consider their in-situ formation as a result of the reaction of accumulated Na or K-rich aerosols with SO_3 and vanadium in the pores of the catalyst. Vanadium and iron compounds are know to catalyze the formation of pyrosulfates. Hartenstein (2008) also incorrectly states the range of melting points of the pyrosulfate phases (650 to 750°F). The melting points of selected pyrosulfates are listed in Table 9 and have a range of (535 to 1281°F).

Table 9. Melting Points of Selected Pyrosulfate Compounds

Compound	Temperature, °C	Temperature, °F
$K_3Fe(SO_4)_3$	618	1144
$K_3Al(SO_4)_3$	654	1209
$KFe(SO_4)_2$	694	1281
$Na_3Fe(SO_4)_3$	624	1155
$Na_3Al(SO_4)_3$	646	1195
$NaFe(SO_4)_2$	690	1274
$Na_2S_2O_7$	401	754
$K_2S_2O_7$	300	572
$(K_{1.5}Na_{0.5})S_2O_7$	279	535

Differences in Flue Gas Composition

The flue gas derived from the cyclone combustion of high sodium lignite contains an abundance of alkali-rich aerosols. This is well known and has been published by Benson and others (1983) as well as other investigators. The abundance of alkali rich aerosols is similar to that found in biomass combustion systems. Recently, work conducted by Zheng and other (2008) point out the importance of the aerosol particles and catalyst poisoning.

Hartenstein again makes the incorrect claim that "sodium is not a catalyst poison at SCR operating temperature" and dismisses the uniqueness of the flue gas derived from high sodium lignites. However, he provides no example of a coal fired in a boiler that produces a flue gas that is characteristic of flue gases produced from North Dakota lignite where SCR has been installed and successfully operated.

Catalyst Poisoning, Blinding and Plugging

The pores of the catalyst exposed to the alkali-rich flue gas derived from the cyclone-fired combustion of ND lignite at the Coyote pilot test were plugged. Penetration into the pores was extensive. Sulfation of the alkali components resulted in filling and plugging of the pores of the catalyst. Cyclone firing increases the abundance of alkali and other flame-volatilized species in the flue gas stream. The more refractory components end up in the slag. The alkali-rich flue gas stream is deficient in larger entrained ash particles derived from quartz and clay mineral in the flue gas stream. Upon gas cooling the alkali components will largely condense homogeneously to form alkali-rich aerosols because of the low abundance of larger ash particles for heterogeneous condensation. This results in a flue gas with higher alkali aerosol content than produced by pulverized coal fired systems.

The aerosols diffuse into the catalyst pores and are subsequently sulfated or interact with catalyst active sites resulting in plugging/blinding and deactivation, respectively. There does not appear to be a catalyst material that has shown significantly improvement over the past catalyst relative to the performance in high sodium containing system. The specific question was asked to Flemming Hansen of Haldor Topsoe (Hansen, 2007) as to whether improvements have been made in catalysts over the ones tested at Coyote Station that warrant further testing. He indicated that no formulation or design changes have been made to improve their performance in high sodium containing flue gases.

Applicability of SCR Development for Texas Lignite

EPA provided several comments regarding future application of high-dust SCR at TXU's Oak Grove facility as an example that it should not be eliminated as technically infeasible (at MRYS) on the basis of catalyst plugging and deactivation. The EPA mentioned catalyst vendors' beliefs, and an opinion by Electric Power Research Institute (EPRI) issued on September 7, 2006 and determinations by the Texas Commission on Environmental Quality. The EPA also states that "while the properties of North Dakota and Texas lignite might not be the same…" that the "same basic principle applies that the accelerated catalyst replacement requirements are a matter of economics and not technical feasibility" (U.S. EPA, 2008, Enclosure 2).

As responses to previous EPA opinions on this subject have been presented elsewhere (Minnkota, 2007A, 2007B, 2007C, 2008), the EPA fails to recognize conclusively that ash chemical and physical properties of Texas lignite (Wilcox formation) that TXU proposes to burn at the new Oak Grove powerplant do not represent what is fired in North Dakota, and its technical feasibility and expected performance in an SCR application is not transferable to North Dakota lignite-fired cyclone burner units due to the significant differences in flue gas and ash chemical and physical properties.

The EPA also fails to recognize and acknowledge that significant pilot testing has been conducted at several power plants in Texas that fire lignite supplied from various locations in Texas, and that there are no cyclone-fired boilers in Texas. The EPA has gone down the same path that tried to compare German SCR applications which lack significant cyclone boiler experience and is not currently required for lignite-fired boilers to be appropriate and comparable to North Dakota lignite-fired cyclone burner units. These are misleading statements and contrary to the presentation of the body of information submitted in support of the NDDH's preliminary BACT determination for MRYS.

SCR Catalyst Erosion and Cleaning

Various means of resolving catalyst erosion have been previously discussed in earlier comments and responses (Minnkota, 2007A and 2007B). While hardened leading catalyst surfaces may be resistant to erosion from entrained flyash, the more important issues to consider are effectiveness and damage from on-line catalyst cleaning methods. Hans Hartenstein (2008) does not address this issue in his comments.

Effective on-line cleaning of catalyst deposits seen in the Coyote pilot testing, especially with the micropores plugged with sodium-sulfur compounds, does not appear to be achievable.

No examples of on-line cleaning methods nor catalyst that would prove resistant to damage from such methods that would be effective in removing surface blinding and pore plugging deposits such as those seen in the Coyote pilot test catalyst even with the suggested edge erosion prevention measures in place have been identified. It is difficult to compare current experience with lower fouling coals with a hypothetical installation on a cyclone boiler firing North Dakota lignite, without having pilot or full-scale testing experience on the subject fuel to expected surface blinding and pore plugging deposits and cleaning operation conditions.

Hartenstein implies, on page A-36 of his report, that catalyst that has been poisoned by sodium compounds can be regenerated in-situ, and that this technique is well developed. ENBW in Germany developed this technique, but it has never had a commercial success. Regarding the contention of Hartenstein, there is extremely limited experience with in-situ catalyst cleaning on coal-fired units. It also has never been used for blinded or chemically poisoned catalyst, but only for mechanically plugged catalyst (see Appendix A).

Pilot Testing for SCR Catalyst

In many cases where SCR technology has been applied to fossil fuel-fired boilers located throughout the world burning a variety of coals and solid petroleum byproducts, extensive pilot testing programs have been performed prior to the implementation on full-scale utility boilers: Germany in the 1980's, the United States in the 1980's for low sulfur and high coals, and in Texas since year 2000 on Texas lignite. The application of SCR technology to coal-fired boiler in Germany has been almost exclusively on non-lignite fired units. Both in Germany and in the United States, it has been demonstrated that it is very difficult to solely rely on SCR catalyst suppliers' experience with similar coals and pulverized coal-fired boilers when developing SCR system designs and understanding process issues that are important to the successful deployment, operation, and maintenance of such emissions reduction technology in strict compliance with regulatory and subsequent permit requirements.

Many pilot test programs have been conducted to implement SCR technology when new and unknown process issues have been raised. There have been multiple pilot tests and research and development programs involving application of SCR technology to fossil fuel-fired utility boilers in Germany. Several are described in Appendix A by Burns & McDonnell's SCR technology consultant assisting in these responses, who participated in them.

These described pilot SCR test programs include a high dust SCR on a wet bottom boiler before the first high dust SCRs were built in Germany, and a TESCR application. The first tests determined that the catalyst deactivated rapidly, which contradicted what the catalyst suppliers believed, which was that such testing was unnecessary. The HDSCR pilot test revealed the fact that arsenic was unknown as a strong catalyst poison. Most of the German utilities decided not to retrofit wet bottom boilers that had fly ash recirculation with a HDSCR so that arsenic poisoning could be avoided (see Appendix A).

Utilities built tail-end SCRs in Germany that included a wet scrubber ahead of the reactor to avoid the arsenic poisoning problems with the catalyst. Again, pilot testing led to the discovery of a new catalyst poison (SiF_4) which caused the first catalyst layer to lose more than 50 % activity in less than 2,000 hours. This demonstrates that SCR catalysts can be severely deactivated even when boilers burn coals with a SCR configuration that were not expected to cause such problems (see Appendix A).

A recent pilot SCR test program in the Southeast United States involving eastern bituminous coal, Venezuelan coal and pet coke at a utility boiler was performed to account for the influences of the fuel on the NOx activity and SO2 oxidation rates of the catalyst. With limited worldwide experience on such a range of fuels, the Utility decided to conduct an extensive pilot program to assess impacts on the catalyst (see Appendix A). Following completion of the pilot testing, the catalyst vendors found it necessary to significantly modify and/or completely withdraw the guarantees they had offered prior to the testing.

Mr. Hartenstein and his co-authors support pilot programs for those SCR applications in which new and uncertain process considerations are encountered. In the referenced technical paper (Hartenstein, 1999), Mr. Hartenstein states: *"In principle, the reduction of NOx emissions with SCR catalysts is a mature technology, which was developed many years ago. Nevertheless, experience has shown that in many applications, special features were required that necessitate* *further optimization of the DeNOx system. In particular, standard solutions were often not possible or optimal when retrofitting existing power plants."*

In the case of Milton R Young, the uncertainty associated with the high sodium concentration and the presence of sodium aerosols in the flue gas raise serious concerns pertaining to catalyst performance. The potential application of any SCR technology at Milton R. Young suggested by the EPA and Mr. Hartenstein is not standard, and is very unique, due to the special considerations pertaining to the lignite, boiler operating temperatures, flue gas reheating, among others. Pilot testing is certainly warranted before any claims that this technology is feasible at M.R. Yong Station can be confirmed. The pilot testing must utilize new concepts and designs that alleviate the problems associated with alkali aerosols. These new concepts and designs do not appear to be currently available from the vendors.

We disagree with catalyst vendors and Mr. Hartenstein that pilot testing is not required for HDSCR, LDSCR, or TESCR prior to application to the boilers at MRYS. They have not cited any substantiated data that show successful SCR experience from coal-fired boilers with similar boiler- and fuel-specific conditions as present on North Dakota lignite-fired cyclone boilers that make this technology infeasible at Young station. The lack of evidence shown to prove that such factors have been solved such that any form of SCR technology would not require extensive pilot testing and design development for these applications is significant and important in supporting the NDDH's arguments against adopting SCR technology as BACT for MRYS boilers.

As we have stated previously, the application of emission reduction technology that requires such extensive pilot testing and design development should not be considered as available and technically feasible for the purposes of a BACT determination (U.S. EPA, 1990).

Vendor Guarantees for TESCR

Burns & McDonnell's consultant (Tackticks LLC) has significant experience in dealing with SCR system suppliers and catalyst vendors involving their initial willingness to offer guarantees and what they will actually agree to sign in the form of a contract. Mr. Hartenstein (2008) frequently states that various catalyst and SCR system vendors would be willing to offer performance guarantees for the Milton R. Young Station TESCR.

Examples of cases where SCR vendors have initially said they would guarantee performance without hesitation then subsequently changed their offer or settled a claim by the utility for failure to meet guarantees are described in Appendix A.

It is typical for vendors to do this in the absence of a detailed technical specification and contract with commercial conditions and liquidated damages. Actual performance guarantees that the SCR vendor intends to agree with for the purpose of a entering a binding contract will only be offered once all technical issues and challenges have been identified and addressed in the system specification. The vendors will not present performance guarantees for negotiation without having assessed their risk mitigation strategy. As the cost of potentially having to provide one or several levels of replacement catalyst in order to make it through the guarantee and warranty periods is significantly less than 10 percent of the total installed cost for a typical coal-fired SCR project, and the total liquidated damages should such replacement be required prematurely are only a fraction of the utility's potential actual and consequential damages, the supplier's financial exposure is decidedly much less than the buyer's (utility) should such failure to meet guarantees and warranties occur.

Temperature Variations for HDSCR

Hans Hartenstein's comments agree with the NDDH's position that such large boiler flue gas exit temperature variations, as shown in Minnkota's April 2007 response letter (Minnkota, 2007B), would not be tolerable for a high dust SCR at MRYS. Mr. Hartenstein (2008) went further to state this would not be tolerable for any HDSCR installed after any type of firing system burning any type of fuel. The ability to successfully control SCR reactor inlet temperatures in a high-dust SCR application at MRYS without impairing lignite pre-drying has not been confirmed.

The EPA's, Plains Justice's, and Hans Hartenstein's comments (2008) all assume that the SCR catalyst system suppliers (boiler original equipment manufacturers) will solve the stated temperature problems. None of the catalyst vendors queried offered to guarantee their catalyst's performance with the current situation of too low and excessively high operating temperatures on these boilers under various operating conditions. The SCR system suppliers queried did not offer any examples of successful application of proven solutions to the conditions existing at MRYS (B&McD and EERC, 2008). It is speculative and would be inappropriate to assume these challenges have been or will be solved or to expect meaningful responses from vendors knowing the nature of the conditions involved have not been resolved.

Mr. Hartenstein states, on page A-9 of the referenced opinion report (2008), that no flue gas reheating is typically required for HDSCR (and LDSCR). This is incorrect. The majority of coal-fired boilers with HDSCR technology cannot maintain minimum operating temperature over the entire load range, therefore reheating with economizer bypass, split economizer or supplementary heat input from duct burners is necessary (see Appendix A). Because of the unique arrangement of economizers in the flue gas ductwork from Minnkota's boilers, and lack of a natural gas pipeline serving the plant, this has already been dismissed in previous responses to the EPA's comments (Minnkota, 2007A, 2007B, 2007C, 2008).

Burns & McDonnell's SCR Experience

The NDDH's Preliminary NOx BACT Determination included a statement attesting to the "extensive experience with the design and operation of SCR systems" of Burns & McDonnell, which was refuted by the DOJ's commenter (Hartenstein 2008). A brief summary of Burns & McDonnell's size, years in business as an engineering firm and both general and specific areas of experience and technical expertise, particularly in regards to utility powerplant boiler NOx emissions control was presented to the NDDH and EPA in May, 2007 (B&McD and EERC, 2007).

The issue of experience with SCR systems in this response is a question of relevance. It will be helpful to first discuss what typical phases a project may go through from start to completion. These are:

- Preliminary study and investigation
- Conceptual Design

- Detailed design
- Procurement
- Fabrication and delivery
- Construction
- Commissioning
- Startup and tuning

Project execution involves all phases listed above and, depending on the project and the contracting strategy; the architectural and engineering (A&E) firm's role may involve all of the above or selected portions of the listed phases while remaining portions are delegated to other entities such as technology suppliers, system vendors, or the owner.

Is Burns & McDonnell's SCR Experience even a relevant factor at this stage of the project? Burns & McDonnell's role in this project has been to perform the BACT analysis, not to design two SCR systems for Units 1 and 2 at Milton R. Young Station. Our experience on performing BACT for utility powerplant units located in the United States is relevant and extensive. Some engineering firms only work on the environmental permitting and study aspects of pollution control and emissions reduction projects while others focus more on the implementation and construction. Burns & McDonnell has successfully worked in both areas and continues to provide these services to our clients. Mr. Hartenstein seems confused as to the role of an engineering firm and from that lack of understanding has made some irrelevant commentary.

What constitutes "SCR Experience"?

Relevant experience in various aspects of a project and specifically a retrofit air pollution control project has to be considered. Burns & McDonnell's role in an air pollution control retrofit project does not typically include the "process design" portion but there are many aspects of retrofit projects that are not specific to just an SCR retrofit project. For example, our structural engineers that are experienced at ductwork arrangement, detailed design of hot flue gas ducts, foundation design, structural steel design, consideration for wind, snow, seismic as well as component thermal expansion and movements all contribute to the project. None of those aspects are specific to SCR process design but all are relevant for SCR system design and Burns

& McDonnell has successfully provided these engineering and design efforts on many projects including SCR retrofit projects.

The specific issue discussed in the EPA's comment document on NDDH's Preliminary BACT Determination (NDDH, 2008) is in regard to SCR process design and catalyst design. In this type of retrofit emissions control project, Burns & McDonnell's role is to serve the Owner's needs and gather the data, resources, and expertise needed to execute the project. Burns & McDonnell would develop and specify the operating conditions, fuel, and flue gas parameters and values that form a basis of design which the catalyst supplier relies on, along with their expertise and proprietary knowledge of their products, to offer a proposed catalyst type, pitch and volume required to meet certain performance guarantees and warranty requirements. The catalyst supplier is in the best position to determine how they propose to meet the specified performance responsibility, understand how that offer fits their business' commercial/financial impact, and whether this may impair or enhance the long term supply of their product.

It is within Burns & McDonnell's ability to assess the relevance of the various catalyst suppliers' offers, their experience, and their level of understanding of the site, the project, the fuel and other system concerns in order to advise the owner as to which vendors are deemed qualified for bidding and executing the pertinent portions of an SCR retrofit project. Many utility owners are not comfortable with performing such technology and vendor assessments alone, nor do they maintain the in-house resources that have expertise to do such tasks to a level that significantly reduces their risk of selecting a vendor to provide a product that ultimately does not meet their requirements nor satisfy their expectations.

As has been pointed out in NDDH's Preliminary BACT Determination (NDDH, 2008) and other supporting documents (Minnkota, 2007A, 2007B, 2007C, 2008; B&McD and EERC, 2007 and 2008; Appendix A), significant concerns exist about the unique characteristics of the fuel burned, type of firing, and flue gas and ash constituents and their influence on the viability of SCR application on these units. We recognize this site-specific situation falls outside the current knowledge and experience base of the potential catalyst suppliers. Additionally, some of the significant concerns on this project have nothing to do with what the catalyst supplier can address, such as the boiler exit temperature. This concern and ways to address it are rightly placed in the boiler design firm's realm of expertise. Burns & McDonnell's role in this phase of the project is to gather, manage, and assess the technical information and advise the owner based on what these entities claim and what has been done elsewhere as well as to investigate publicly-available technical data that is relevant.

Burns & McDonnell's SCR Experience can be categorized in four distinct areas:

- Preliminary studies
- Conceptual designs and cost estimates
- Engineering management of project implementation
- Detailed design engineering duties

Each of these roles serves an important function during the overall project timeline. We can elaborate and provide more details on each category of specific experience on various projects. This is considered business proprietary information and will only be made available if needed. We do not feel this project-specific information is relevant to the current issue raised by the Hartenstein (2008), and have not included these details at this time but can if required. A summary of the roles and experience is provided below as we feel it will suffice to demonstrate our capability and viability for the role we have served thus far on this effort.

- Preliminary studies

  Burns & McDonnell has performed studies for utility clients for many years. The level of detail in what is deemed a preliminary study can be described as typically evaluating various alternatives. In a pollution control retrofit study, various compliance scenarios are evaluated in a screening analysis where technologies are reviewed with regard to several criteria: whether or not the technology is commercially available or under development, the level of experience of the technology, what suppliers are qualified, an evaluation of regulatory impact, very rough screening level cost estimates of the project, discussion of contracting alternatives, and schedule. In some cases when there is uncertainty or a range of alternatives and compliance scenarios, where more than one pollutant is involved, and more than one unit, possible variable levels of control for each pollutant, a matrix of alternatives and potential outcomes is developed to help narrow the focus of the overall strategy. Burns & McDonnell has performed many studies as described that have involved a wide range of complexity. This experience includes studies for utility clients with multiple unit sites and multiple sites covering SO_2, NOx, Hg, and particulate emissions along with some current work that includes CO_2 control as potential regulatory impacts are being assessed. Other studies have been specific single unit evaluations of SCR application only that were done to provide the owner a relative cost and impact on the utility operation. In summary, Burns & McDonnell has performed numerous studies of these types over the past thirty plus years, of which SCR technology retrofit was included in nearly every one of them over the past five years.

- Conceptual designs and cost estimates

Typically after the screening level or preliminary study has been performed, many owners need a more definitive and site specific evaluation of the retrofit project for their unit at the site. Burns & McDonnell has performed these evaluations for SCR retrofits; particulate control retrofits including new pulse jet or reverse air fabric filters; electrostatic precipitator projects including rebuilds, upgrades, conversion to fabric filter, and hot side to cold side conversions; and various SO_2 control alternatives including wet flue gas desulfurization (FGD) or semi-dry FGD, including spray dryer scrubbers, and circulating fluidized bed (CFB) dry scrubbers. FGD technology studies have included processes based on various reagents such as wet lime, wet limestone, ammonia, lime spray drying, and a few of the more developmental proprietary processes that are fairly new to the market. Also, we have performed evaluations of upgrades to existing particulate and SO_2 removal systems where upgrade and refurbishment is being evaluated along with new equipment system retrofits to look for the best solution comparing capital cost, arrangement, operating costs, outage requirements, and construction constraints. The level of detail required or desired by an Owner on this type of project can vary. Some of these projects can extend over 12 months in duration and can involve 20-30% of the design effort being complete whereas others are less detailed and can involve 4-8 months of engineering and evaluation.

The main point here is that Burns & McDonnell's experience and expertise is relevant to our role in providing BACT Analysis study reports, additional information and responses as inputs to the NDDH's BACT Determination process. It includes retrofit and new utility and industrial powerplant air pollution control projects involving SCRs and other technologies, and involves individuals who apply process design and operating knowledge, whether they exist within Burns & McDonnell or are available through technology suppliers or consultants, to the specific conditions involved. To suggest that A/E firms provide no value to clients for these projects (Hartenstein, 2008) is personal opinion not based on an informed understanding of project roles and responsibilities nor utility owner perspectives.

Comments by Sargent and Lundy on SCR Experience

On page A-31 of Mr. Hartenstein's report, Hartenstein calls into question the SCR experience of Sargent and Lundy (S&L). The following response to Mr. Hartenstein's comments has been prepared by Mr. William Depriest of S&L (Depriest, 2008):

> "S&L's involvement in the U.S. Power Industry's SCR program in the late 1990's and 2000's as presented to the NDDH in May 2007 represents NOx reduction activities associated with the NO_x SIP CALL and various projects related to NOx non-attainment areas in the U.S. These NO_X reduction programs represent the vast majority of SCR work in the U.S. during that time frame but it does not include any new unit work or any gas fired combined cycle work which we would classify in a different category of experience. Specifically, we were involved in 53 of 113 units in-service or near to in-service at the time of May 2007 to the best of our knowledge. Again, it is important to note that these NOx programs represent by-far the vast majority of SCRs in progress in the U.S. at that time and that S&L was clearly a leader in this area.
>
> In regard to Mr. Hartenstein's claims to S&L's role on these projects, I have the following comments:

- S&L provided all of the process design on the vast majority of our SCR projects. In some cases (6) we "teamed" with another entity with SCR expertise and shared in the process design role.

- S&L specified the process design criteria for the catalyst on all of our projects short of the actual formulation chemistry which is typically proprietary to the catalyst supplier.

- S&L has never made claims to either an S&L guarantee position regarding catalyst performance or direct operating experience with SCR systems."

Comments on Hans Hartenstein's Qualifications for Expert SCR Opinions

Enclosure 1 of the EPA's referenced letter (EPA, 2008) included descriptions of relevant work experience, and the resume Mr. Hans-Ulrich Hartenstein in Appendix D. Mr. Hartenstein also made numerous statements in his comments regarding the NDDH's Preliminary NOx BACT Determination attesting to his considerable technical knowledge and personal experience with the design and operation of SCR systems (Hartenstein, 2008).

According to Burns & McDonnell's consultant assisting in these responses to Mr. Hartenstein's and the EPA's comments on SCRs, Hartenstein's claimed personal experience and technical expertise on the design of German SCRs, especially of the tail-end variety, is not what it appears to be (see Appendix A). It is difficult to determine the true extent of Mr. Hartenstein's SCR technical experience, but his qualifications state that his direct involvement with SCR technology on coal-fired boilers has largely occurred since 1999 in the United States, not in Germany during the majority of the mentioned SCR retrofits. Mr. Hartenstein's involvement with SCR technology seems to be mostly business development related.

As Mr. Hartenstein states himself on page A-6 of the referenced opinion report (2008), he was not involved in SCR retrofits for utility boilers until 1993. Experience claimed with waste-to-energy LDSCR systems, which are completely different and not comparable to LDSCR systems on fossil fuel fired boilers, does not transfer effectively to the North Dakota lignite cyclone-fired units in question.

Fuel Switching

While clean fuels may be considered to meet BACT requirements, clean fuels may only be considered when the permit applicant proposes to meet BACT using clean fuels. See Pub. Law No. 101-549, § 403(d), 104 Stat. at 2631 (1990) (U.S. Senate Report of the Committee on Environment and Public Works to Accompany S. 1630 (Dec. 20, 1989) discussing the addition of "clean fuels" to the definition of BACT in the 1990 Clean Air Act Amendments).

Fuel switching/blending/cleaning was mentioned in the EPA's comments (EPA, 2008, Enclosure 2) but only fuel cleaning was questioned as a potential technique that was not fully considered in the NDDH's analysis. Fuel cleaning has typically been practiced where removal of sulfur, typically as inorganic pyrite form (FeS), is performed by simple density separation methods ("air jigging" in a classifier separate from or within coal pulverizers which reject the heavier pieces). This reduces the amount of sulfur introduced into the furnace and potentially emitted to the downstream gas cleaning equipment.

In Minnkota's NOx BACT determination case, fuel cleaning would presumably not be attempting to remove nitrogen from the fuel, for reduction of the formation into NO_X, as this would be impractical from a solid fuel. Nitrogen oxides are also created from nitrogen in the combustion air being exposed to high temperatures in the cyclone burners. So the issue of fuel cleaning is really one of trying to remove elements in the lignite besides nitrogen, for the purpose of mitigating other problems associated with those specific elements. Thus, it appears that the EPA and Plains Justice are raising this issue in trying to use fuel cleaning as an "enabling technique" so that SCR technology could be deployed without resolving the problems associated those problem elements.

Ash is included in the Center lignite supplied from the adjacent mine. Some ash comes from the mineral layers that are above and below the lignite seams as a result of the practical inability to completely separate the lignite from the burden material during mining. The remainder and majority of ash in the lignite is bound within the coal particles. Reducing the amount of bound ash in the lignite prior to introduction to the boiler would not be practical with known methods of fuel cleaning.

In cyclone boilers, ash is not normally problematic if it melts within the cyclone burner barrel and drains out to become bottom ash. In the case of North Dakota lignite-fired cyclone boilers, there is a high amount of ash that is not captured and drained from the cyclones and lower furnace as bottom ash. Thus, a higher than typical 70:30 bottom ash: flyash ratio for cyclone boilers occurs at MRYS, closer to a 50:50 split. This means that a significant amount of ash is released from the burners as flyash, where these particulates escape and become entrained in the flue gases rising up through the furnace.

As previously discussed in earlier responses, it is sodium and potassium-related elements that would cause SCR catalyst deactivation. These troublesome elements are mostly in forms where they are organically-bound within the coal particles, so simple "air jigging" classification methods are believed to be ineffective.

The arguments for coal cleaning also do not cite specific examples where minerals such as sodium and potassium have been removed economically and would not require pilot testing in order to demonstrate that the technology is developed sufficiently to be successful for this application

Non-SCR NOx Controls

Plains Justice implies that because various non-SCR NO_X reduction technologies have been demonstrated or pilot-tested on any utility boiler, the control technology would be technically feasible at MRYS. This ignores the differences in specific conditions at the MRYS boilers compared with where the technology has been demonstrated that are pertinent to whether the technology is appropriate and could be successful at MRYS.

Successful implementation of NO_X controls is highly dependent on the specific configuration and process conditions that lend themselves to be compatible within the limits of constructability, survivability, and effectiveness. Just because a control technology is "technically feasible" based on Plains Justice's interpretation of the NSR Manual (U.S. EPA, 1990) does not mean it will work effectively at MRYS to reduce NO_x emissions. Many comments by Plains Justice give the impression that they did not review Minnkota's BACT Analysis study reports (B&McD, 2006), or understand the technical reasons why such non-SCR NO_x control technologies were not evaluated for MRYS.

An example of this is Plains Justice's suggestion that injection of a fluxing agent to increase melting of solid combustion products will reduce catalyst poisoning due to a reduced amount of flyash. Superficially, this sounds plausible, but where fluxing agents have been added to coal for reduction of impact on SCR catalyst, it is due to the practice of flyash reinjection or firing of bituminous coal with low calcium-to-arsenic ratio. For the cyclone boilers firing North Dakota lignite, the fuel and its response to melting is more complex than other coals where the use of fluxing agents has been demonstrated as described. These cyclone boilers are designed specifically to melt the fuel ash in the cyclone burners as part of the combustion process. Flyash reinjection is not practiced, and arsenic is not significant in North Dakota lignite-fired cyclone boilers; however, sodium is a known catalyst poison and is present in abundance in ND lignite.

The problem with Plains Justice's argument is that the use of the fluxing agent mentioned would not prevent melting of sodium compounds which creates a fine fume that does not get captured in the molten slag. Sodium, in fact, is preferentially released from the slag that forms in the cyclone burners and lower furnace and is then exhausted where it is available to react with sulfur and calcium to foul and deactivate SCR catalysts. This is the main source of sodium that ends up in the boiler's exhausted flue gas instead of remaining in the slag. This has been explained in numerous ways by EERC in previous responses to EPA comments (Minnkota, 2007A, 2007B, 2007C, 2008; B&McD and EERC, 2007 and 2008).

Most of the "commercially available solutions" to facilitate the use of SCR that Plains Justice lists involve coal cleaning and drying or beneficiation. MRYS already has cyclone lignite drying systems, which are required for preparing the fuel for proper combustion in the cyclone burners. The arguments for coal cleaning also do not cite specific examples where minerals such as sodium and potassium have been removed economically and would not require pilot testing in order to demonstrate that the technology is developed sufficiently to be successful for this application.

Minnkota's BACT Analysis reports and previous responses to EPA comments (Minnkota, 2007A, 2007B, 2007C, 2008; B&McD, 2006; B&McD and EERC, 2007 and 2008) have explained that other non-SCR technologies, such as various forms of enhanced selective non-catalytic reduction (SNCR) with natural gas or coal reburn, low NOx burners, and flue gas recirculation are not appropriate for the operating conditions experienced inside the boilers at MRYS. Plains Justice appears to ignore the arguments previously presented regarding the expected limitations of effective NO_X reduction at MRYS with modest cyclone air-staged combustion compared with lower NO_X emissions demonstrated at Ameren's Sioux plant with deeply staged cyclones using lower furnace urea reagent injection. Oxygen-enhanced combustion, NOx adsorption from flue gases using activated coke, and various chemical treatment processes have not been demonstrated on cyclone boilers or lignite fuels, and thus would require extensive pilot or full-scale testing in order to assess their potential performance and economics. The interpretation of the NSR Manual (U.S. EPA, 1990) noting that requiring extensive pilot or full-scale demonstration of the technology is outside the BACT process beyond step 2 has already been presented in previous responses (Arfmann and others, 2007).

Conclusions

In the end, EPA's objections to NDDH's Preliminary BACT Determination may be reduced to disputing NDDH's characterization of the gas stream characteristics and the impacts of those characteristics on boiler and emissions control operations. EPA and Hartenstein suggest that these impacts can be resolved by the use of TESCR, and that TESCR technology will work at MRYS (2008). We believe their arguments are flawed because they fail to recognize the significance of these facts:

- There is no prior experience with full-scale SCR on any unit firing North Dakota lignite.
- Results from the only known example of simulating SCR catalyst exposure to high-alkali containing flue gases produced from firing North Dakota lignite in a cyclone boiler showed severe catalyst blinding and plugging due to sodium and potassium rich species

(Benson, 2005). Coyote pilot-scale SCR test was intended to evaluate the fouling potential of SCR on lignite coal results. The Coyote test was developed by a consortium of three catalyst vendors, EPRI, U.S. DOE, and other participants that design and install SCR systems as well as end-user utilities that have applied SCR on their boilers. This team was competent and Minnkota believes this testing was valid for its intended purpose. From this sole test, it was determined that there are significant impediments to using SCR on MRYS. Peer-reviewed literature written by many authors has verified that sodium and potassium species are fatal to the catalyst life.

- European SCR experience at lignite-fired utility boilers has been very limited. One HDSCR installation was at Voitsberg Unit 3 (Austria) and there were HDSCRs on three units at the Bayernwerk Schwandorf plant in Germany. These units were not cyclone-fired, the fuel burned was much lower in sodium than North Dakota lignite, and the units are no longer in operation (see Appendix A).

- There have never been, to the best of our knowledge, any tail-end SCRs applied to coal-fired utility boilers burning lignite, whether in Europe or North America (see Appendix A).

- There have not been, to the best of our knowledge, any TESCRS installed on any coal-fired utility boiler anywhere in the world since 1991, when the TESCR on the Siersdorf power station in Germany was placed into service. Siersdorf did not burn lignite, did not have a Wet FGD system, and has since been decommissioned (see Appendix A). This 17-year span since the last TESCR installation on a coal-fired utility boiler belies EPA's contention that TESCR has been universally applied and represents BACT for NOx control on a North Dakota lignite-fired cyclone boiler.

- Contrary to statements made by Mr. Hartenstein (2008), there are no currently active or planned TESCR installations in the U.S. on coal-fired utility boilers. PSEG Mercer Station does not have TESCR configuration (it is LDSCR), and the SCR systems at South Oak Creek Station for WE Energies will also be LDSCR, not TESCR as stated by Hartenstein. The change in SCR type at South Oak Creek was made due to the technical incompatibility of full scrubbing Wet FGD and the type of gas-to-gas heat exchanger

(GGH) required for TESCR. Neither of these plants burn (or will burn) high-sodium lignite (see Appendix A).

Tackticks, LLC

Introduction

Mr. Volker Rummenhohl, Tackticks, LLC, has prepared the following comments to Mr. Hans Hartenstein's Expert Opinion Report pertaining to the "Feasibility of SCR Technology for NOx Control Technology for the Milton R. Young Station, Center, North Dakota (July 2008)."

The following comments address five general topics rather than a point by point rebuttal of Mr. Hartenstein's statements. These five general topics are: Mr. Hartenstein's qualifications, information not reported by Mr. Hartenstein, incorrect information presented by Mr. Hartenstein, vendor guarantees and catalyst poisons / pilot tests.

In general, Mr. Hartenstein mainly reports the opinion of third parties and not his own. In some cases where his own opinion is offered, significant materially-related information is either missing or the information he presents is incorrect. For instance, he mistakenly refers to the SCR systems at PSEG Mercer Station as tail end systems. Mr. Hartenstein does not have hands on experience with the design, commissioning, operation or maintenance of tail end SCR systems (TESCR) for coal fired boilers. He also does not have experience with design or commissioning of Low Dust SCR systems (LDSCR) for coal fired boilers.

In his report, Mr. Hartenstein focuses entirely on the catalyst and ignores problems that have occurred with the subsystems of a SCR plant.

Qualifications

As Mr. Hartenstein states himself on page A-6 of the referenced opinion report, he was not involved with SCR retrofits for utility boilers until 1993. His direct involvement with SCR technology on coal-fired boilers has largely occurred since 1999 in the United States, not in Germany during the majority of the mentioned SCR retrofits. Mr. Hartenstein's involvement with SCR technology seems to be mostly business development related. Experience claimed with waste-to-energy LDSCR systems, which are completely different and not comparable to SCR systems on fossil fuel fired boilers, does not transfer effectively to the units in question. The size is much smaller and this allows the use of different pre heat equipment. All waste-to-energy plants in Europe have either activated carbon injection or fixed bed activated carbon plants. Those take out all poisons such as all acidic components, arsenic etc. from the flue gas.

The dead line for the retrofit of SCR systems for fossil fired units was January 1, 1990 in Germany. All but one TESCR system was built and commissioned by that date. The last TESCR system was installed in 1991 at the 170 MW Siersdorf power station, firing bituminous coal, equipped with a dry circulating fluidized bed scrubber and electrostatic precipitator with natural gas-fired duct burners ahead of the TESCR reactor. Mr. Hartenstein was not involved with that project. The author was responsible for process design and commissioning for the Siersdorf power station's SCR system constructor. This power station has since been decommissioned and dismantled.

Missing information

On page A-11, Mr. Hartenstein references the high dust SCR system (HDSCR) that was installed in 1990 at the Voitsberg Power Station in Austria. This paragraph concludes with the implication that lignite-fired boilers are among the 30,000 MW of SCR systems installed in Europe. However, Mr. Hartenstein does not offer the information that more than 20,000 MW of lignite fired units in Germany were not required to install SCR in order to comply with the national regulation. These units were exempted from the regulation despite the fact that they would not achieve the required emission limit of 200 mg/Nm^3. It should be noted that high dust SCR systems were installed and operated at the lignite-fired Bayernwerk Schwandorf plant in Germany. The units fired a Czech lignite and were decommissioned in the late 1990s. Voitsberg Unit 3 and the units at the Bayernwerk Schwandorf plant in Germany, which were not cyclone-fired, have been the only SCRs ever to operate on European lignite, and the fuel they burned was much lower in sodium than contained in North Dakota lignite. To the best of my knowledge, there have been no TESCRs built nor are any currently operating anywhere in the world on lignite-fired utility boilers.

Mr. Hartenstein also did not state in his report that Germany had only one cyclone-fired (slag tap) unit with a SCR system. This unit is Walsum 7, the NOx emissions control system is a LDSCR, and the unit does not burn lignite.

Mr. Hartenstein also did not explain that the Voitsberg lignite-fired dry-bottom pulverized coal unit operated only for a very short period of time with high dust SCR, before the boiler was taken out of business and decommissioned. The power station does not exist any longer.

Mr. Hartenstein also fails to explain that on utility boilers you cannot send saturated gas from the scrubber to the gas-gas heat exchange (GGH) for the TESCR. The gypsum in the flue gas will deposit on the SCR GGH surface and lead to a fast pressure drop increase. It is extremely difficult or impossible to clean this during an outage. The FGD GGHs are frequently washed with liquid water during operation, which keeps them clean.

Mr. Hartenstein, on page A-10 of his report, displays a diagram purporting to be the configuration of a TESCR downstream of a wet FGD system. What he fails to explain is that there is no TESCR on any utility boiler anywhere in the world that uses this configuration successfully downstream of a wet FGD. For the reasons noted above, the GGH of the TESCR cannot accept the flue gas immediately from the FGD without reheat. This diagram offered by Mr. Hartenstein represents an infeasible configuration.

Mr. Hartenstein reports on page A-50 regarding the "We Energies South Otter (*sic*) Creek Generating Station" and implies that this SCR project proves the viability of TESCR. He fails to explain that for this project, which is located at the South *Oak* Creek plant, Alstom and Howden, which are the main GGH suppliers for the SCR market, both required that the flue gas be free of moisture droplets and preheated to allow the use of TESCR. Otherwise they would not offer performance guarantees. This particular project has now changed the SCR system to a LDSCR due, in part, to issues related to the GGH.

In the German TESCR installations, a rotary GGH could be used because the required FGD removal efficiency was about 80% , and the flue gas leaving the FGD could be reheated with bypass or by other means prior to entering the GGH for the TESCR. This is confirmed by the data shown in the boiler process flow diagram from an operating utility boiler plant shown by Mr. Hartenstein on page A-49 of his report. It is clearly seen that the flue gas temperature entering the GGH for the TESCR is 87 °C, or more than 30 degrees C above the saturated flue gas temperature at the FGD absorber outlet (typically 55 °C). Obviously, although not shown on his diagram, the flue gas at this plant has been reheated prior to the inlet to the TESCR GGH. The FGD systems in Germany typically use an "FGD GGH" to accomplish this reheat. However, leakage across the FGD GGH makes a rotary GGH infeasible for TESCR systems following high SO_2 removal efficiency FGD systems, as required in the U.S.

Mr. Hartenstein references several times the "ill-designed" pilot test plant that was conducted at the Coyote Station. However, he does not offer a single reason why the pilot plant was "ill-designed".

Incorrect Information

Mr. Hartenstein states, on page A-9, that no flue gas re-heating is typically required for HDSCR and LDSCR. This is incorrect. The majority of the units cannot maintain minimum operating temperature over the entire load range, therefore reheating with economizer bypass, split economizer or duct burners is necessary. Vectren installed duct burners on four units.

Denmark and the Netherlands did not have SCR by the end of the 80s, as stated by Mr. Hartenstein on page A-11.

While rotary, tubular and plate type heat exchangers have been used for re-heating flue gas, as noted by Mr. Hartenstein on page A-12, not a single coal fired unit with a LDSCR or TESCR system has a heat exchanger other than rotary. As discussed above, this poses a problem with fouling and leakage when located directly downstream of a wet scrubber without reheat.

Mr. Hartenstein states on page A-12 for turbine limited units: "In this case, the heat rate penalty of the unit may be eliminated completely". This is complete nonsense. There will still be a penalty since more heat input is necessary for the same electrical output.

Mr. Hartenstein states on page A-13 that it can reasonably be assumed that the retrofit cost today would be the same as stated in an EPRI report from 1989. The cost for rotary heat exchangers for LDSCR and TESCR are much higher today.

Further, Mr. Hartenstein states on the same page that TESCR technology was "generally adopted as a universally applicable SCR solution for all types…" There has never been another TESCR built after Siersdorf, which was finished in early 1991, in the US or Europe.

The following is an excerpt from page A-19 of Mr. Hartenstein's report concerning minimum operating temperature:

"As a matter of fact, the only thing that dictates the minimum SCR operating temperature are the residual SO_2 and SO_3 concentrations in the flue gas, which determine the ABS reaction equilibrium and thus the probability for ABS deposition on the catalyst and in the gas/gas heat exchanger. This, however, is not an irreversible catalyst poisoning issue but rather a reversible fouling problem not related to the SCR catalyst per se but simply to the reaction chemistry between H_2O, SO_3 and NH_3 in the flue gas at various temperatures."

It is factually incorrect that the temperature depends only on the SO_2 and SO_3 concentration of the flue gas. It is independent of the SO_2 concentration. Minimum operating temperature depends primarily on the SO_3, ammonia and moisture concentrations in the flue gas. Catalyst fouling is only reversible if no calcium has reacted with the ammonium bisulfate. Once that has happened it becomes irreversible.

On page A-19, Mr. Hartenstein states:

"The reaction equilibrium between ammonium sulfate ($(NH_4)2SO_4$) and ammonium hydrogen sulfate (NH_4HSO_4), which is often incorrectly referred to as ammonium bisulfate or ABS, in the flue gas. Both ammonium sulfate and ammonium hydrogen sulfate are products of the inevitable reaction of gaseous sulfur trioxide (SO_3) and ammonia (NH_3) contained in the flue gas upstream of the SCR catalyst."

Ammonium hydrogen sulfate is a different name for ammonium bisulfate.

Mr. Hartenstein discusses, on page A-22, "Ceram's extensive experience with lignite.." With only one plant with CERAM catalyst having operated for a short period of time on lignite and a few pilot programs, it is impossible to say that CERAM has extensive experience on lignite fired plants.

Mr. Hartenstein devotes an entire section to soluble sodium (Section 6.3, page A-27). He notes in the second paragraph a statement from one of the catalyst suppliers that sodium is not a catalyst poison at SCR operating temperatures.

Yet, on page 5 of the technical paper, "Utility Experience with SCR in Germany," presented at the Sixteenth Annual International Pittsburgh Coal Conference in October, 1999, Mr. Hartenstein and his co-authors reported SCR catalyst deactivation due to

sodium at the RWE Staudinger plant in Germany. Specifically, it is reported on page 5 that "…the fly ash from the German coal formed highly adhesive deposits, while the portion of South African coal contributed to the formation of a liquefied fly ash.
The reason for this was determined by a chemical analysis of the fly ash. It can be seen that the content of the alkali sulfate, which adheres to the surface of the fly ash particles, favors the tendency to agglomerate. A phase analysis of the deposits revealed crystalline sodium aluminum sulfate and potassium aluminum sulfate ($NaAl(SO_4)_2$;$KAl(SO_4)_2$)."

This information would tend to support the Department's opinion related to the formation of sodium–related deposits on the SCR catalyst and accelerate the deactivation of the catalysts. This information would also tend to conflict with Mr. Hartenstein's statement, on page A-28 of his expert report, that the "…the intrusion of liquid pyrosulfates is no major concern with respect to a severe, rapid catalyst deactivation."

Mr. Hartenstein states on page A-29:

"…of less than seventy two (72) hours, SCR reactors are typically "buttoned up hot," which means the SCR reactor is isolated from the flue gas path during shut down by means of putting it in a bypass mode while the SCR is still at its design operating temperature. The cooling rate of such a "buttoned up hot" SCR reactor is known to be extremely slow. Unless forced cooled with ambient air no "buttoned up hot" SCR reactor loses more than approximately 50-100 degrees and therefore gets nowhere near the sulfuric acid or even the moisture condensation temperature in a seventy two (72) hour period."

This is a statement, which is incorrect and must be based on the lack of practical experience. I have been involved in several measurements of cool down rates for SCR units. The rate differs in a range between five and ten degree Fahrenheit per hour depending on the quality of the dampers and the insulation, the unit size, catalyst volume installed and the ambient conditions. It must also be considered that the boiler is operated at low loads before during the shut down phase. This means the starting temperature is already very low. Almost all units are below the acid dew point after 72 hours and most of them at the water dew point.

Mr. Hartenstein takes exception to the Department's statement on page A-29, as excerpted below:

"The Department concludes that "the flue gas generated at M.R. Young Station is different from the flue at any plant where SCR technology has been applied." The absoluteness of this statement, which is not even limited to power plans, is quite amazing as it indubitably implies that the Department has complete detailed knowledge not only of the flue gas composition of every other power plant in the world equipped with an SCR system but also of every other plant in the world where the SCR technology is applied. Even though theoretically possible, the lack of any data from all these other plants

strongly suggests that this may be highly questionable and largely overreaching. As a matter of fact, I am sure that I could easily present to the Department several plants where the SCR technology has been applied successfully that the Department doesn't even know that these plants existed."

The statement of the Department can be easily supported since there is not a single SCR system in operation on a lignite fired boiler in the United States, nor in Europe, at this time.

The statements on pages A-31 and A-32 that Burns & McDonnell never has given a guarantee and never provided process design are incorrect.

On page A-32, Mr. Hartenstein states:

"As a matter of fact, all catalyst related performance guarantees (NOx removal efficiency or activity, SO_2/SO_3 conversion rate, catalyst life or deactivation rate, etc.) are never provided by anyone other than the catalyst manufacturers. Even the SCR equipment suppliers only pass through the catalyst performance guarantees obtained from the catalyst manufacturers to the end customer. And at least two (2) of these catalyst manufacturers, namely Haldor Topsoe and CERAM were clearly willing to provide industry standard type performance guarantees for their catalyst."

This statement can only be explained by a lack of involvement in the design of SCR plants. Catalyst performance guarantees are not always a pass through from the system supplier. Depending on the contract, there are a lot of other issues that are not done by the catalyst supplier. Distributions, pop-corn ash screens, control system, and analyzer system all impact the performance of the SCR catalyst but may not be guaranteed by the catalyst supplier. These are typically warranted by the system supplier.

On page A-39, Mr. Hartenstein states:

"Yet, the most successful SCR retrofits in the U.S. were done as turn-key installations without the use of an A/E."

There are certainly many examples of successful SCR projects which were executed on different contractual conditions.

Mr. Hartenstein states on page A-50 that the SCR systems at PSE&G Mercer Generating Station are TESCR. This is incorrect. Both SCR systems at this plant are LDSCR with flue gas re-heating. Mr. Hartenstein also states that the SCR systems at WE Energy South Oak Creek Station will be TESCR. This is also incorrect. South Oak Creek started out as TESCR, but technical difficulties have forced the change to a LDSCR.

Vendor Guarantees

Mr. Hartenstein frequently states that various catalyst and SCR system vendors would be willing to offer performance guarantees for the Milton R. Young Station SCR. It is typical for vendors to do this in the absence of a detailed specification and contract with commercial conditions and liquidated damages. Performance guarantees will only be offered once all technical issues and challenges have been identified and addressed in the system specification. The vendors will not present performance guarantees for negotiation without having assessed their risk mitigation strategy.

A recent example of this occurred on the retrofit of SCR systems on two units in Florida. Three catalyst vendors provided totally different sets of preliminary guarantees at the beginning of the project. All three suppliers changed their guarantees after a 2,000 hour pilot test significantly identified the effects of various fuels on the expected performance of the catalyst.

Another example occurred several years ago on three SCR units in Pennsylvania. Two catalyst suppliers (Haldor Topsoe and CERAM) provided guarantees based on their experience with similar coals, but were very surprised about the rapid deactivation of the catalyst. These companies are those most cited in Mr. Hartenstein's paper. The money the utility received in a settlement with the turn key supplier was a very small fraction of the long term operating costs absorbed by the Utility to maintain SCR system operation.

Catalyst Poisons and Pilot Projects

In many cases where SCR technology has been applied to fossil fuel-fired boilers located throughout the world burning a variety of coals and solid petroleum byproducts, extensive pilot testing programs have been performed prior to implementation on full-scale power plants: Germany in the 1980's, United States in 1980's, and in Texas since year 2002.

There are two pilot tests and one R&D program in which the author was involved with in Germany. The results of these programs emphasize the importance of understanding design and process issues for certain applications. These also demonstrated that it is very difficult to solely rely on experience with similar coals and boilers.

The first was a pilot program for a high dust SCR on a wet bottom boiler at the Franken power station in Germany. This was before the first HDSCRs were built in Germany. All catalyst suppliers said that it would be unnecessary to conduct a test program, since these companies had sufficient experience basis from the units in Japan. It turned out that the catalyst deactivated rapidly. Some catalyst types lost almost all of their activity in just 200 hours. At this time, arsenic was not known to be an issue for the catalyst because it had not been observed in the Japanese SCR systems. The pilot test revealed the fact that arsenic is a heavy catalyst poison. Most of the utilities decided not to retrofit wet bottom boilers that had fly ash recirculation with a HDSCR so that arsenic poisoning could be avoided.
